Olfaction is greatly involved in reproduction — in sexual attraction or the excitation of females by the rutting male, which may induce simultaneous oestrus in a wide group of females. In that most human of animals, the tortoise, the female in the early stages of courtship rubs her forearms against her chin glands and then proffers her perfumed arms to passing males. Even pregnancy may be upset by olfaction: in female mice the presence of a strange male or just his urine may prevent implantation of existing blastocysts in the female and may even terminate pregnancy more than half-way through gestation. Also, after birth, odour plays an essential role in forging the bond between mother and young. Olfaction can be important in the isolation of species: among mice the odour preference by the female seems to accord with sound genetic policy in that she prefers an unrelated male of the same stock, avoiding males of remote strains and rejecting siblings.

The author naturally devotes much attention to the marking of territory — a world of sense and a complex language which it is difficult for us to understand. It would seem, in general, that marking does not serve to keep intruders out but acts rather as a bond within the colony which boosts self-confidence and thus the ability to get the better of unwelcome intruders.

In a final chapter the author outlines some of the ways in which an understanding of the role of olfaction in the ecology of vertebrates may be utilized in improving husbandry or combating vertebrate pests. He does not claim too much. But in his eyes the grass looks greener on the other side of the fence; he gives a brief account of the use of pheromones in insect control which might fairly be described as optimistic.

This book is packed with information, well organized and fully documented with references. The author favours theories based on observational or experimental science. He is sceptical of conclusions based on anecdotes and pays only minimal attention to Freudian fantasies. He is therefore a good guide for the serious student of ecology. □

Sir Vincent B. Wigglesworth is Emeritus Professor of Biology in the University of Cambridge.

Towards less formal arms control?

What will happen to the cause of arms control if the Salt II treaty is never ratified? More than a year has now passed since the treaty, the product of seven years of negotiation, was signed by the Soviet Union and the United States. Since then, the treaty has languished in Washington, awaiting a fair wind in the US Senate where, like any other treaty, Salt II has to command a two-to-one majority before it can be ratified. The time has never been right. Faced with the prospect that the treaty would be thrown out by the Senate a year ago, the Administration let proceedings hang fire while lobbying for the support of individual senators. The Soviet intervention in Afghanistan was, ironically, a godsend for the treaty. The Administration was able to put the treaty on ice and thus to avoid the near-certainty of outright defeat. So far as can be told, the Soviet Union has been sympathetic. While Soviet spokesmen repeatedly complain at the delay in ratifying the treaty, none of these complaints has been coupled with the obvious threat that the treaty will be abandoned if the Senate does not quickly give its consent. Indeed Mr Brezhnev has gone so far as to suggest that Soviet ratification is by no means automatic, thus giving the impression that the US Senate is not the only cause of delay. Yet a treaty has no legal force if it is not ratified. As things are, either of the signatory governments could repudiate Salt II without turning a hair — and there are some in the United States who guess that precisely this will happen if Mr Ronald Reagan wins the election next month. What in the circumstances, should be done?

The first need is not, at this stage, to abandon hope. The outcome of the presidential election will be important but not decisive. Mr Carter's re-election would not by itself assure quick passage for the treaty; the re-election of the supporters of the treaty in the Senate — people like Senator Hart — could be more influential. On the other hand, if Mr Reagan is president of the United States in the new year, it is unlikely that he will act as intemperately as he was suggesting when he was still campaigning for the Republican nomination. Like all his predecessors, he would find that there is precious little room for manoeuvre. Given the widespread recognition in the United States that a continuing relationship with the Soviet Union is an indispensable component of national security, and public knowledge of the importance of Salt II in Soviet eyes, no new president is going to tear up the treaty. What might, with advantage, be done is to explore the possibility of modifying the treaty and, in the process, of improving it. Thus the expected five-year lifetime of Salt II is absurdly short. If it takes a decade or more to develop new strategic weapons, what sense can there be in a treaty which limits the numbers of missiles deployed only for a period of five years? Talks about improvement would help to get both Mr Carter and Mr Reagan off the hooks on which they are now impaled.

Even so, Salt II may remain in limbo. What would be the consequences for other initiatives in arms control? The most obvious dangers lie outside the strictly bilateral relationship of the Soviet Union and the United States. At the beginning of September, the signatories of the Non-Proliferation Treaty made loud complaints about the failure of the super-powers to ratify Salt II (see *Nature*, 11 September) — and even demanded that, pending ratification, the two governments should declare their intention of behaving as if ratification were a fact. (For the United States, such a course would be unconstitutional and, in any case, is prohibited by the US arms control legislation.) Most probably, the super-powers will be able to hold this ring. A more serious difficulty is that, hitherto, other items on this still thin agenda of arms control have been dependent on the conclusion of Salt II. This is why it is a hopeful sign that the Soviet Union and the United States seem willing to start talking about limitations of nuclear weapons in Europe — a process which West Germany in particular is keen to see begun. The main lesson seems to be that the frustrations of Salt II seems not to imply that other negotiations on arms control must be brought to a halt.

But what to talk about? In what forum? And what, in any case, would be the objectives? The negotiations about a comprehensive test-ban treaty are the most advanced, but the United States administration cannot realistically think of signing such a treaty until after the new Senate has had its say about Salt II. There is also an urgent need, not yet realized, for exploratory talks on the deployment of chemical weapons. After a ten-year moratorium on the manufacture of chemical weapons in the United States, the Department of Defense is now embarking on a programme for the manufacture of binary chemical weapons — devices in which two chemical components of a nerve gas are mixed together only when the shell or bomb that carries them is detonated. The decision has been influenced by the opinion that the Soviet Union is redeploying chemical weapons along the European border, but the evidence is only thin. Chemical weapons may not be central to strategic arms control, but they are powerfully symbolic. No harm but only good would come from bilateral negotiations on this subject.

Intermediate-range nuclear weapons, principally in Europe, are a harder problem for two different sets of reasons — political and technical. First, there is a serious dispute among the interested parties about the list of participants for Salt III. The Soviet Union has a simple line — negotiations about nuclear weapons in Europe must be conducted bilaterally between itself and the United States. No doubt it would be an embarrassment if the other members of the Warsaw Pact were allowed to have their say on matters which have hitherto been decided unilaterally by Soviet strategic planners. In the West, however, multilateralism is in the air. Nobody in Western Europe will be satisfied with a bilateral deal on non-strategic nuclear weapons between two super-powers which would not necessarily be in the front line if the weapons concerned were ever used in anger. Such a deal, arrived at without the consent of Western European governments, would probably turn Western Europe into a Gaullist citadel, more determined than at present to paddle its own canoe, both in planning for defence and in negotiations. Although the Soviet Union and the United States have this week (in Vienna) begun talking about the problem of the so-called Euromissiles, their talks will be mere chats if they do not devise some way of securing the open participation and consent of at least the Western European governments.

But what will these talks accomplish? Salt II was successfully negotiated only because limitations of long-range strategic weapons could be defined arithmetically. Each partner in the negotiations appears to be content with a fixed number of long-range missiles, based in silos and in submarines. (No doubt the knowledge that the quantity of nuclear explosives permitted is vastly greater than that needed for virtually total destruction of the other side has helped to make these limits acceptable.) The technical obstacles to a corresponding agreement on Euromissiles are more serious. What on one side is equivalent to what on the other? Will it be possible to distinguish between strategic and tactical delivery systems? What are the consequences of the geography of Europe? At this stage, nobody can tell whether

0028-0836/80/420571-02$01.00

these obstacles can be surmounted. In the end, an agreement on Euromissiles (if there is to be one) may have to be quite different in character from Salt II. It helps that the Soviet Union and the United States have at least begun flirting with the problems. It may not be a productive negotiation, but it cannot fail to be educative.

The outcome will not, however, be a formal treaty unless Salt II is ratified. The Soviet Union has made that plain. What, in the circumstances, can be the outcome of the Vienna talks (which are likely to drag on for years to come — unless Mr Reagan is ever in a position foolishly to put an end to them)? If the two sides merely understand each other's views of strategic weapons more fully, that will be worthwhile. In retrospect, it is clear that the negotiations ten years ago about anti-ballistic missles helped to persuade both sides that their deployment would be counter-productive, with the result that Salt I (with its limitation on anti-ballistic missiles) was something of a formality. Thus there is something in the view that in arms control negotiations the process may be as valuable as the product. This recognition has tempted some to go further and to argue that, in arms control, tacit understandings between the major powers are in some ways preferable to formal treaties. Mr McGeorge Bundy, adviser on national security to Presidents Kennedy and Johnson, was making this case only last week at a seminar at Massachusetts Institute of Technology. That tacit understandings might be more easily agreed, and even more ambitious, is beyond dispute. The snag is that almost by definition they cannot be policed or relied upon internationally. But if Salt II remains in limbo, or if Mr Reagan is elected and does his worst, they may be the best hope for arms control in the 1980s.

The space agency's neglect of science

The death last week on a climbing expedition in the Himalayas of Dr Thomas A. Mutch, associate administrator of the US National Aeronautics and Space Administration (NASA) will be widely mourned. In the past year, since his move from Brown University, Dr Mutch has helped to give NASA's support of scientific research a sense of greater civility than has often been the case in the past.

Sadly, however, Dr Mutch's death will inevitably prompt futher questions about the adequacy of NASA's general strategy on scientific research. From the beginning, the agency has lived in an uneasy and ambivalent relationship with the scientific community. For many people and groups, of course, it has been a source of unaccustomed and even unexpected largesse. But there has also been a constant grumble, from universities and other places where space vehicles are thought of as a means to an end, that the agency takes too short a view of its contribution to scientific research. There is a large stock of anecdotal evidence that it is far easier to wring from NASA quite large sums of money for putting things in spacecraft of various kinds than for the frequently less expensive task of making good use of the data which are eventually collected. What with one thing and another, but especially because of the way in which getting the space shuttle built is eating into NASA's budget, there is a nasty fear that science will be a conspicuous casualty of the years ahead.

The symptoms of present discontents are easily listed. The most evident is the prospect that, in the immediate future, there will be a dearth of Earth satellites and other spacecraft whose purposes are primarily scientific. Each interested party has a particular sense of grievance. Some most of all regret that projects like that to send a spacecraft to Halley's comet (due back within shooting range in 1986) may not get the funds they need in next year's budget. Others weep about the impending premature demise of the Einstein X-ray observatory, and the near certainty that there will not be a comparable instrument to replace it within this decade. The device known as a solar polar orbiter, the chief objective of which is to make measurements of the solar wind well away from the Sun's equator, survived only by the narrowest squeak the budgetary process earlier this year, largely because of the intervention of Dr Frank Press, the President's Science Advisor, and is probably now safe. It is also likely that the Large Space Telescope, the instrument confidently planned as the next big step forward in visual astronomy, will not now see its way into orbit until the second half of the 1980s. Some gloomy folk even fear that the cost of the telescope (likely to be more like $1,000 million than the original estimate of half as much) will itself turn out to be an internal pressure within the NASA budget.

The prospect that there will be a shortage of hardware in the remainder of this decade is, however, less alarming than that which faces the groups which have grown up in recent years and which are primarily concerned with the design of instruments carried on spacecraft and the interpretation of the results which they produce. NASA has rightly taken the view, since its earliest times, that one of its objectives should be the encouragement of research in universities and elsewhere. On several occasions, as for example when there was more Moon rock to be cut into specimens than there were suitably equipped investigators, NASA has glad-handed its dependants in an almost lavish way. Yet even where that huge (and expensive) harvest of material is concerned, the first flush of enthusiasm has not been matched by sustained effort. Although the Einstein satellite is reckoned in its truncated life to have produced so much data that those now working with it could be kept busy for six or seven years, there is a suspicion that the funds needed to make the most even of what exists will not be forthcoming. Certainly the data needed to make the most of the data which exist — and which, for example, may be especially important in making sense of variable X-ray sources — will not now be available until the next decade. One result is, that some of those who flocked into X-ray astronomy only a few years ago, when the Einstein satellite was being planned, are now flocking back again to their earlier fields of interest — wiser, perhaps, but also more cynical. People understandably have the sense that NASA as a whole is more interested in the ballyhoo that attends the launching and the operation of a major scientific satellite than in the more tedious but necessarily continuing task of making sure that the mission has been worthwhile.

To those responsible for NASA as a whole, views such as these may seem but evidence of base ingratitude on the eve of the close encounter of Voyager I with the system of Saturn and its rings, planned for 12 November. Between now and then, increasingly spectacular photographs of the planet and its satellites will no doubt be increasingly frequent in the daily newspapers. And in any case, the administrators will say, there is Voyager II, following six months behind, still to come. What on earth can be the complaint? The simple answer is that even at this late stage there is no confidence that there will be funds to support the continuing work of the groups now concerned with harvesting data from these encounters. People who have cut their teeth on these endeavours will find themselves looking for jobs elsewhere.

For NASA, the problem is one not merely of budgets but of procedures — or that, at least, is how the agency should set about putting its house in order. It is of course entirely understandable that an agency committed, wisely or otherwise, to a novel project such as the space shuttle should be unable to keep every programme intact when the costs turn out to be far greater than originally foreseen. It does not, however, follow that the agency has no choice but to sit back and accept the fate which Congress and the Office of Management and Budget decree when things go wrong. And if the need to accommodate the cost of the shuttle within the limits laid down by the Administration means that much valuable scientific data is literally wasted, NASA has not merely a right but a duty to tell its paymasters that money is being wasted. In short, if NASA shares the view that science is being needlessly neglected, it should say so. Otherwise, it should let the scientific community know more clearly where it stands.

Another route to fusion to be explored

US looks hard at inertial confinement

Washington

The Department of Energy (DoE) is proposing to set up what one official describes as a "bluest of blue ribbon" review committee to look at the prospects of developing inertial-confinement fusion (ICF) techniques as a commercial source of nuclear power.

The decision to take a hard look at ICF comes close on the heels of a new bill signed into law by President Carter two weeks ago pledging support for a substantially expanded programme of research into magnetic confinement fusion, at present the front runner in the fusion race.

The Administration has been persuaded to back the Magnetic Fusion Bill by a report from the DoE's Energy Research Advisory Board. This says that results using magnetic confinement techniques at, for example, Princeton University's Plasma Physics Laboratory, are sufficiently impressive to justify the next stage of the development programme.

The bill proposes setting up a National Magnetic Fusion Engineering Center to look at the technical problems involved in scaling up laboratory experiments. It also requires DoE to produce a five-year programme for magnetic fusion detailing budget and research schedules.

The same committee, chaired by Dr Solomon Buchsbaum of Bell Laboratories, has now been asked to look at the progress and prospects of ICF. DoE's proposal is contained in a letter from Energy Secretary Mr Charles Duncan to the Office of Management and Budget, accompanying the department's budget request for the fiscal year 1982.

Department officials feel that, largely as the result of significant advances made during the past year or so, research on the civilian applications of ICF has progressed sufficiently to make it possible to evaluate the relative merits of different systems now under development.

Research on ICF has also been given a boost by a recent DoE decision to start declassifying previously secret information on high-energy X rays produced by the explosion of deuterium–tritium pellets — the source of fusion energy.

Three weeks ago, the department reported that it had decided that the following statement should no longer be considered a military secret: "In some ICF targets, radiation from the conversion of focused energy (such as laser or particle beam) can be contained and used to transfer energy to compress and ignite a physically separate component containing nuclear fuel".

DoE officials play down the impact of classification on the civilian programme, insisting that this has not prevented its own scientists from weighing the relative merits of different approaches. University scientists, however, have long argued that classification has been a barrier to their research; designs for ion drivers, for example, have required access to details of pellet behaviour in order to optimize beam/pellet interaction. "This is the news we have been waiting for", said one person on hearing DoE's decision.

The main problem now facing the ICF research community is how to choose the best technology for moving on to the logical next stage, the construction of a facility to probe the engineering difficulties that may lie ahead.

There is a general consensus that for magnetic fusion the Russian Tokamak design is still clearly the front-runner, but several options remain for the drivers needed to produce the energy that ignites the pellet for ICF. These include gas lasers, glass lasers and particle accelerators using light and heavy ions.

For the medium term, the best prospects seem to lie with either glass lasers or light-ion accelerators. Support for the former, in particular, has been increased by recent results from the University of Rochester, demonstrating that halving the wavelength of the light produces an ultraviolet laser beam that interacts much more efficiently with the pellet than does an infrared laser.

Dr Moshe Lubin, director of Rochester's Laser Energetic Laboratory, said last week that it was now possible to reach an efficiency of at least 80 per cent in converting the wavelength of the laser beam. This raises the possibility that crucial scaling-up experiments could be carried out much sooner than expected.

Further ahead, both glass lasers and light ions could face major difficulties. The lasers are difficult to cool, and it might therefore be hard to achieve tha high repetition rates necessary for the large-scale production of power. Light ions, although effective at close range, are difficult to focus accurately.

Here, two other options may come into their own — krypton fluoride lasers, now being developed at the University of California's Lawrence Livermore Laboratory, and heavy-ion beams, at present being squeezed for funding by a congressional preference for glass lasers with potential military applications, but eagerly supported by nuclear physicists as an extension of particle accelerator research.

DoE officials are more sceptical, suggesting that some of the claims of nuclear physicists have been over-optimistic and partly motivated by inter-laboratory competition for funds. Nevertheless, they admit that heavy ions are a serious contender for eventual commercialization, and hope that the new review committee will throw some light on where research priorities should lie.

David Dickson

Canada's uranium with strings attached

There is a prospect of a dispute between Canada and Euratom over uranium supplies. Canada is prepared to stop uranium supplies to Europe if Euratom states fail to comply with Canadian non-proliferation policy. But Euratom "is not going to surrender", according to Euratom and Canadian officials.

The confrontation will come to a head later this year, when an interim arrangement reached in January 1978 expires. And since Australia is taking a similar stance to that of Canada and the position of the United States — the other potentially large uranium supplier in the 1980s and 1990s — is clouded by the 1978 Non-Proliferation Act, uranium supply negotiations are becoming an increasingly sensitive element in the future growth of nuclear power.

Australia is furthest ahead in its negotiations with Europe. West Germany has a major share in the new Ranger mine, which will give the country 20,000 tonnes of uranium oxide in 1982–86 according to a recent agreement with the Australian government — provided Australia secures satisfactory non-proliferation agreements with Euratom. (Euratom currently negotiates safeguards with suppliers for its nine members, and must "approve" any bilateral supply deals. But its supra-national authority is under strong challenge from France — a further complication.

France also has a draft deal with Australia for the supply of 2,000 tonnes of uranium a year — a fifth of its estimated need in 1990 — but again that awaits an agreement between Australia and Euratom. The draft deal itself includes outline safeguards arrangements; but both sides have dodged giving them firm interpretation. Australia, mindful of the strong anti-nuclear lobby at home, has a public commitment (as does Canada) to ensure that none of its uranium is used for weapons building; so its policy is to require "prior consent" for re-transfers of its uranium outside Euratom states, for re-processing and for enrichment beyond 20

0028-0836/80/420573-02$01.00

per cent. According to Australia, the draft deal with France is in accord with policy; but according to French statements it offers no restrictions on reprocessing.

French industry minister André Giraud said recently that "we have no intention of using a single gramme of Australian uranium for our military programme" but, challenged on safeguards, said "we can say exactly where our power plants are and how Australian uranium will be used".

Hoping that such statements will satisfy the Australians, Euratom negotiators expect to tie up an accord soon, thus clearing the tables for Canada. Euratom fears Canada most; the US position is too uncertain to consider yet.

Canada — which already supplies 50 per cent of Britain's uranium (the rest comes from Namibia) — has the experience of India's 1974 nuclear test, which used Canadian uranium, to keep her resolution firm. The Indian test raised a storm of public protest; and although non-proliferation is no longer an election issue, it could become one if a similar incident occurred with Canadian involvement. And then uranium export might be halted. Thus, Canadian officials argue, it is in the interests of security of supply that Canada requires clear controls over its uranium.

Canada's position is ostensibly the same as Australia's — requiring prior consent for reprocessing, re-transfer and high enrichment. But, say Euratom states, such an arrangement would interfere with national sovereignty, complicate fuel management and give Canada unfair advance warning of impending international commercial deals. Canada, after all, with its fuel-efficient Candu reactors and heavy-water plants, is in the nuclear business as a whole, and not just in uranium exporting.

In the end, everything depends on exactly what is meant by "prior consent". Euratom could be expected to object strongly if it means that each sensitive step in the fuel cycle must first be cleared with Canada: for since fuel streams are inevitably mixed when fuel elements are fabricated and fuel enriched or reprocessed, any reporting of movements to Canada would involve reporting — and clearing — all steps in the cycle. France has stated openly that it would accept no restrictions.

On the other hand, Canada has indicated that it is prepared to interpret prior consent "more broadly". For example, Canada might accept an agreement which stated that its uranium was to be used only for energy, and specified the facilities at which the uranium was to be reprocessed. Canadian experts would still have to be satisfied that Euratom's uranium bookkeeping was effective, and that Canadian uranium could be "tracked" through the system.

And Euratom need be in no doubt about the firmness of Canada's commitment. "We stopped all uranium shipments in 1977 and we can do it again" said a Canadian nuclear official last week. Canada has already cancelled deals with India, Pakistan, and recently Switzerland — which objected to "prior consent". To cancel arrangements with Euratom would be more expensive (the UK needs contracts for another 2,000 tonnes of uranium per year by 1990, and France another 8,000 tonnes worth some $500 million dollars a year) but that appears not to frighten anyone in Canadian government. It does, however, frighten Europe. **Robert Walgate**

Swedish guidelines

Cloning committees

Stockholm

The regulation of hybrid-DNA research in Sweden is in a mess. Delegates to a recent microbiological conference at Umeå bemoaned the bureaucratic confusion foisted on them by a new regulatory system; and one firm has given up and is moving its activities abroad.

Since 1 January this year, any researcher wanting to work with hybrid DNA has been legally obliged to apply for permission under two existing laws: the Occupational Health and Safety Act (Arbetsmiljölagen) and the Law on the Protection of the Environment (Miljösyddslagen). The bodies that deal with the applications are the National Board of Occupational Safety and Health (NBOSH: Arbetarskyddsstyrelsen) and the Franchise Board for Environmental Protection (FBEP: Koncessionsnämnden förmiljöskydd), respectively. Both bodies are served by a Recombinant DNA Advisory Committee, set up in January under NBOSH. The committee's main task is risk classification. It has 17 members excluding its chairman (the director-general of NBOSH) and vice-chairman: four scientists, four members of parliament, five delegates from relevant authorities (National Board of Health and Welfare, Natural Science Research Council, etc.), three trades union representatives and one representative of industry and employers.

Both NBOSH and FBEP refer applications to the committee, which in turn passes them on to its working group on risk classification. If the application came from NBOSH, the working group classifies it and decides whether or not it is for new research (under the Occupational Health and Safety Act, only applications for new research have to be approved). The working group then makes its recommendation to the committee, which passes it on to NBOSH. The trouble with this is that nobody is quite sure what "new" research is. "It is difficult to interpret the meaning of this law", says Gustaf Brunius, who is in charge of DNA questions at NBOSH. "But *E. coli* K12 is a system that has been very thoroughly investigated, and if an application involves this system it is considered unnecessary to get permission for it unless the DNA sequences for toxins."

The procedure is even more complicated when the application comes from FBEP. FBEP sends the application not only to the committee, but also to 14 other bodies (including local government and health authorities and the Environment Protection Board), and asks for their comments. When all of them have replied — which takes months — FBEP holds a public meeting at which the application is publicly made and the various bodies which wish to comment publicly do so. FBEP then writes a judgement.

University researchers say they have not received any information about this system, and that they do not know how to apply. In practice, they are continuing their research without applying for permission at all, which technically makes criminals of them all. Only one firm has so far applied, and it is holding up its experience as an example of bureaucratic ineptitude. KabiGen which, in conjunction with Genentech Inc., owns the world rights for the production of human growth hormone, had applied for and been given permission to go ahead with developmental work under the old voluntary regulation system. When the new system was brought in, the firm made another application to use hybrid-DNA techniques to produce genes for human growth hormone, somatomedin B and human secretin. Six months later, permission was granted (in volumes of not more than 10 litres); but NBOSH specified P1 conditions, whereas FBEP specified P3. FBEP evidently did not take into account the revision in the National Institute of Health guidelines which occurred while it was considering the application. So KabiGen put in a new application to FBEP for permission to do the same work in P1 conditions. No decision has yet been made. The firm also applied again to NBOSH for a more general permission to do developmental work, and no decision has been made on that either. "We can do 10 litres here, but we want to do 400 litres", says KabiGen's research director, Dr Bertil Åberg. "It would take too long to get permission for that, and we'd lose too much money. We'll do it in England instead".

Some delegates to the Umea conference, which was organized by the Swedish Microbiological Association (universities) and the Foundation for Biotechnical Research (industry), suggested that the researchers themselves should take some of the blame for the present chaos. "There must be experts on the Recombinant DNA Advisory Committee, but they need not be in the majority", said Staffan Normark, Professor of Microbiology at Umeå University. "But everyone taking part in the committee's decisions must know what the research is about. We in the field haven't told them; and perhaps we should."

Wendy Barnaby

Academic freedom

Promise for Poles

Poland is to introduce new legislation designed to meet the demands of the academic milieu for greater autonomy, according to Janusz Gorski, the Minister of Science, Higher Education and Technology. The first draft of the new bill should go before paliament in December, but many of its provisions regulating dealings between his ministry and the universities would come into force immediately. In particular, he said, the ministry would not appoint university rectors without prior consultation with the university senates.

Another development in the Polish academic world concerns the University of Warsaw, which has in the past couple of weeks had a sudden change of rector. The highly unpopular Dr Zygmunt Rybicki resigned shortly before the opening of the academic year, to be hastily replaced by historian Dr Henryk Samsonowicz. The significance of this change is not entirely clear — Polish academic life, like Polish life in general, is something of a melting pot at present. However, on 28 September, the university senate issued a statement which is, in effect, a blueprint for the restoration of academic autonomy.

The statement pays tribute to the new "self-governing" trade union movement, which has now spread to the university students, and makes a number of demands for the liberalization of society as a whole, including electoral and censorship reform. It then discusses the role of the universities which it says is, basically, to "carry out scientific research and to serve national culture and public education". Science, and the results of research, said the senate, should be implemented for the benefit of society a commission of experts should be established, and science should be involved in decision-making at all levels.

The statement advocates open and unhampered discussion and demands a basic reform of the higher education system. The main points of such a reform, said the Warsaw senate, should be:

(1) Self-governing and democratic status of universities and colleges of higher education, collegiate bodies, senates and faculties to decide on directions of research; secret elections of these bodies, with students and the working staff of the institution also represented; curricula to be decided in consultation with the relevant ministries.

(2) Free access to publications and sources of scientific information.

(3) Proper means and conditions of work guaranteed to students and staff.

(4) Freedom for students to organize their own lives.

(5) Academic appointments to be made on the basis of qualifications only.

(6) The Supreme Scientific Council to possess all necessary competence for shaping academic policy.

(7) The awarding of academic degrees to be the business of the collegiate bodies, faculties and senates, the Central Commission for Qualifications and the Council of State.

The question is, of course, how far these proposals will be implemented in the new legislation. Minister Gorski suggest that there will be some reforms in the awarding of higher degrees by the Central Commission for Qualifications.

However, the proposals announced for improvements in the student grant system have clearly met with less enthusiasm than Gorski had expected. The majority of Polish students, who have flocked to join the new "self-governing" student unions, appear more concerned with the lifting of censorship restrictions.

One good omen for the future, however: Miroslaw Chojecki, the young chemist dismissed in 1977 from the Swierk Nuclear Institute because of his membership of the then Workers' Defence Committee and on trial earlier this year for participation in the "independent" publishing movement, has been reinstated under the terms of the Gdansk accords. At least half of the Swierk staff, said Chojecki, personally endorsed his application for reinstatement.

Vera Rich

Endangered species

Mediterranean acts

The fifteen or so well-managed nature reserves around the Mediterranean are around ten times too few, the International Union for the Conservation of Nature (IUCN) is arguing at an intergovernmental meeting in Athens this week. Papers produced by IUCN for the meeting specify dozens of threatened species of mammals, amphibians, fish and plants.

The principal threat is tourism — expected to reach 200 million tourists a year by the year 2000 — with its demands for coastal hotels, marinas, and baubles such as coral, sponges and tortoiseshell.

The most endangered species is the monk seal, *Monachus monachus*. Besides one colony on the coast of Mauritania in West Africa, there are just 1,000 monk seals around Turkey, Greece, Yugoslavia and Tunisia, and numbers are falling by a hundred or so each year. Numbers are now so low, and groups so dispersed, that the seals are threatened by restricted genetic diversity. The marine turtle is in similar danger, as the beaches where it lays its eggs are turned over to tourism. Other species at risk include the Iberian midwife toad, the Mediterranean spur-thighed tortoise, the

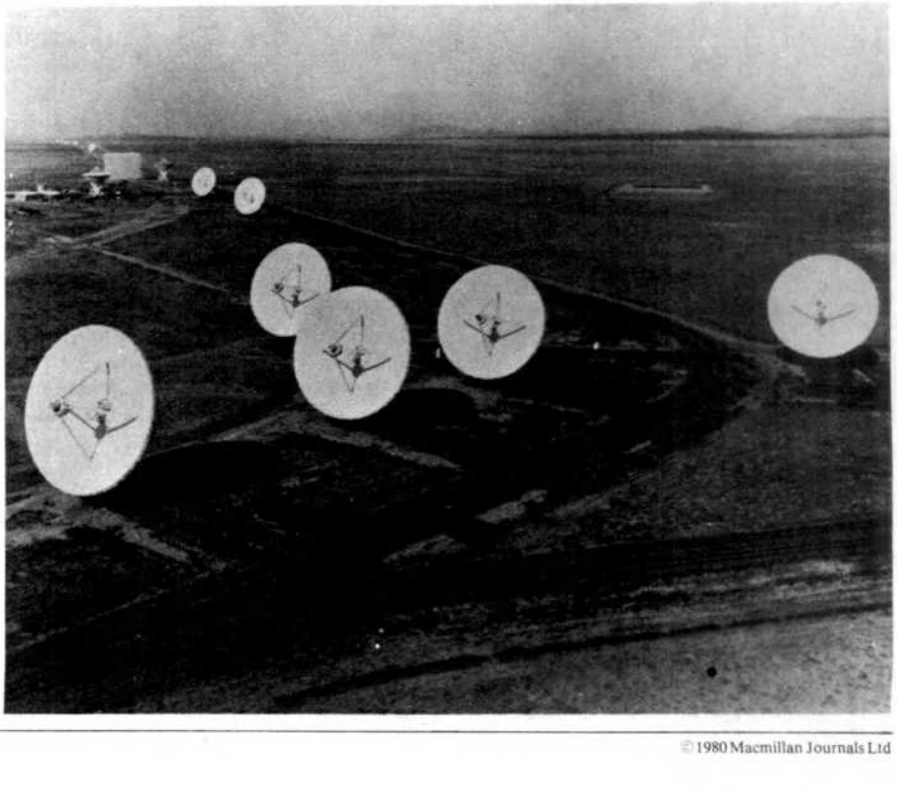
Biggest radio telescope in the world

The Very Large Array radio-interferometer was inaugurated last week in New Mexico by Dr Frank Press, the President's Science Advisor.

The array, which consists of twenty-seven steerable parabolic dishes 82 feet in diameter, has been brought progressively into operation since October 1975. Individual dishes move along three double railway tracks at angles of 120 degrees — two of the tracks are 13 miles long and the third is more than 11 miles long. The array, operated as a national research facility by the National Science Foundation, is capable of greater angular resolution than any other instrument of its kind.



0028-0836/80/420575-02$01.00

La Scuola wall lizard, the Israel painted frog, the smooth snake, the meadow viper and the spectacled salamander.

But it is not just a question of protecting pretty animals, according to Dr Pierre Hunkeler, the Swiss ecologist who organized the scientific side of the Athens meeting Colonies of coastal plants and animals of great scientific interest need protection. Turkey and Greece have the richest coastal flora, followed closely by Morocco and Spain. Greece has 670 species of plants unique to the area (compared with Britain's 15) claim IUCN, and many of them are threatened.

Many of the ecosystems under attack are not yet well specified scientifically: in the wetlands, for example, like the protected Camargue (the Rhone delta), bird life is well understood but much less is known of the plants and water-dwelling animals. Ecologists and zoologists must have a chance to study these regions, argues Hunkeler, if only to give a baseline against which to measure the effects of pollution and development.

Representatives from ten Mediterranean nations had gathered in Athens by Monday: Greece and Turkey, France and Italy, Algeria, Libya, Tunisia, Israel, Yugoslavia and Malta were there. Representatives from Monaco and Cyprus were "on their way" from another meeting. The EEC was represented, but no sign had yet been seen of Spain, Morocco, Lebanon, Syria or Egypt.

The Athens meeting will avoid defining precise geographical regions to be protected. At that point, local political and development interests come into play, and costs and benefits must be worked out. If protected areas also mean protected fisheries, and increased amenities for the local populations and for tourists, then perhaps a deal can be reached which will satisfy both the ecologists and governments. But the Athens experts are leaving that to the politicians. **Robert Walgate.**

Plates in contact

Africa's slow movement towards Eurasia probably caused last Friday's 7.3-magnitude earthquake in El Asnam, Algeria, which destroyed 80 per cent of the city 20,000 killing perhaps people.

El Asnam, sits on a tectonic boundary between two plates — or so it appears, for the region is not seismically well characterized. The 1954, 6.7-magnitude earthquake in the same area, which killed 1.200, occurred before the world seismic monitoring network had been established. But measurements of magnetic anomalies between Africa and the United States, and between the United States and Eurasia, across the midatlantic ridge, indicate that the Africa–Eurasia boundary is closing.

The grisly event has one positive outcome: it will increase geological knowledge of the zone dramatically. Seismic stations can now pinpoint the epicentre to within 5 km, and by following the expected series of diminishing aftershocks (one of magnitude 6.2 occurred three hours after the main quake) determine the nature of the movement. This is expected to be a thrust, rather than strike-slip with Africa riding up over the Eurasian plate — the Atlas mountains themselves being part of the result.

Algerian authorities may not have a spot-on repeat of 1954; but they were criticized this week for not taking sufficient care to protect their buildings. The building codes for the El Asnam region call for stiffening to resist an extra 10 per cent weight static load, said Dr F.K. Farma of Imperial College, London, a civil engineer who made a study of the area. "But for that quake they needed 50 per cent". **Robert Walgate**

Electric cars

Win some, lose some

Washington

Plans for the development of a battery-driven electric car have taken one step forward and one step back. Scientists from the University of California's Lawrence Livermore Laboratory have announced the successful testing of a new aluminium-and-water battery which, they claim, can power cars for much greater distances than other batteries under development.

The announcement came only a few days after reports of tests by the Department of Energy (DoE) suggesting that Gulf and Western (G + W) may have been premature in some of the claims made for its new zinc-chloride battery, launched last June.

The Livermore results, presented at a meeting of the Electrochemical Society in Miami, are the products of research jointly sponsored by DoE and two large industrial corporations, Continental Group Inc. (working with the Lockheed Corporation) and the Diamond Shamrock Corporation.

The battery works by submersing an aluminium plate in a solution of sodium hydroxide. The reaction of the two with air produces an electric current and hydragillite, an aluminium compound which subsequently crystallizes out so that the aluminium can be recovered.

Unlike more conventional storage batteries which require overnight charging, the new battery is claimed to need only to be refuelled with tap water every 250–300 miles. The aluminium plates would be replaced every 1,000–3,000 miles, but the operation should take only 15–30 minutes.

One drawback is the cost. Operating the new battery — including in particular the need to replace the aluminium plates at regular intervals — would cost the equivalent of between $2 and $3 a gallon, about twice the present US price.

However, this may still be competetive with gasoline made from coal — and it would be as efficient to use coal for making the aluminium plates as for producing gasoline.

Meanwhile, a report in the *Wall Street Journal* that G + W is encountering technical problems in developing its zinc-chloride battery has raised questions about the extent to which the announcement was designed primarily as a publicity exercise. The newspaper quoted DoE reports that although G + W had claimed that the battery could power a standard car for 150 miles driving at 55 m.p.h., technical difficulties with charging the battery suggested that these figures were over-optimistic.

A spokesman for DoE, which has invested more than $15 million in the G + W project, accepted last week that the development of the battery had encountered several technical difficulties, and that as a result some of the claims made by the company last June were probably premature. But he denied that the department had lost enthusiasm for the programme. **David Dickson**

Nuclear wastes

Small disposals

Washington

Much to the relief of many east coast hospitals, universities and medical schools, the Nuclear Regulatory Commission (NRC) is proposing that liquid scintillation media used for detecting low levels of radioactivity in biological samples need no longer be buried in nuclear waste disposal sites.

At present, almost all scintillation media used in this way for biomedical research, as well as the carcasses of animals in which chemicals containing radioactive tracers have been studied, have to be transported in special drums 3,000 miles across the continent for disposal.

This expensive exercise — Harvard Medical School and its associated hospitals spent almost half a million dollars last year disposing of 3,000 drums in this way — has been necessary since the state of South Carolina announced a year ago that it was no longer prepared to accept low-level wastes from hospitals and research laboratories at its Barnwell storage site. Shortly afterwards, the nation's other two radioactive waste dumps at Richland in the state of Washington and at Beatty in Nevada announced that they too were closing their doors in protest at the poor way in which low level waste was being packaged and shipped.

Alarm spread quickly through the medical research community. Scientists said that many cancer research programmes would have to stop if liquid scintillation media and animal carcases containing trace amounts of radioactive elements could no longer be disposed of in this way. Some medical schools claimed that storage space was so tight that research

0028-0836/80/420576-02$01.00

could continue only for a few weeks if no action was taken.

Following this outcry, the contractor responsible for the Nevada and Washington sites announced that they would be reopened to receive laboratory wastes. However, the South Carolina site remains closed, and the two west-coast sites are being used by all major research laboratories which have not been able to obtain a licence for disposing of radioactive materials by other means.

Now NRC is proposing that liquid scintillation media and animal carcases containing less than μ0.05Ci of tritium or carbon-14 per gramme can be disposed of merely as toxic chemicals "without regard to their radioactivity".

The commission says that, since the potential dose to any individual exposed to these wastes would be less than 1 mrem a year, such a move would have a negligible effect on health aspects.

Using the same reasoning, it is also proposing that research laboratories and hospitals should be allowed to release up to 5 Ci of tritium and 1 Ci of carbon-14 a year into the sanitary sewage system, in addition to the present limit of 1 Ci per year for all radionuclides.

If these changes are approved, the commission estimates that research institutions and hospitals will save up to $13 million a year. Disposal of the wastes by more conventional means would cost only $3 million a year, compared with the $16 million it now costs to package and ship the materials to the west coast sites.

The proposed change in the rules is intended to conserve waste burial capacity that is already in short supply at nuclear dumps. At present, between 200,000 and 400,000 gallons a year of liquid scintillation media — mainly toluene containing heavily diluted radioactive tracers — has to be stored at these sites, taking up 400,000 cubic feet of space, with animal carcases taking up another 70,000 cubic feet.

Many university safety officers have welcomed the proposed changes in the rules. Others, however, are being more cautious, pointing out that the material will still have to be disposed of under strict federal, state and local regulations. Liquid scintillation media such as toluene are highly flammable and potentially carcinogenic — one of the reasons that South Carolina decided it no longer wanted to handle the wastes — and pose chemical and biological hazards which NRC says are a greater health problem than their radioactivity.

The result is that disposal will have to be carried out under strict new laws to deal with toxic wastes in general, such as the Resource Conservation and Recovery Act. The Environmental Protection Agency, however, has still to agree on how it intends to carry out the requirements of the act, and research laboratories are consequently uncertain of the new demands that they may have to meet. **David Dickson**

Soviet cosmonautics

Cuban went up

All the most interesting aspects of Cuban science have been reflected in the Soviet–Cuban space mission, according to Wilfredo Torres Yribar, President of the Cuban Academy of Sciences. Half of the 20 experiments planned for the flight, he said, reflect the interests of the Cuban economy.

Although space research began in Cuba "just five years after the victory of the revolution", Yribar admitted that the initial contribution had been "rather modest". In the beginning, he said, space research had not even come under the Academy of Sciences, but had been supervised by the Ministry of Communications. However, for the past ten years, Cuba had been making extensive use of data from meteorological satellites. At first this was only for weather forecasting, but now, he said, the Meteorological Institute was working out programmes for monitoring industrial pollution and studying the influence of the earth's climate on the ripening of sugar cane.

Many of the experiments performed in orbit by Cuban cosmonaut Arnaldo Tamayo Mendez and his Soviet crew-mate Yurii Romanenko, appear to be simple extensions of the regular Salyut programme. As usual, there was an experiment to grow semiconductor materials using the Soviet-designed Splav furnace, while Cuba, as the non-Soviet participant, provided the experimental capsule — in this case, the target substance was epitaxial aluminium-doped gallium arsenide — and an appropriate code-name "Caribba".

The MKF-6 camera and the Bulgarian-made Spektr-15 apparatus (so named because it can record 15 radiation channels) have been standard equipment on several Salyut missions, although on this occasion they were used in the "Tropika" experiment (photography and field observations of a defined area of Cuba) and in "Antilla" — an examination of the dynamics of the physical, chemical and biological characteristics of agricultural land and part of the surrounding seas.

Medical experiments, too, are a regular part of such missions. In this case, they included a Cuban-designed "coordinograph", which determined the accuracy and time characteristics of the cosmonauts' coordination of right and left arm movements. Another new medical experiment, "Cortex", was described by the Cuban back-up cosmonaut Jose Lopez Falcon on Moscow radio: the cosmonauts, he said, are fitted with bonnets which include sensors and electrodes; light and sound signals are transmitted, and the data recorded.

The most specifically "Cuban" experiments, however, were "Sakhar" and "Zona". These are designed to study the growth of sugar monocrystals in conditions of weightlessness — the first time an attempt has been made to crystallize an organic substance in orbit. Also of Cuban provenance is the "Support" experiment, which uses special Cuban-designed shoes that place a given load on the support areas of the feet. Returning cosmonauts, it seems, have a tendency to platypodia, and "Support" was intended to determine whether this change in the arch of the foot was a significant factor in post-flight posture disturbance. Although only Mendez wore the shoes on this occasion, they are to be worn by Soviet cosmonauts on future flights. **Vera Rich**

Forgotten martyrs

Perhaps the most interesting aspect of the Mendez–Romanenko flight is the light it throws on the early days of Soviet space research. Speaking last week on the twentieth anniversary of the Committees for the Defence of the Revolution, Fidel Castro paid tribute to the "scores of Soviet cosmonauts" who had paved the way for the Cuban flight. In particular, he recalled the "many who had died in their attempt to go into space or during their descent from space".

Those who died during descent are well known: Komarov in 1967 and the three crew-members of Soyuz 11 — Dobrovol'skii, Volkov and Patsaev — in 1971. It is less clear who he meant by those who died attempting to go into space. Yurii Gagarin died in a plane crash in 1968, while still officially on the space team, and a back-up cosmonaut, Seregin, was killed with him. Two other trainee cosmonauts are believed to have perished in high-altitude training missions. The Soviet space planners have always been highly reticent about such accidents, and the rumours of the early 1960s often complete with cosmonauts' names and family details, seem for the most part to have had little or no foundation. Even Gagarin's historic flight was rumoured to have been the back-up mission to a disaster the previous day — a story which seems to have been generated by a premature TASS announcement — although no signs of any launch were picked up by the US monitoring stations in orbit. (Just conceivably, of course, a spacecraft could have blown up on the launch pad.)

Castro referred to having visited a "gallery of martyrs" at, presumably, Baikonur, where he observed that the loss of life had been "relatively high" before space flights were "made safer". Since no westerner — except possibly Charles de Gaulle — has ever visited this gallery, Castro's remarks have renewed speculation as to just whom it commemorates.

CORRESPONDENCE

Non-proliferation

SIR — The widespread use of nuclear power plants has caused concern regarding the proliferation potential of commercial plutonium. In a recent article (*Nature* 28 February)[1], Lovins concluded that "with modest design sophistication, high-burn-up plutonium from power reactors can produce powerful and predictable nuclear explosions".

The disadvantage of using even-plutonium isotopes in a nuclear explosive stems from different physical factors, which might be underestimated if considered separately. An example of this is the effect on the critical mass (neutron multiplication and balance)[2,4] or neutron generation time[3,4] of using even-plutonium isotopes in a nuclear explosive. However, by considering (1) the neutron multiplication factor, (2) the neutron generation time, (3) the subcritical multiplication by approaching the criticality and (4) the neutron background due to spontaneous fission, we have found that the explosive yield of a nuclear bomb is decreased rapidly by the presence of significant amounts of even-plutonium isotopes. Our analysis showed that it would not be possible to exceed an explosive yield of 1 kton or 100 ton TNT in the presence of 15 or 25% even-plutonium isotopes, resepectively, in the core of the critical assembly, even using high design sophistication.

However, even a low-yield fissile explosive can ignite a thermo-nuclear explosive. Also, the radioactive hazards of a low-yield nuclear explosive are substantial, as Lovins states[1]. Hence the problems of commercial plutonium with regard to proliferation remain.

The nuclear power countries will not be able to prevent the non-nuclear power countries from going ahead with the commercial exploitation of nuclear energy. The only way in which non-proliferation can be attained will be through a political decision by the non-nuclear power countries.

Technical innocence

SIR — It seems likely that 37½ years in the Scientific Civil Service enables me to comment on your article (*Nature* 25 September, p.264).

Frustration and unease are not caused simply by the inability of administrators to comprehend the same "world-image" as we do; nor even is it just that they appear to take our advice or not according to lofty criteria that depend on the (? almost esoteric) concept of "policy" — which may sometimes not be within our own world-image, even though we may have been on more than one management course. Apart from these things we are human beings. Therefore we resent the fact that an administrative or management mandarin is, even when of "equal button", always "equal and above", as expressed in terms of money and in advancement-potential. Scientists, said the late Walter Elliott, should be "always on tap, but never on top". This cynical dictum still "rules" — but it is not OK, and never will be. It is not necessary to try to turn us into "managers" or "administrators" in order to value us as equals, of whatever button. This is the true "parity".

Read the small print

SIR — I wish to draw attention to a potentially dangerous trend in the presentation of scientific papers. In a paper published in this journal almost a year ago (Meltzoff, A.N. and Borton, R.W. *Nature* **282**, 403-404, 1979) the widely publicized conclusion was that 1-month-old human neonates possess intermodal matching abilities. Although I feel that this conclusion, whether true or false, is derived by fallacious argument, my concern here is with a fault in the presentation of the paper; a fault which may account for the general acceptance of the paper's conclusion; and a fault encouraged in your "Guide to authors".

The authors of the paper use a modified version of a well tried, even "classical", experimental method in their investigation. Regrettably, they confine the description of their modifications to a densely printed figure legend, where it is embedded in the mass of relatively trivial detail intended for any who wish to repeat the experiment. More regrettably, the narrative of the paper carries what appears to be a complete account of an experimental method — the unmodified "classical" method — but it carries no hint whatever that this "classical" method has been modified by the manoeuvres which are mentioned only in the figure legend.

Thus, although all mention of certain heuristically significant experimental detail is omitted from the narrative of the paper, nothing suggests that the argument which is presented in that narrative, and which may impress the reader as being conclusive, fails to take account of all relevant factors.

When the description of experimental detail is fragmented as it is in this paper, there is a risk that fallacious conclusions may acquire an apparent but spurious validity, and a persuasive yet equivocal paper pass unchallenged into "the literature". There is, of course, no way of knowing how often the latter happens. Similarly, no amount of advice in a "guide to authors" can entirely eliminate its occurrence. But the practice of relegating experimental detail to figure or table legends is probably becoming more common; and the more common it is, the more dangerous: for readers learn to assume that authors *never*(!) displace heuretically significant detail from the narrative of a paper without due notice.

Authors cannot be prevented from inadvertently misleading readers, even referees; but perhaps your advice to them should be reconsidered: "Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends." — Is it?

DAVID BELASCO

Swaffham,
Norfolk, UK

Generating costs

SIR — Richard Marshall's letter (*Nature* 18 September, p.184) on the Central Electricity Generating Board's published cost forecasts for new nuclear and coal-fired stations, requires some comment. First, the load factor on any station in any year is a function of two parameters — the availability of the plant and the proportion of total electricity demand which it is economic to allocate to that particular plant. Nuclear stations for most of their life and new coal stations early in their life will normally be operated economically to the limit of their available capacity. In later years they will come a time for both types of plant when, because of the construction of still newer capacity, their load factor will fall below the maximum permitted by availability. Since coal-fired stations have a much higher operating cost than nuclear stations this process will start earlier for coal-fired stations, which will therefore achieve a somewhat lower lifetime load factor than nuclear stations.

The load factor projections are therefore not arbitrary; they derive from a careful estimate of expected economic loading on each plant in each year. The load factors so far achieved on the Hinkley B advanced gas-cooled reactor (AGR) station reflect the fact that this is the first commercial AGR station ever built, still in its early years of experience. Inevitably its availability to date reflects teething troubles. Our projections of future availability are made on the reasonable basis that in due course new plant yet to be built would benefit from this experience.

We would therefore not expect coal to achieve a 70 per cent load factor while nuclear achieved only 50 per cent, but even if this were to happen, the cost projections quoted by Mr Marshall are still incorrect. Accepting for the sake of argument 50 per cent and 70 per cent load factors for new nuclear coal-fired plant respectively, the adjusted generation costs would be 2.6 and 3.1 pence per kWh, thus still retaining the cost ranking as predicted. These figures differ from Mr Marshall's because only the fixed component of the generation cost varies with load factor when working in pence per kWh.

NEWS AND VIEWS

Nutrition and metabolism

from Mary Lindley

ON the top floor of the medical library at Johns Hopkins' University a modest display reminds visitors that last year was the centenary of the birth of E.V. McCollum, discoverer of vitamins A and D. After becoming professor emeritus at Johns Hopkins in 1944, they are told, he spoke out against the fortification of foods, arguing that a well balanced diet was the key to good health. The visitors might reflect that since then, as fads and fashions have dictated nutritional trends, it has not always been clear what a well balanced diet might be, and the answer does not seem to be at hand. Delegates to a recent symposium* at Johns Hopkins on the effects of nutrition on metabolism may well have departed thinking that only the bravest would recommend a universally healthful diet, when food can have such apparently profound influences on the body.

One influence that has been fully appreciated only in the past year centers around the role of brown fat, which, as J. Himms-Hagen (University of Ottawa) pointed out, is now seen to have a fundamental role in the body's thermogenic response to food as well as to the cold. During the past twenty-five years brown fat (otherwise known as brown adipose tissue) has been seen as a possible site of thermogenesis, producing heat, especially in animals waking from hibernation and in the newborn. The homeostatic mechanism that keeps babies warm can also be demonstrated in rats exposed to a cold environment. They develop the capacity to increase their metabolic rate and thus maintain body temperature, in response to noradrenaline released by the sympathetic nervous system, whenever re-exposed to the cold. Muscle has also been suggested as the site of this non-shivering thermogenesis and only in the past few years has brown fat been firmly acknowledged as the tissue responsible.

The most recent stage in the story of brown fat has been the clarification of its role in generating heat in response to overfeeding. As M.J. Stock (St George's Hospital, London) explained, studies of human subjects had shown that some individuals generate heat in response to excess energy intake, but further investigation had been hampered by the lack of a suitable animal model. Now Sclafani and Springer's cafeteria method has proved effective in inducing rats to supplement their diet of chow with delicacies such as bananas, biscuits and popcorn so that their voluntary energy intake increases by up to 80 per cent. Just like the human subjects, some of those rats do not become obese, but respond by generating heat. The site of this diet-induced thermogenesis turned out to be brown fat, pointing to a role for this tissue in energy balance as well as thermoregulation (Rothwell & Stock, *Nature*, 281, 31; 1979).

That idea has suggested a new way of looking at individuals who become obese in response to overeating. It is tempting to speculate that they have a defect in their brown fat and cannot dissipate the excess energy consumed. A hint that this may be correct is provided by the inability of obese animals to maintain their temperature in the cold, but, as W.P.T. James (Dunn Nutritional Research Laboratory, Cambridge) cautioned, a simple explanation of obesity is unlikely. Complications include factors such as thyroid hormone metabolism. E. Danforth (University of Vermont) explained that thyroid hormones regulate energy expenditure and are themselves regulated by diet; their metabolism is slow after a decrease in calorie consumption and accelerates after an increase.

The role of the sympathetic nervous system in the body's response to dietary stimulus is being investigated by L. Landsberg and J.B. Young (Harvard Medical School, Boston). They have measured noradrenaline turnover to show that sympathetic activity is suppressed in fasting rats and mice and stimulated when the animals are overfed by giving them access to sucrose in addition to their normal diet. The results indicate that the hypothalamus integrates those changes and that insulin may be an important link with the dietary stimulus. Landsberg suggested that such a system for controlling noradrenaline turnover, which is separate from the stimulatory effect of hypoglycaemia on the adrenal medulla, could be a mechanism to dissipate excess calories through thermogenesis and to conserve them when in short supply.

All this proved somewhat perplexing for the clinicians, who wanted to know what to do with their obese patients if a reducing diet would depress the activity of both thyroid hormones and sympathetic nervous system. Danforth advised them to complement dietary treatments with a programme of exercise; diet alone will never be effective in controlling obesity, he said.

During the past ten years the brain has also proved to be subject to dietary influence in spite of the blood-brain barrier, which, J.H. Growdon (Massachusetts Institute of Technology, Boston) explained, was long thought to isolate it from the rest of the body. Variations in concentrations of choline and amino acids in the plasma can be correlated with fluctuations in the brain's content of neurotrasmitters and their precursors. J. Fernstrom (Massachusetts Institute of Technology) explained that a diet containing largely carbohydrate and little protein stimulates the synthesis of serotonin, because its precursor tryptophan can enter the brain without competition from other amino acids, most of which are taken up by muscle. But when the diet is rich in proteins, competition from other amino acids prevents an increase in brain tryptophan, so that serotonin is not affected. The situation is different with tyrosine, the precursor of dopamine and noradrenaline. As C. Gibson (Massachusetts Institute of Technology) explained, tyrosine is more plentiful in food than tryptophan, and a diet rich in protein will supply sufficient of the precursor to enter the brain in spite of the competition and to influence the rate of synthesis of the two neurotransmitters.

A.J. Gelenberg (Massachusetts General Hospital, Boston) described how these three precursors are being used in clinical research as potential drugs to treat certain neurological disorders. Two examples are Alzheimer's disease, which involves recent memory loss and deficiency of choline acetyltransferase, and Parkinson's disease, a progressive motor disorder in which dopamine is deficient. Although it is not possible to assess the full therapeutic potential of neurotransmitter precursors, results so far have encouraged continuing studies.

As would be expected, malnutrition can have severe metabolic ramifications. The systemic immune response, for example, has often been shown to be subject to the vagaries of malnutrition, with T cells especially vulnerable. But N.F. Pierce

---

*The thirteenth Miles International Symposium, on Nutritional Factors: Modulating Effects on Metabolic Processes, was held at Johns Hopkins University, Baltimore on 18-20 June. It was organised by Dr R F Beers and the proceedings will be published by Raven Press.

Mary Lindley is an assistant editor of Nature.

0028-0836/80/420579-02$01.00

(Johns Hopkins University) said that less is known about the response to invading microorganisms although they can have a devastating impact, particularly in the developing world where diarrhoea and respiratory infections are common afflictions of childhood. Using immunonofluorescence to detect cells producing IgA, Pierce and his colleagues have examined the effect of protein malnutrition on the rat's mucosal immune response to cholera toxin. They found the response impaired in rats fed a diet containing 4 per cent protein compared with the usual 24 per cent.

F.B. Bang (Johns Hopkins University) reported that mice with a gene that normally makes them resistant to hepatitis will succumb to infection by that virus when maintained on a diet low in protein. In such cases malnutrition apparently affects the functioning of the macrophage system.

Malnutrition also influences infection by certain bacteria. E. Griffiths (National Institute for Medical Research, London) described how *Escherichia coli*, *Salmonella* and *Klebsiella* can sequester iron within their hosts. Those bacteria secrete enterochelin, which can remove iron from the binding proteins, transferrin in blood and lymph, and lactoferrin in mucosal secretions and milk. Once bound to enterochelin, the iron is taken up into the bacteria for their use. Of course the bacteria also have to contend with the host's immune system, which normally affords an effective defence. But children with the malnutrition syndrome kwashorkor, which depletes transferrin, and also impairs the immune system, will be extra susceptible to infection from bacteria that can thrive due to the increased availability of iron, especially if iron therapy is started during refeeding.

W.E.M. Lands (University of Michigan, Ann Arbor) introduced a fresh aspect to the debate over polyunsaturated fatty acids, already controversial for their proclaimed ability to lower plasma cholesterol. Some of them can inhibit the conversion of arachidonic acid to prostaglandins and thomboxane, and their prevalence in the diet may influence the amount of those two substances produced in response to the appropriate stimuli. J. Dyerbeg (Aalbrog Hospital, Denmark) provided epidemiological and experimental evidence to support that suggestion. The Eskimoes of Greenland, whose diet is rich in the polyunsaturated fatty acid eicosapentaenoic acid (EPA), a constituent of many marine oils, have a longer bleeding time and lower platelet aggregability compared with Caucasians. They also have a low incidence of myocardial infarction. In the experimental study, people given six grams of EPA per day for three weeks experienced a moderate decrease in platelet aggregation and prolongation of bleeding time. Dyerberg stressed, however, that the evidence so far does not justify recommendation of EPA as an anti-thrombotic agent.

Those who are brave enough to attempt to formulate guidelines for healthy living based on the disparate influence of diet on metabolism must also remember the influence of genetics. For example, A.M. Altschul (Georgetown University, Washington DC) pointed out that the evidence linking salt consumption with hypertension indicates that there is likely to be a positive correlation only for people with a family history of hypertension.

B. Childs (Johns Hopkins University) issued a warning by recounting his cautionary variation on the nursery rhyme — Jack Spratt could eat no fat, his wife could eat no lean. Mr Spratt apparently avoided the consumption of fat because he had hypercholesterolaemia and his father had died of a heart attack. Mrs Spratt, on the other hand, became dizzy and sick whenever she ate food rich in protein. Due to a mutant gene on one of her X chromosomes she had a partial deficiency of ornithine transcarbamylase, preventing the normal production of urea, and leading to the accumulation of toxic ammonia.

For Mrs Spratt and those with other defects of the urea cycle some hope seems to be offered by dietary manipulation facilitating the removal of waste nitrogen in some form other than urea; for example, supplementation with arginine increases the production of arginosuccinate, which is excreted by the kidneys. Although such examples represent the extreme of sensitivity, individual responses to dietary variation are likely to span a wide range, making the ideal diet impossible to formulate. □

Scanned image microscopy

from I. R. Smith and D. A. Sinclair

A recent conference* showed that new types of scanning microscope which promise unique imaging capabilities are rapidly being developed. As well as improved optical microscopes, X rays and acoustic waves are being used for high resolution scanned imaging and energy conversion techniques are being employed in the design of photo-acoustic and photothermal microscopes.

In a scanning microscope a tightly-focused beam is is scanned over the specimen and the transmitted or reflected energy is made to modulate the brightness of a scan-synchronized display to form an image. The resolution of the system is dependent upon the width of the beam (in general, comparable with the walelength of the radiation employed), whilst the image contrast depends upon the interaction of the radiation with the specimen. The development of new types of microscope is possible because the constraints upon the focusing elements of a scanning microscope are relaxed when compared with an imaging one. In particular, wide field performance is not required.

Scanned optical microscopes (SOM) are a factor of 1.4 times better in resolution than their imaging counterparts because of the use of a confocal lens arrangement in which the 'condenser' lens itself forms a diffraction limited spot upon the specimen (G. J. Brakenhoff, University of Amsterdam). Resolution may be further increased by the use of shorter wavelength ultra-violet radiation. Still higher resolution may be obtained in electron microscopes but these are unsuitable for imaging living cells. Scanning microscopes allow a great diversity of operating modes. One, demonstrated by T. Wilson (Oxford University), uses the SOM to probe semiconductor devices. The focused laser source of the SOM generates hole/electron pairs within the semiconductor, and these can be measured by monitoring the current in a p-n junction. The image shows how much current was generated over the device, and regions of low generation indicate the presence of electrically active defects, such as impurities, dislocations and grain boundaries, which can contribute to device failure.

X-ray microscopy has potentially very high resolution. At a wavelength of 3nm there is a large difference in the X-ray absorptivity of water and protein so it is possible that images of living cells can be obtained with both high resolution and contrast. Only synchrotron sources are currently bright enough for microscopy so widespread use must await the development of a compact, coherent X-ray source.

Above the 'soft' ultra-violet region, conventional refracting optical components become highly inefficient. Three solutions to this problem are being tried. In the first an unfocused X-ray beam passes through a very small (μm) aperture which is scanned over the object (H. Rarback, University of New York). The

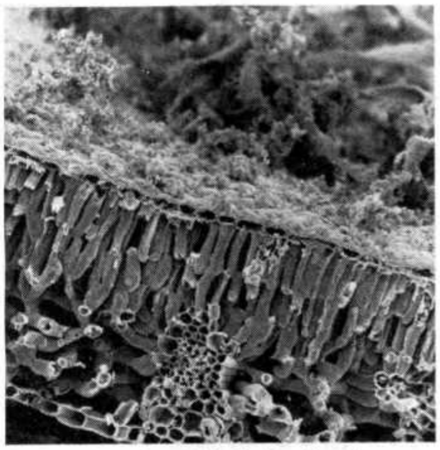
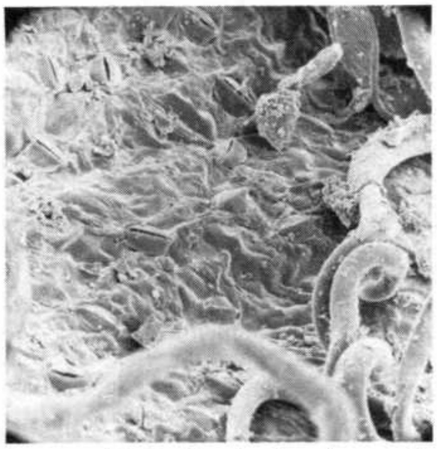
Ash from Mt St Helens

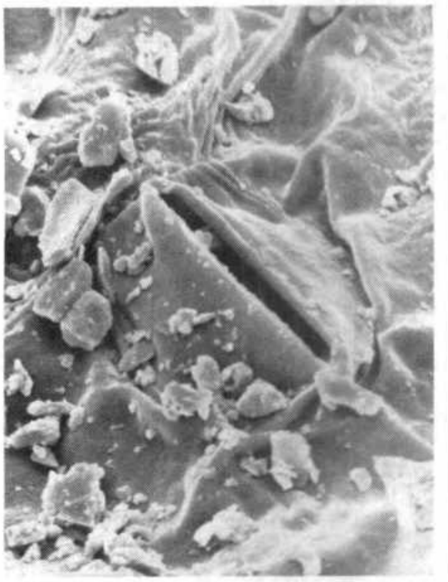
from Robert A. Kennedy



Cross section of apple leaf with ash on the upper epidermis.



Lower apple leaf surface showing ash among the trichomes and stomata.



Ash inside a stoma on the lower epidermis of an apple leaf.

After the May 18th explosion of Mount Saint Helens ash fell on nearly seven million hectares of land in the State of Washington and in some places reached depths of 75cm. The pictures of plant leaves shown above were taken one and a half months after the explosion at Pullman, Washington, more than 250 miles from the volcano. Although over three inches of rain had fallen since the eruption large amounts of ash particles remain on the leaf surfaces, coating both the upper and lower epidermis and even finding their way into stomata.

The direct effect of the ash is to reduce light penetration; a one mm thick coating on the leaf absorbs 90 per cent of the light and virtually stops photosynthesis. More indirect and longer term effects may come from the presence in the ash (in concentrations of up to 10ppm) of the toxic element fluoride.

Robert A. Kennedy is associate professor in the Department of Horticulture and Landscape Architecture, Washington State University.

aperture defines the beam width, and hence the resolution. The second approach is the use of a Fresnel zone plate for focusing the radiation (G. Schmahl, University of Gottingen; N. M. Ceglio, Livermore Laboratories), a technique which has has resulted in 0.15 μm resolution. The third method uses a focusing mirror with multi-layer coatings to increase reflectivity (E. Spiller, IBM New York; R. P. Haelbich, University of Hamburgh) and seems likely to yield the highest resolution.

The development of scanning acoustic microscopy (SAM) has two main objectives; the attainment of at least sub-optical resolution and the determination of the object's elastic constants. A sub-optical resolution microscope implies the use of a low-velocity, low-loss acoustic coupling liquid. Lemons (1974) has defined a coefficient of merit, M, which normalises the resolution attainable with a particular liquid to that with water — the liquid conventionally used in the SAM. Cryogenic liquids, for example, Argon at 87K for which $M=3.7$ and Helium at 1.95K and 0.4K for which $M=3.7$ and 23 respectively offer potential improvements in SAM resolution. J. Heiserman (Stanford University) described a cryogenic reflection SAM designed to use these liquids and which currently works with liquid Helium down to 1.95K where the wavelength is 360 nm. The banded structure of human chromosomes has been clearly imaged with this system.

High pressure gases are, as pointed out by H. K. Wickramsinghe (University College, London), an attractive alternative to cryogenics since $M=4$ and 5 for Xenon and Argon at 40 and 250 atmospheres respectively. This suggests that resolutions just less than 100nm can be achieved. Room temperature operation is an additional advantage that will allow simple sample preparation techniques and the imaging of living cells.

To measure an objects elastic constants C. F. Quate (Stanford University) described a technique in which the output voltage, V, of a reflection SAM is recorded as a function of defocusing distance, z, at a single image point. The $V(z)$ curve obtained is a characteristic function of the elastic properties of the object surface. Both the density and the longitudinal velocity of the sample may, under certain conditions, be computed in this way.

The SAM has been used to image a wide range of objects. Coal may be characterised, as suggested by C. F. Quate, by its acoustic reflectivity. This technique should offer an increase in sensitivity of forty times over the comparable optical technique. He also showed using $V(z)$ techniques that the SAM is eminently suitable for detecting delaminations in thin films such as chrome on glass. The large impedance mismatch between the surface of a metallic object and the water coupling the lens to the object may be overcome by replacing the water with a liquid metal such as mercury or gallium. This and the use of shear waves in addition to the liquid metal coupling can provide improved resolution due to the decreased wavelength and reduced spherical aberration in the object (J. Attal, Universitie des Sciences et Techniques du Languedoc).

Interest in the photoacoustic effect, first demonstrated by Bell in the 1880's, has increased dramatically in the last decade with the development of several photoacoustic imaging systems capable of microscopic resolution. In what has become conventional photoacoustic microscopy (PAM) a modulated light beam is scanned across a solid surface. A microphone is used to detect the pressure waves generated in the gas above the surface by virtue of the periodic heating at the sample surface. Since a lock-in amplifier is normally used in the detection system both the amplitude and phase of the photoacoustic signal can be mapped out across the sample. A. Rosencwaig (University of California) and G. Busse (ZWE Physik) pointed out the components of the signal detected at different phases relate to information from different depths within the sample. The system resolution is determined partly by the optical spot size and partly by the thermal wavelength in the solid. This latter quantity is inversely proportional to the square root of the beam modulation frequency and affects the depth of penetration of the thermal wave in

0028-0836/80/420581-01$01.00

the solid.

G. Cargill (Watson Research Centre, IBM) and Rosencwaig showed that the beam in a SEM may also be used to generate a thermal wave in a sample. A piezoelectric detector bonded to the back surface of the sample collects the acoustic wave generated by the thermal expansion in the solid. In this technique of electro-acoustic microscopy much smaller spot sizes can be used to illuminate the sample and the resolution is then only limited by the thermal wavelength. Submicron resolution should be possible using 1-10 MHz modulation frequencies. Rosencwaig demonstrated the detection of a 2 micron crack beneath a solder pad in a ceramic substrate. By selection of the appropriate phase of the electroacoustic signal subsurface imaging is possible. He presented images showing phosphorous dopant regions in a Si substrate beneath a SiO$_2$ layer.

A technique related to PAM again uses a modulated light beam to illuminate the sample surface. An infrared detector is, however, used to directly, but remotely, monitor the sample surface temperature. The detector output is a function of both the optical and thermal properties of the sample. P. Nordal (Laser and Applied Optics Laboratories, Blindern) showed that this technique of photoinfrared microscopy was sufficiently sensitive to detect a single monolayer of aspartic acid in a chromatogram.

In conclusion, scanning microscopes offer higher resolution and a natural imaging environment for living cell cultures, whilst in the field of non-destructive evaluation, give information inaccessible to conventional techniques. □

Gluon fusion

from V. Barger

THE production of particles made of charm or b-flavor quarks has been under intensive study for several years. Of special theoretical interest in the production of these quark flavors is the large mass scales involved, which permit perturbative calculations of strong forces using the theory of quantum chromodynamics (QCD). Recent data from experiments with muon beams at CERN[1] and Fermilab[2] give evidence for copious production of charm and anticharm, which can be compared with QCD expectations. The successful description of these data was a major topic[3] at the XXth International Conference on High Energy Physics held at the University of Wisconsin-Madison in July.

A muon beam (μ^+ or μ^-) interacts with a nucleon target via the electromagnetic interaction through the exchange of a virtual photon. In the scattering of the virtual photon with a gluon constituent (g) of the nucleon, a charm-anticharm quark pair ($c\bar{c}$) can be created (Fig. 1). These quarks materialize with probability unity as charmed hadrons through the confinement force. The subsequent weak decays of the charmed particles can lead to additional muons (Fig. 2), which provide a clear experimental signature for charm events. On the average, the decays of a charm particle yield a muon about 10 per cent of the time, with a μ^+ originating from charm decay and a μ^- from anticharm decay. Counting the primary muon from the beam scattering, charm pair production results in dimuon and trimuon events. The muon emitted in charm decays is accompanied by a neutrino (ν), whose energy and momentum are unobserved. Thus multimuon events from $c\bar{c}$ production are characterized by missing energy.

Unlike the muon signals from charm decays, multimuon sources from other electromagnetic processes mediated by two virtual photons have zero or little missing energy. Fortunately, contributions from these non-charm sources can be reliably estimated.[4] By appropriate experimental cuts the charm signal can be isolated.

The theoretical calculation of photon-gluon fusion[5] (Fig. 1) depends on the strength of the gluon to $c\bar{c}$ strong interaction coupling, which is fixed by QCD analyses of other reactions. Another necessary ingredient is the probability density for finding a gluon carrying some fraction of the nucleon momentum. From inelastic electron scattering, it is known that gluons carry about half of the nucleon's total momentum. Using conventional theoretical prejudices about the shape of the gluon probability distribution,[6] the predictions of the photon-gluon fusion model are found to be in excellent agreement with the multimuon data.

The fusion approach also applied to the production of bound $c\bar{c}$ states, such as the ψ-particle. It is assumed[7] that ψ-production is proportional to the density of $c\bar{c}$ states produced near the ψ-mass. The model is in good agreement[8,9] with "elastic" ψ-production events[1,2] that have little accompanying hadronic energy. For inelastic ψ-production additional fusion diagrams enter, with an extra quark or gluon carrying away energy.[10].

In hadron-hadron collisions the creation of $c\bar{c}$ or $b\bar{b}$ pairs occurs via gluon-gluon fusion and via the fusion of light quarks q with their antiquarks $\bar{q}$ (Fig. 3). Data on the hadroproduction of the ψ and Υ particles allow the extraction of gluon distributions for pions, kaons, and nucleons. A consistent fusion description of the hadroproduction of heavy quark bound states emerges,[9] with the same gluon distribution for the nucleon as determined from virtual photoproduction.

These successes of the fusion model are somewhat clouded by the present situation concerning the hadroproduction of unbound charm, where the predicted rates are too small. One possibility is that yet to be calculated higher order QCD diagrams are important in hadron-hadron collisions. □

On the Lost Art of Seeing where Things are Going

from Simon Heywood

No one disagrees that one of the most important perceptual tasks to confront a sophisticated and mobile organism is the capacity to detect and discriminate movement, whether of itself or of other organisms or objects. It therefore seems obvious to devote research to the processes underlying the perception of movement, whether in terms of the psychological or phenomenonological characteristics of such processes or their putative realisation in neural machinery.

A recent NATO-sponsored symposium* called together some eighty workers in the area to review and to extend our knowledge of these processes. However, it must be admitted that simple as the problem of movement perception may sound, four days of conference served to illustrate that there remains considerable theoretical disagreement over what the proper object of study actually is. The explosion of "facts" unearthed by more or less ingenious physiological, psychophysical and psychological experiments has all too clearly not been parallelled by a development of theory to establish the meaning of such facts.

While it is obvious that we can and do perceive movement (just as we can and do perceive form or colour) it cannot be assumed that, therefore, the logic of investigating its physiological substrates is the same. Microelectrode studies reveal that a significant majority of visual cells in the cortex or the midbrain of animals respond to the movement of stimuli through their receptive fields; studies of great elegance classify the response types of these neurons in terms of stimulus velocity, or of their sensitivity to stimulus position change or of the position of their receptive fields and so on. But a moment's thought suggests that the relevance of these studies to the perception of movement is entirely unclear. In the great majority of visual environments, the predominating mass of visual objects and textures are actually stationary; a small subset moves. However, for any organism in motion (especially one with highly mobile eyes, like ourselves) the retinal images are constantly moving. The inescapable conclusion is that in order to interpret visually what is actually moving in the world we must first be able to establish the stability of the visible frame-of-reference within which and with reference to which that movement occurs. Single unit studies have (with a few notable exceptions) indicated only that cells respond to retinal stimulus motion, and hence fail to tell us whether such cells subserve the perception of movement or that of stability.

The simplest (and the oldest) solution is to argue that we establish stability by combining the retinal movement information with information about eye and head (and possibly body) movement. Thus perceived stability is achieved when the movement on the retina is matched and congruent with movement produced by the organism's oculomotor and neck musculature. In this case, the movement sensitive visual cells could at best only be understood in the context of other non-visual information, about whose distribution in the brain we are at present almost entirely ignorant.

Unfortunately two kinds of experimental results cast doubt on even this as a basis for the perceived stability (and hence perceived motion) of objects in the world. First, any such corollary signal from the eye and head moving systems to the perceptual apparatus appears to be far too "sloppy' to achieve the nicety of stabilisation that we perceive. Second, recent work, reported at the symposium, shows that high-level cognitive processes may be more important in assigning stability or movement than the exact relations between retinal image shift and eye/head movement. What is important, and dominant, in perception is the visual *relationship* between objects and frames-or-reference; it appears that the perception of movement in natural environments can be understood primarily as an object-relative phenomenon. This, of course, makes the interpretation of electrophysiological data even more problematic.

However, consensus does appear to be emerging on broad lines of how the visual perception of movement and stability may have to be structured; a number of speakers from quite different research backgrounds were echoing dichotomies first proposed in 1968 by Schneider, Trevarthen, Ingle and Held. There appear to be many ways of expressing these dichotomies and it is not yet clear how precisely they relate to each other and at what levels of description they operate, but three that were frequently mentioned were a) a distinction between a "movingness" (velocity-based) and a "displacement" (amplitude-based, hence perhaps related to position) system, using Claude Bonnet's terminology; b) a distinction between "central" and "peripheral" vision (which is not necessarily to be taken as an anatomical distinction, though there is clearly a spatial differentation between them), and c) a distinction between two modes of oculomotor activity, one designed to hold part of the retinal image still on the retina and assumed to be primarily driven by retinal image velocity, and the other designed to shift the retina fast underneath the retinal image and assumed to use primarily positional information. Such dichotomies are clearly interrelated and related to the dichotomies used elsewhere between sustained and transient channels, or ambient and focal vision, or *x* and *y* cell systems, or saccades and pursuit eye movement. Perhaps if we could devote the next symposium not to the presentation of many new facts, but to the elucidation of these concepts and their functional relationships, we should move closer to understanding not only our perception of movement but how such perception is related to the structure and control of our own activity. □

Optical discs for information storage

from A. E. Bell

The high density optical disc may provide a new way of meeting the need for low cost information storage. A 12″ diameter optical disc can store as much as 10^{11} data bits, and recording rates up to 50 Mbits s^{-1} for a single channel have been demonstrated. By comparison to magnetic disc recording, optical recording increases the data packing density by about two order of magnitude, producing a much lower cost per bit stored.

The key component of the optical system is the recording medium and several possibilities, including an organic dye-in-polymer[1], generally satisfy the requirements of recording sensitivity and playback signal quality. Current research is now concentrated on improving the permanence of the information once stored as this is a key factor in the final selection of a suitable recording medium.

A typical high density optical recording system is shown in Fig. 1. The recording light source is a gas laser which emits a continuous, collimated and linearly polarised beam with a very well defined wavelength. The beam passes through a modulator to which the input data signal is applied and then via some optics and a polarising beam splitter/quarter-wave plate combination into the entrance pupil of the focusing lens. The lens focuses the intensity modulated beam to a spot on the recording medium, coated onto the surface

A. E. Bell is in the RCA Laboratories, Princeton, New Jersey.

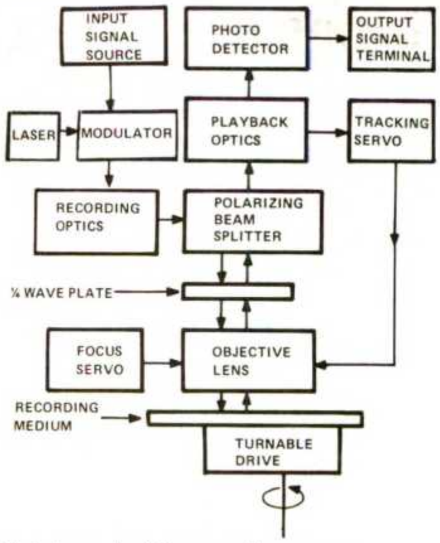

Fig 1 An optical disc recording system.

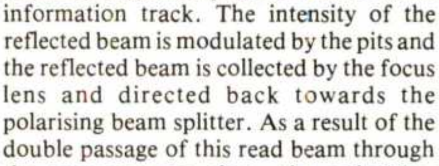
of the rotating disc substrate. Where the incident intensity is above threshold the recording medium is melted or vaporised so that the a record is made as a series of micronsized pits along the track (Fig. 2). These change the local reflectivity (or transmissivity) of the medium permitting optical playback of the recorded data.

To retrieve the data, the laser intensity is reduced below the recording threshold and a low intensity read spot is focused onto the information track. The intensity of the reflected beam is modulated by the pits and the reflected beam is collected by the focus lens and directed back towards the polarising beam splitter. As a result of the double passage of this read beam through the quarter-wave plate, the polarising beam splitter separates the read beam and directs it via the playback optics chain to a photodetector. The electrical output of the photodetector thus represents the original input data signal.

Three basic servo control are required by the optical recording system. The focus servo continuously adjusts the position of the focus (objective) lens to compensate for the uneveness of the disc substrate, and maintains the focused recording or readout spot in the plane of the recording medium. The tracking servo ensures that during playback the readout spot is centered on the information track of interest (the separation of tracks can be as low as two microns). The turntable servo controls the speed of rotation to preserve timebase information.

Fig 2 Scanning electron microscope image of melted pits recorded in a 30 nm thick tellurium film.



The simplest[2–4] recording medium is a disc substrate coated with a single vacuum deposited layer of metal (∼ 30-50 nm thick). As the recording mechanism consists of melting the coating to form a submicron diameter pit surrounded by a rim of resolidified material (Fig. 2), the quality of the playback data signal is largely determined by the geometrical regularity of the pit shape. The process by which the melted pit is formed is currently being investigated and while no complete detailed model exists it is clear that surface tension, viscosity and the presence of nucleation centres on the substrate can all play an important role.

The laser power required to melt the pit is determined by the thermal characteristics of the metal layer. The element, tellurium, which has unusually low thermal diffusivity and a melting point of 452°C, has been widely investigated.[4] Since the metal layer is so thin, even during the rapid recording pulse (a data rate of 10 Mbit s^{-1} corresponds to a 50 ns recording pulse) a significant fraction of the heat generated within the metal layer can be conducted into the substrate. To avoid this the thermal diffusivity of the substrate material should also be as low as possible. Low cost plastic substrates such as poly-(methyl methacrylate) or poly-(vinyl chloride) satisfy this requirement.

Of equal importance in determining the sensitivity of a recording medium is the fraction of the incident beam which is absorbed. As in single layer structures about 40 per cent of the beam may be reflected, antireflective coating configurations have been proposed[5] and investigated.[6,10] The bilayer structure, Fig. 3 *a* is most suited to moderately absorptive materials such as organic dyes, or organic dyes in polymer mixtures. A highly reflective aluminium layer is first vacuum-deposited onto the substrate. The recording medium itself is then deposited (by spin-coating or vacuum deposition) to a thickness of approximately one quarter-wavelength of the recording beam in the recording medium (that is, ∼ $\lambda/4n$) This thickness results[5] in a very low reflectivity with up to 90 per cent of the incident beam being absorbed in the recording medium. When the pit is formed, the interference condition is disrupted and the pit exhibits a very high reflectivity, as a result of the exposed, but unperturbed, aluminium layer. The bilayer approach thus gives a high sensitivity and a high playback signal contrast between the reflective pits and the antireflective lands in between.

Another approach which permits low reflectivities to be obtained even with strongly absorbing metallic recording media is the trilayer structure, Fig. 3*b*. The aluminium reflector layer is first coated with a transparent dielectric (such as silicon dioxide) and then a very thin layer (5-10 nm) of the highly absorbing recording medium. By manipulating the thicknesses of the dielectric and absorbing layers,[5], the phase and amplitude relationships required to produce destructive interference and thus low reflectivity, can be separately controlled. In a low reflectivity design up to 95 per cent of the incident beam is absorbed by the 5-10 nm thick layer of recording medium. Melting of the thin layer of recording medium disrupts the interference condition and results in a highly reflective pit. The reduced thickness of the metal absorber in the trilayer structure as compared to the single layer structure leads to improved signal-to-noise ratio (more uniform pit rims). Furthermore, the antireflection properties of the trilayer structure can be 'tuned' to a variety of recording wavelengths simply by adjusting the thicknesses of the dielectric and absorbing layers.

Some problems are common to any high density data disc design; these include the substrate preparation and the encapsulation of the recording medium to protect it from dust particles. Clearly, since the density of data storage is very high (∼10^8 bits cm^{-2}) even microscopic defects in the substrate disc can result in significant loss of data. Highly polished glass surfaces approach the level of perfection required, but they are both expensive and bulky. Low cost molded plastic substrates have a high level of surface imperfections and require surface improvement before use. The simplest procedure is to spin-coat the disc substrate with a thin layer (<20 μ) of liquid polymer resin which is then cured either by heat treatment or UV irradiation.

STRONGLY ABSORPTIVE RECORDING MEDIUM
$\sim \frac{\lambda}{4n}$
TRANSPARENT DIELECTRIC
ALUMINIUM REFLECTOR

b.) TRILAYER STRUCTURE

Fig 3 Antireflection structures for optical recording media.

The surface defects of the original substrate surface are filled in and the cured surface of the polymer layer can match or even exceed the surface quality of specially polished glass.

As dust particles falling onto the recording medium would rapidly introduce errors, the direct encapsulation of the recording medium with a relatively thick (180μ) layer of transparent polymer may be a valuable final step in the disc fabrication procedure. Dust particles will be on the outside surface of the encapsulation layer and out of focus.

High density optical recording may have very wide applications including the storage of computer, satellite, financial, X-ray and government statistics data, as well as video pictures. At the moment, the key problem is the permanence of the optical data as the minimum useful lifetime for most large volume applications is about 10 years. Of particular significance is the continuing development of relatively high power solid state diode lasers[9] and compatible media[10,11] since by comparison to the gas lasers these devices offer compactness, low power consumption, direct modulation capability and potentially increased reliability. □

Neuronal competition

from Dale Purves

ALTHOUGH the idea of competition between nerve cells during development is hardly new, it is enjoying a distict renaissance. There are several good reasons for this flurry of interest.

Early evidence for a competitive interaction between neurons came from the work of Hamburger and Levi-Montalcini[1]. They showed that about half of the nerve cells initially generated in some parts of the vertebrate embryo die during later development, and that the amount of this cell death is modulated by the neuronal target. Thus the vast majority of neurons in a population degenerate if their intended target (the limb, for example) is removed early in development and, conversely, the incidence of cell death is reduced if an additional target is provided (by implanting a supernumerary limb[2]). Taken together, these findings show that the death of some neurons is not a predestined affair, but depends on the ability of individual nerve cells to respond to some property of the limb. The importance of the target in regulating cell death by a mechanism that is, in a broad sense, competitive has been widely confirmed, most recently in a detailed study of the dependence of ciliary ganglion cells on the iris[3].

As with any idea that threatens to become a dogma, there has been some dissent, most recently expressed by Lamb[4]. He reported that when both right and left hindlimb motor neurons of the frog are made to project to a single limb at an early stage of development, the total number of surviving motor neurons in the relevant part of the spinal cord is greater than the number of neurons that normally survive to innervate that limb. He concludes that the "limb does not limit the number of survivors and therefore the hypothesis (of peripheral competition) is refuted . . .". Many neurobiologists, however, will take this result as an argument against a particular (one-to-one) conception of the neuron's dependence on its target, rather than an argument against competition as the basis of nerve cell death in normal development. Lamb's result suggests that the number of surviving neurons is not related to the amount of available target in a simple linear manner. A simple relation is not expected if neurons regulate the target property that they seek; a plausible notion since many properties of muscle fibers are regulated by the innervation they receive.

A central reason for renewed interest in the idea that neurons compete for some aspect of their target is that it seems likely that competition also regulates the number and arrangement of synaptic connections in the nervous system. Several phenomena in development and maturity have led to this view. For example, both muscle fibers and autonomic ganglion cells are innervated by more axons at birth than they are a few weeks later, indicating an extensive rearrangement of connections in early postnatal life[5]. In the central nervous system, a probable counterpart to the early elimination of some synapses in the periphery is a reduction in the number of climbing fibers innervating each cerebellar Purkinje cell in neonatal rats[6]. An especially intriguing example of central synapse elimination is the postnatal segregation of thalamic projections to the visual cortex of monkeys and cats[7]. At birth, axon terminals activated by one or the other eye are distributed throughout layer IV of the primary visual cortex, and may contact the same cortical neurons. During the subsequent weeks, however, the projections from the two eyes become separated so that cortical neurons in this layer are ultimately driven by either the left or the right eye. The axon terminals carrying information from the two eyes actually become segregated into domains that have the appearance of zebra stripes when mapped on the cortical surface. While the mechanism and purpose of this segregation in the brain remain a mystery, the underlying rearrangement of connections is in many ways similar to the winnowing out of some initial synaptic contacts in the periphery. In several parts of the nervous system, then, there is a gradual tuning of synaptic connections. These adjustments are competitive in the sense that the fate of particular terminals is not predetermined, but depends on an interaction with the target and with fellow axons.

The idea of a competitive balance of synaptic connections is by no means the exclusive province of developmental neurobiologists. It is well known that mature axons sprout and make additional synapses if their target is partly deprived on innervation, and, conversely, that adult axons can reduce the number of synapses they make on target cells under a variety of conditions[8]. These phenomena suggest that the number of synapses present in maturity continues to be regulated by interactions at the level of the target, much as competition between neurons for survival is regulated at an earlier stage of life.

What, then, is the relevant target property? A clue to the regulatory mechanism of both cell death and the ultimate equilibrium of maturing synaptic

connections is the action of the protein called nerve growth factor (NGF). In the early 1950s, Levi-Montalcini, Hamburger, and their colleagues[9] extracted from a mouse tumour an agent that stimulates the growth of two types of mammalian neurons (sympathetic and dorsal root ganglion cells). Long considered a curiosity rather than a molecule of fundamental significance, NGF's biological importance has now been firmly established[10]. In brief, neonatal animals immunologically deprived of this agent grow to maturity with dramatically stunted sympathetic ganglion cells[11] while, on the other hand, neurons in ganglia surgically isolated from their target can be temporarily rescued from death by exogenous NGF[12]. These trophic effects are associated with NGF binding to specific receptors on the peripheral processes of sensitive neurons, and subsequent internalization and retrograde axonal transport[10]. The structure of the molecule is now known, and several groups have begun to unravel its mode of action[13]. Thus, for some neurons, there is considerable evidence that the object of competition in the struggle for survival is NGF produced at or near the ganglionic target. The weakest link in this argument for the function of NGF has been the inability (for technical reasons) to demonstrate in an unequivocal manner production of the protein by the usual targets of NGF-sensitive neurons. This part of the story has now been considerably strengthened by a report that at least one sympathetic target (the iris) does indeed produce NGF under appropriate conditions[14]. Since it is clear that NGF's influence is limited to a small proportion of neuronal types, a major effort is underway to discover agents presumed to operate in an analogous manner in other parts of the nervous system[15].

A further aspect of the effects of NGF suggests that a common mechanism may underlie a neuron's struggle for survival and the later competition between axons during synapse formation. Campenot[16] has shown that terminal processes of sympathetic neurons are influenced by local concentrations of NGF *in vitro* in a way that seems closely related to the proliferation and regression of synaptic connections observed *in vivo*. In Campenot's experiment a special culture chamber was used that allowed cell bodies and their processes to be exposed to media of different composition. When the neuronal processes were bathed in medium containing NGF they remained healthy; terminal processes regressed, however, when NGF was available to cell bodies, but absent in the vicinity of the processes. An attractive inference, therefore, is that competition of nerve terminals for trophic factors is also involved in the formation and maintenance of synaptic connections.

Neuronal competition is thus emerging as the common denominator of important processes (neuron death, neonatal synapse elimination both in the periphery and centrally, synapse proliferation and regression in maturity) that previously seemed unrelated. As such, it is likely to be one of the dominant themes in neurobiology for some time to come. □

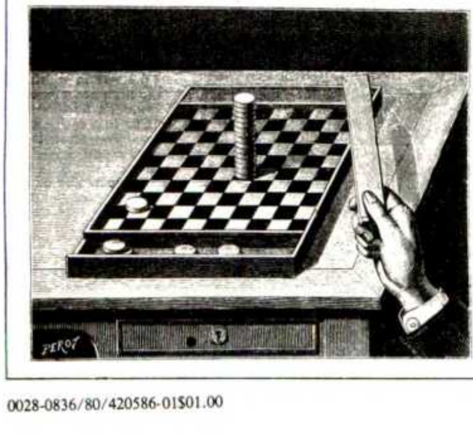
The monster python which is kept alive in the Antwerp museum having had inflammation of the jaw, a Belgian doctor volunteered to enter its cage in order to cure it; but the brute attempted to suffocate the poor doctor, who was glad to escape with his life.

PHYSICS WITHOUT APPARATUS

Inertia may be demonstrated by the following trick: a number of the round wooden "men" used in playing the game of draughts are piled up in a column one upon another. If the lowest one of the pile is dextrously hit with the edge of a paper-knife or other suitable article it may be knocked away from under the others without overthrowing the others. The figure shows how the experiment is arranged, the narrow slip of wood which serves as the lid of the box being here used as the weapon. Beginners in science must not mistake the meaning of the term *inertia* as applied to matter. Matter is not in itself lazy or inert. But it possesses the property of *mass*, and to set mass in motion requires the expenditure of *energy*. If we skilfully spend the energy of the rapid blow upon the one draughtsman, it is knocked away before there is time for any considerable part of the energy to be imparted to the others that are piled upon it.



Another simple experiment, depending partly upon the inertia of matter and partly upon elasticity, is often show as an after-dinner trick. Upon a linen tablecloth is placed a threepenny-piece between two pennies or other larger and thicker coins. Over this an empty wine-glass is placed, and the puzzle is how to get out the smaller coin without touching the glass. The very simple operation of scratching with the finger-nail upon the cloth, as shown, suffices to accomplish the trick, for the little coin is seen to advance gently towards the finger until it has moved completely away from under the glass. The fibres of the linen cloth are elastic; when you scratch with your finger-nail they are drawn gently forward until the force of their elasticity becomes too great and they fly back, to be once more drawn forward, again to slip back, and so on. While the fibres are drawn forward slowly, they drag the coin with them to a minute distance. But when the slip occurs and they fly backward, they do so very rapidly, and slip back under the coin before there is time for the energy of their movement to be imparted to the coin to set it in motion. So the coin is gradually carried forward over the surface of the cloth.

We will next give a simple experiment which illustrates the principle that a substance which is very weak in one direction may be very strong in another. It is possible to lift a decanter full of water by means of a single straw. To do this the straw must be bent as shown, so that the weight comes longitudinally upon the straw. The straw is a very weak thing if it has to resist a force applied laterally. Lay a single straw horizontally, so that the two ends are supported, and then hang weights on to the middle of it: a very few ounces will break it across. But let the weights be fixed to one end of the straw, and the straw itself be hung downwards so that the pull is exerted along it, and it will support one or two pounds at least.

A low velocity zone beneath Mount Etna and magma storage

Travel time residuals and high frequency attenuation of regional and teleseismic events recorded at a seismic network around Mount Etna, Sicily, indicate the presence of a large volume of partial melt beneath the volcano. Petrographical evidence confirms that the anomaly is the main magma storage system and site of crystal differentiation beneath the volcano.

MOUNT ETNA, on the east coast of Sicily, is the largest and most active volcano in Europe. Hamilton[1] was one of the first to note that Etna did not have a simple, single eruptive site, but that the flanks of the volcano were covered with smaller eccentric cones. It was later[2,3] deduced that there has been a NW migration of the main eruption centre with time. Imbo[4] described Etna as having 266 eruptive systems, corresponding to the parasitic cones, spread over an area greater than 30 × 30 km on its flanks. This complex surface structure indicates large-scale subsurface features amenable to seismic investigation.

We installed a seismic network of short-period seismometers covering an area of 60 × 50 km around Mount Etna. The network was fully operational by the end of October 1977, and ran continuously until January 1978. The experiment used localized travel time delays of seismic waves from shots fired at sea, regional earthquakes and teleseisms, as well as waveform analysis to locate the source of Etna's lavas.

Background and geology

Mount Etna lies near the Calabrian arc and subduction zone, but on the side normally non-volcanic making its very existence surprising. The volcano is situated in a region of uplift on an E–W trending anticlinorium which is cut by the Messina–Comiso fault line. Parallel to this line are NNE directed normal faults having an easterly downthrow which suggests that E–W extension of eastern Sicily is responsible for the volcanic activity[5]. North of Etna, subduction beneath the Tyrrhenian Sea is demonstrated by the formation of the Aeolian Island arc. Chemically, however, Mount Etna is quite distinct from these island arc volcanoes, Etna being comprised of derivatives of true basaltic magmas (originating in the upper mantle) while the Aeolian Islands belong typically to the calc-alkaline series.

Petrological studies have revealed two main types of lava forming the volcano. The earliest etnean lavas are ~500,000 yr old, and are considered to be tholeiitic or transitional basalts, having a submarine character to the east, and a subaerial character to the west. These tholeiites are overlain by porphyritic differentiated alkali basalts which constitute the bulk of the volcano[6]. Although there have been periods of stronger differentiation, the overall composition of the differentiated alkali basalts has remained remarkably constant with time[6–10]. Study of single lava flows has also revealed some variation in composition. Chemical differences have been observed between the first and last parts of the 1971 eruption lava, with little variation throughout the intermediate parts of the lava flow[11]. This variation in chemistry of a single flow may indicate a secondary pneumatolytic differentiation within the feeding fissures in the upper volcanic layers before eruption[7,11]. However, the source and evolution of the differentiated alkali basalts are still undetermined. Rittmann[12] suggests that the chemical variation within single lava flows denies the existence of a single magma chamber beneath Etna, preferring a model of abyssal fissures in which crystal or pneumatolytic differentiation takes place, depending on the state of the vents as controlled by the movement of the surrounding crustal blocks. Cristofolini[7] argues that the porphyritic nature and general uniformity of the lavas indicate strong gravitational settling of crystals and mixing with fresh magma in relatively large batches at intermediate depth. Variations within single flows are then explained by compositional gradients in the feeding fissures immediately before an eruption or from tapping different levels of the same chamber, or from tapping different chambers.

There have been few previous geophysical studies capable of investigating beneath the surficial layers of the volcano. Machado[13] compared observed and theoretical seismic intensities of the Messina 1908 earthquake to obtain a large region of negative anomalies which were attributed to the absorption of seismic energy by a magma chamber under Etna. He deduced an approximately elliptical chamber, 40 × 100 km, assuming a mean depth of 5 km. No estimate of the vertical dimensions of the chamber could be made.

In 1968 a large refraction study was performed in northern Sicily[14], the eastern section of the line running just to the north of Etna. Interpretation of the later arrivals on the record sections showed the eastern Sicilian coast to have a typical continental crust, but with low velocity zones in the range 9–24 km. The low velocity zones were attributed to higher temperature gradients caused by deeper magma chambers under Etna. However, the nature of the linear refraction profile prevented the lateral bounds of the anomaly being determined accurately. There is, therefore, good evidence for a body with low seismic velocity beneath the volcano.

The experiment

To investigate further the three-dimensional structure and physical properties of this anomaly, the seismic network was installed on Mount Etna with configuration shown in Fig. 1*b*. The network comprised four arrays each consisting of a base with a 14-channel tape recorder and a three-component set of short-period seismometers, together with three or four radio-linked outlying stations. Each outlying station had a single vertical short-period instrument.

Four shots were fired at sea (Fig. 1*a*) from the RV Shackleton to determine a crustal model for the area. The composite record section constructed from the shots showed clear first arrivals to greater than 160 km, but no correlatable later phases except a strong T-phase associated with the water-wave to P-wave conversion at the Messina Scarp off the east coast of Sicily. As the profile was unreversed, a simple horizontal-layered model could

0028–0836/80/410587—05$01.00

be derived only, using the T-phase as a constraint on the uppermost layers. The crustal model so obtained is shown in Fig. 2, and is in good agreement with the simple structure derived from the reversed line of Cassinis *et al.*[14].

Travel time residuals

The 14 earthquakes which were the clearest regional and teleseismic events recorded by the network were chosen for analysis (Table 1). These events were well distributed in azimuth (329–171°), range (1–10°) and depth (10–485 km), to give a broad distribution of rays with widely varying azimuth and angle of emergence passing through the crust beneath Etna. The average frequency content of the P-waves was 1.5–2.0 Hz, giving a resolution limit of ~4 km in the lower crust.

Using P-wave arrival times to infer crustal structure beneath a seismic network has been successful in determining low velocity bodies beneath Yellowstone, Wyoming[15–17], and other geothermal areas[18,19]. By reducing the observed travel time $(t_i)_{obs}$ from an earthquake to a station by a theoretical travel time $(t_i)_o$, the residual

$$R_i = (t_i)_{obs} - (t_i)_o$$

is formed. These residuals depend on the total ray path (or total travel time), source location and origin time. For any set of residuals $\{R_i\}$ from a single event, these dependencies may be removed by subtracting the mean value $\bar{R}$ of the residuals from each residual, to give the relative residuals

$$r_i = R_i - \bar{R}$$

The need for a reference station is thus removed, and the residuals will depend only weakly on the source parameters.

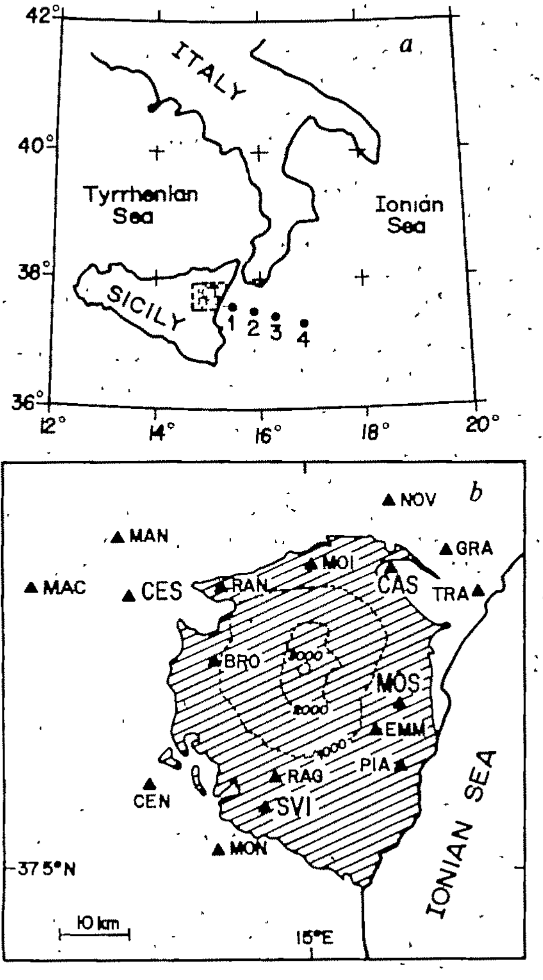

Fig. 1 *a*, Map of Southern Italy and Sicily showing the area covered by the seismic network (shaded), and shot positions (numbered). *b*, Seismic network configuration showing the four bases (CAS, MOS, SVI, CES) and the outlying stations. The shaded area defines the approximate extent of the etnean lavas.

The theoretical travel times were calculated using the US Geological Survey Preliminary Determination of Epicentre bulletins, bulletins of the Centre Seismologique Européo-Méditerranéen, and bulletins of the International Seismological Centre, to obtain source coordinates, and the travel time tables of Jeffreys and Bullen[20].

Wherever possible, the earthquake locations were compared with hypocentre redeterminations using Italian seismological observatory reports. A second set of residuals was obtained by subtracting from the arrival times the best fitting plane wave to the arrival times. The plane wave was calculated by the method of least squares with weighting dependent on the estimated accuracy of arrival time determination. The least squares residuals so obtained were generally in good agreement with those calculated from the theoretical travel times. Where the source location of an event was only poorly determined, the least squares residuals were used in the following analysis. Residuals from the arrival times of shots 2 and 3 were formed by calculating the theoretical travel times from the derived local crustal model.

Arrival times were obtained by visually measuring the first break of the P-wave from analogue records. Peaks, or later zero-crossing times[21,19], were not used as many signals showed increasing high frequency attenuation across the network. Such attenuation, due to lower Q paths, causes a relative broadening of the waveform which would give rise to errors in the timings of the peaks or zero crossings.

Examples of residuals are shown in Fig. 3. The shaded areas delineate approximately the areas of positive residuals (delays). All sets of residuals obtained exhibit similar features to those shown in Fig. 3, with the highest residuals always occurring on the opposite side of the volcano to the incident ray path, indicating the presence of a low velocity body beneath the array.

Several features of the low velocity anomaly may be qualitatively deduced from the general features of the delay patterns. The region of delay is of the order of tens of kilometres in lateral extent, and seems to be roughly ellipsoidal, elongated in a NNE direction. Also, the centre of each delay region seems to be displaced along the line of azimuth away from the centre of Etna, indicating that the anomaly lies at some depth beneath the volcano.

To quantify these observations, the low velocity anomaly was modelled as a tri-axial, ellipsoidal body centred at some depth and at some orientation beneath Etna, inverting for six parameters: ellipsoid axes, (a, b, c); depth to centre of ellipsoid, d; orientation, θ; and velocity reduction, δv (relative to the surrounding crustal velocity). Monte-Carlo inversion procedures are commonly used to invert nonlinear problems, but the random nature of the investigation may lead to poor sampling in parts of the parameter space. An organized grid search in the six-dimensional parameter space of the model was therefore adopted.

Over 20,000 models were tested by comparing the theoretical residuals with those observed. Theoretical residuals were calculated by ray-tracing through the combined crustal model and ellipsoidal anomaly structure for each ray, for each ellipsoidal model. As the velocity contrast was expected to be small, refraction effects at the boundaries of the ellipsoid were assumed to be negligible. The grid search was first performed with large grid intervals, then repeated with successively smaller intervals until the best model corresponding to the greatest reduction in the sum of squares of residual differences (observed – theoretical), $S(\phi)$, was obtained. The extent of the grid is given below, with the best model estimate in parentheses:

a	10–30	(22)	km
b	20–60	(31)	km
c	0–20	(4)	km
d	4–26	(20)	km
θ	5–40°	(13°)	
δv	−1.5–−0.3	(−1.15)	km s^{-1}

A sketch of the best model is shown in Fig. 2.

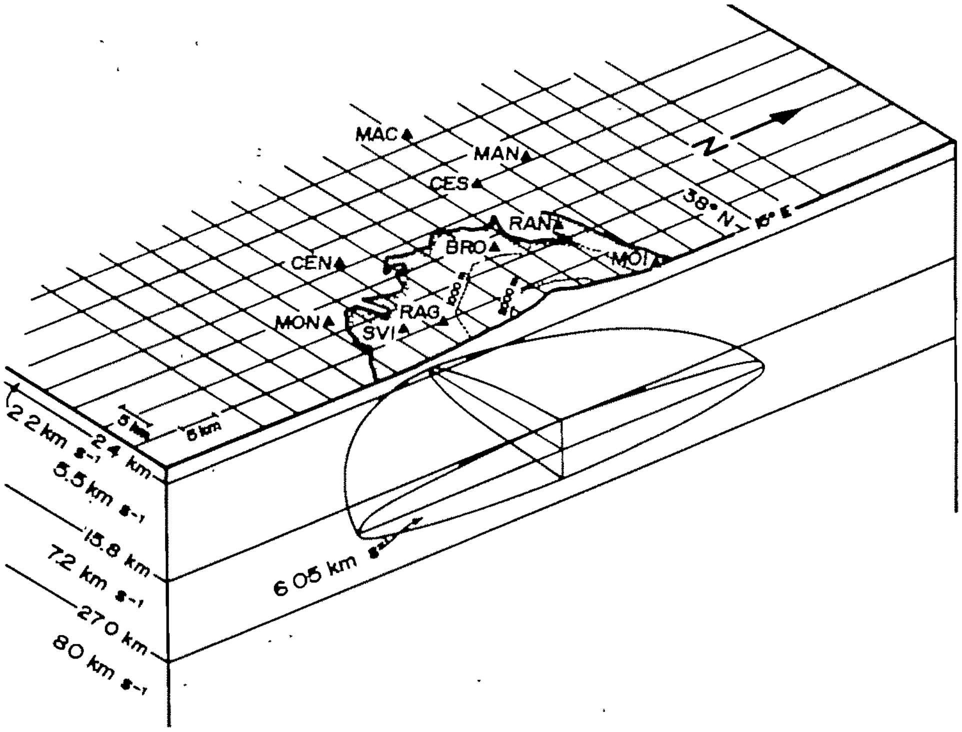

Fig. 2 Cut-away diagram of the crustal model and low velocity anomaly beneath Etna. Crustal layer velocities and depths are indicated. The ellipsoidal anomaly is shown centred beneath the volcano in the 7.2 km s^{-1} layer.

To estimate error limits on the best model, the criterion[22]

$$S(\phi) \leq S(\hat{\phi})\left\{1+\frac{m}{n-m}f(m, n-m, (1-\alpha))\right\}$$

was used, where n is the number of data and m the number of parameters. f is the value of the F-statistic for some confidence limit α, with m and $n-m$ degrees of freedom. $S(\phi)$ is the sum of squares of residual differences for a particular model, and $S(\hat{\phi})$ is the sum of squares of residual differences from the best model estimate. The six-dimensional parameter space surrounding the best estimate for all points satisfying the above criterion with $\alpha = 0.67$ was searched. The Hedgehog inversion procedure[23-25] was adopted to select the acceptable models, being ideally suited to determining the confidence regions of nonlinear problems. The search for acceptable ellipsoid models was constructed within the grid:

a	0	(5)	50	km
b	0	(5)	80	km
c	0	(2)	30	km
d	3	(4)	40	km
θ	0°	(5°)	60°	
δv	−4.0	(0.2)	−0.1	km s^{-1}

The above list shows the limits of the search, with the grid intervals in parentheses. Using the Hedgehog procedure, only those points in the neighbourhood of successful models were tested to give a singly-connected space of acceptable models. The set of acceptable models is shown in Fig. 4. Values for the a-axis and depth of the ellipsoid seem to be well constrained as no acceptable models were found with values for a and d other than $a = 22$ km and $d = 20$ km. Thus, only the variation of the other four dimensions need be examined. This variation is shown in the four-dimensional plot of Fig. 4. From each of the small sets of axes (c-axis versus δv), a trade-off between the height of the ellipsoid (c-axis) and the relative velocity reduction (δv) is seen. The large variation in values for the b-axis may be attributed to the network not being of sufficient extent in a N–S direction to cover the delay anomaly fully. This lack of resolution in the b-axis may also have caused some of the scatter in the determination of the orientation, θ, of the ellipsoid. The well resolved depth parameter confirms the existence of the deep low velocity zone of Cassinis *et al.*[14], and does not admit the possibility that the delay effects may be of upper crustal origin.

The above modelling has determined the ellipsoidal model, and associated error limits, which are the most consistent with the data. However, the single ellipsoidal model does not

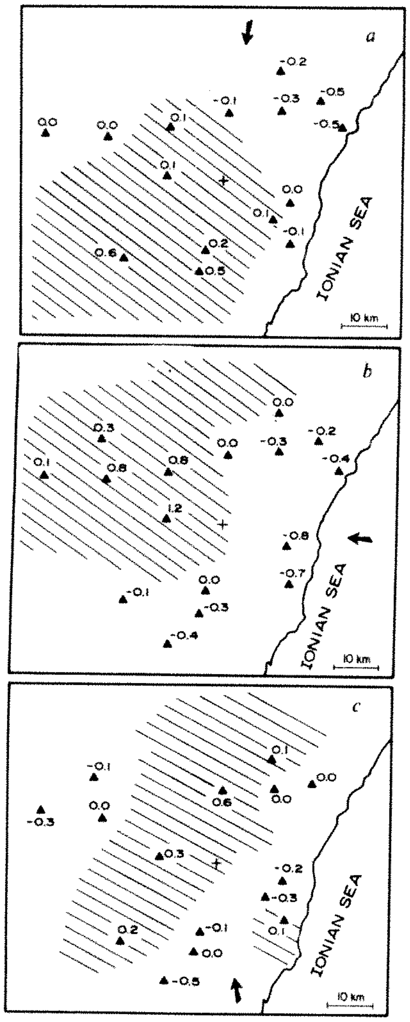

Fig. 3 Examples of travel time residuals from three earthquakes occurring: *a*, To the north, 30 December 1977 18 h 08 min; azimuth = 019°; $\Delta = 2.5°$; $d = 270$ km. *b*, To the east, 28 November 1977 02 h 99 min; azimuth = 96°; $\Delta = 10°$, $d = 74$ km. *c*, To the south, 8 November 21 h 44 min; azimuth = 171°; $\Delta = 3°$; $d =$ 10 km. Hatching shows areas of positive residuals. Arrows indicate the azimuths of the incoming waves as observed by the network.

completely fit some of the highest delays shown in Fig. 3. These large delays may indicate a secondary velocity anomaly or a non-uniformity in the present simple ellipsoidal velocity anomaly. But the present data are insufficient to resolve such finer structures.

High frequency attentuation

Many signals exhibited loss of high frequencies across the network. Figure 5 shows the P-wave arrival of the same earthquake as recorded by two stations. The waveform TRA has travelled from the source to the station without passing through the low velocity anomaly, whereas the waveform MAN has passed through the anomaly and has been attenuated in high frequency relative to TRA. Plotting the logarithm of the spectral ratio against frequency, the reduction in high frequency content of MAN is even more evident (Fig. 5). The gradient of the line may be related to the attenuation factor[26] Q. Assuming an average Q of 50 for the crustal layers surrounding the ellipsoid anomaly, a Q of 9 must be assumed for the anomaly itself to account for the high frequency attenuation.

Interpretation and discussion

Reduction in P-wave velocity may be caused by several factors (for example, a crack system, or simply a rigid body of lower seismic velocity). However, it is doubtful whether an open crack system can be maintained at depths of 20 km (equivalent to pressures of ~6 kbar). The large reduction of high frequencies (low Q) as shown by waveforms passing through the anomaly implies that the body is not completely rigid. This agrees with Machado's model of a magma chamber[13].

The simplest explanation of the observed results is that the ellipsoidal anomaly is the seismic manifestation of the main crustal magma storage region beneath Etna. The velocity reduction within the anomaly is 16% indicating that the ellipsoid is not completely molten. Assuming the body to be a partial melt composed of solid (7.2 km s^{-1}) and melt (3.0 km s^{-1}), the percentage of melt within the body is found to be 14%—corresponding to 1,600 km^3 of melt in a total of 11,424 km^3. Thus the magma chamber is not completely molten in the 'classical' sense, but rather it is likely to be formed by a complex series of veins (or fissures) of melt running through the ellipsoidal body.

Geological evidence supports these conclusions. The results of Cristofolini[7], and Romano and Sturiale[11] require that there must be a large magma storage system beneath Etna in which differentiation (gravitational crystal settling) takes place. Although Rittmann[12] argues that there is no single great magma chamber, his model of Etna does require differentiation of parental magma within "abyssal fissures". Thus the two geological models are not completely dissimilar, both requiring the temporary storage of magma at some depth.

The new geophysical model, although very approximate, demonstrates that there is a substantial quantity of magma stored beneath the volcano, and that the storage mechanism is more likely to be in a series of (interconnecting) fissures, rather that a single, completely molten chamber. The orientation and elongation of the geophysical model also agrees with the regional tectonic dislocations, N–S and NE–SW[6], supporting the hypothesis that etnean volcanism is related to lithospheric extension in that area[7–12,27].

Mineralogical studies[8,9] show that plagioclase is the dominant phenocryst material of the trachybasalts, having 20–30% by volume of plagioclase phenocrysts. Taking 'pyrolite'[28] as the parental material, Duncan[29] showed that fractional crystallization producing plagioclase phenocrysts must occur at depths less than 25 km. Hammill[30] also showed that differentiation trends in the fractional crystallization of high alumina clinopyroxene and titaniferous magnetite indicated differentiation at pressures of ~10 k bar. These findings agree well with the geophysical model of partial melt in the depth range 16–24 km.

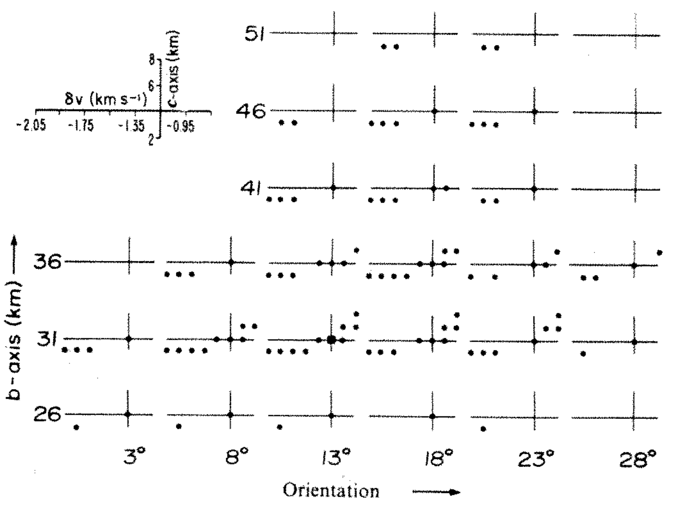

Fig. 4 Four-dimensional plot of all acceptable models from Hedgehog inversion. The small pairs of axes represent the velocity reduction δv (abscissa) and ellipsoid c-axis (ordinate), as shown in the inset. Each axes pair has an associated value of orientation θ, and ellipsoid b-axis which are given on the large horizontal and vertical axes, respectively. ■, The 'best' solution. As no acceptable model was found with a-axis and depth values other than $a =$ 22 km and $d = 20$ km these may be regarded as constants associated with each of the plots.

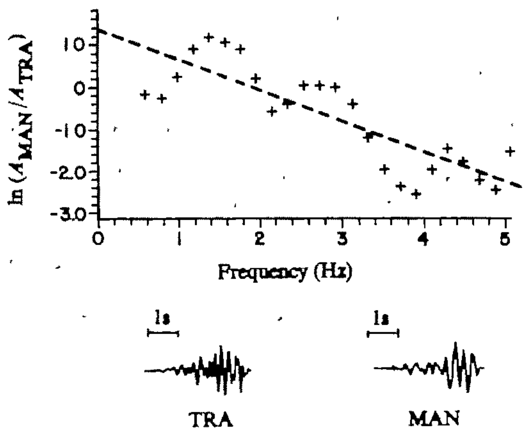

Fig. 5 P-wave arrivals from a single earthquake as recorded by two stations. The waveform TRA has not travelled through the anomaly, whereas the waveform MAN has passed through the anomaly and exhibits a loss in high frequency content relative to TRA. The plot shows the logarithm of the spectral ratio of the two signals, ln (A_{MAN}/A_{TRA}), plotted as a function of frequency. The average slope indicates a difference in the Q values of the two paths. Minor deviations from the average slope may be attributed to small differences in the crustal structure at the two stations.

It is also significant that the local etnean micro-earthquakes have a maximum depth[31] of ~12 km, suggesting that they occur in a brittle region overlying the volume of partial melt.

Conclusions

From a seismic network study of the etnean volcanic region, anomalous P-wave delays and high frequency attenuation of seismic signals have been observed. Simple three-dimensional modelling and inversion procedures show that the anomaly can be well represented by a triaxial ellipsoid of axes 22 km, 31 km (horizontal) and 4 km (vertical), at a depth of 20 km below Etna. The ellipsoid is elongated in a NNE direction, similar to the regional tectonic dislocations, and the velocity reduction of 16% indicates that the anomaly is most likely to be a series of fissures containing melt (14% by volume), rather than a completely molten chamber.

We conclude that lithospheric extension of eastern Sicily allows basic parental magma to rise from the upper mantle which is then trapped in a complex series of fissures at depths of 16–24 km, just beneath the 5.5/7.2 km s^{-1} discontinuity. Crystal fractionation, including some mixing with the parental magma, takes place within the fissures[7]. The differentiated magma then ascends into higher feeders, generally along the lines of tectonic dislocation, where secondary pneumatolytic differentiation takes place before eruption, causing minor fluctuations in the chemistry within individual lava flows[11].

Small variations in the differentiates with time may either be due to a change in the supply of parental magma with time, or a change in the time during which the magma is stored in the fissure system. The latter could be controlled by the tectonic movements of the surrounding crustal blocks[12].

We thank Dr D. H. Matthews for firing the sea shots, and for support, Dr H. M. Iyer for his help and encouragement, Dr G. C. P. King, I. Asudeh, G. Ballard, T. Owen, C. Soufleris and S. Morgan for help during the fieldwork. We thank the Istituto di Scienze della Terra and the Istituto Internazionale de Vulcanologia, Catania, for support, especially Mimmo Condorelli. Finally Dr J. K. Gardner is thanked for use of the Hedgehog inversion subroutines. This project was funded by the NERC a studentship for A.D.L.S. and a post-doctoral fellowship for P.M.D. The later stages of this work were also supported by US DOE grant AS03–76SF00034.

Agulhas Basin magnetic bight

H. W. Bergh & D. M. Barrett*

Bernard Price Institute of Geophysical Research, University of the Witwatersrand, Johannesburg, South Africa 2001

The discovery of a magnetic bight in the Agulhas Basin places unique constraints on the relative motion between South America, Antarctica and Africa in the late Cretaceous.

RECONSTRUCTIONS of the predrift configuration of the three Western Gondwana continents (South America (SAM), Africa (AF) and Antarctica (ANT)) have relied heavily on the matching of selected bathymetric contours. Only in fitting AF against SAM and the northern edge of the Falkland Plateau has tightly constraining geophysical evidence been available. This sort of evidence (from fracture zone trends and recognition of linear magnetic anomalies) is only sparsely available for the separation history of the AF and ANT plates.

Well-documented Cretaceous and Eocene magnetic anomalies have been found[1] in the Mozambique Basin eastward of the Prince Edward Fracture Zone. A Mesozoic magnetic anomaly sequence in the Antarctic Basin[2] points towards a simple history of ANT–AF separation, while recently reported[3,4] Mesozoic anomalies in the northern Mozambique Basin provide evidence for the same simple manner of seafloor generation west of the Prince Edward Fracture Zone. No direct determinations have

been made of past relative motion between SAM and ANT.

We describe here results from a geophysical survey of a small area of deep ocean south-west of the Agulhas Plateau (see inset, Fig. 1, for area location). Within this region we can clearly recognize an Upper Cretaceous magnetic bight at two points in time. The new data enable us to describe the behaviour of the triple junction SAM–AF–ANT at ~80 Myr ago. Previously unpublished data in the Antarctic Basin, combined with our new findings, are used to reconstruct the relative SAM–AF–ANT geometry at that time.

Magnetic bight data

Figure 1 shows total magnetic field anomalies plotted perpendicular to ship's track on a bathymetric chart of the survey area. The magnetic measurements were made from the MV RSA during October 1977. Bathymetric coverage on that cruise was supplemented by data from Lamont-Doherty Geological Observatory (Vema and Conrad) and by one Atlantis II track[5] run by the Woods Hole Oceanographic Institute.

Seafloor relief south-west of the Agulhas Plateau is generally small and sediment cover thin (between 0.0 and 0.5 s of two-way travel time). The slight elevation around 45 °S, 20 °E, called the Southwest Spur[6], appears to be partly due to raised basement and partly to increased sediment thickness. The deeper region between here and the Agulhas Plateau is heavily scoured, with scattered erosional outcrops hinting at a possible linear continuity of elevated basement.

The magnetic anomalies clearly delineate a chevron-shaped strip of negatively magnetized sea floor even where this is right-laterally offset in the south-east. The two limbs of this magnetic bight strike 150° (north-west limb) and 125° (south-east limb). We interpret these two limbs as being respectively related to relative motion between the plate pairs SAM–AF and ANT–AF. Correlation of the magnetic anomalies with the geomagnetic reversal time scale is based on the findings between Antarctica and Africa. Recent data between these two continents[7] show clearly that magnetic anomaly sequences are symmetric about the present spreading axis at 52.5 °S, 18 °E and almost complete out to anomaly 34 on either side. In Fig. 1 the northernmost anomalies are numbered, 30–34, of this complete sequence. The region with dotted negative anomalies corresponds to sea floor generated between anomaly 33 and 34 time. In terms of a recent reversal time scale[8] this refers to the period between 79.6 and 76.5 Myr ago. It corresponds to the A-section of the proposed type-section[9] from Gubbio in Italy.

Unique identification of magnetic anomalies on the north-west limb of the bight depends on their continuity with the same anomalies on the south-east limb as we are unable to recognize clearly identifiable anomalies immediately younger than 33 between South America and Africa. This is partly because of

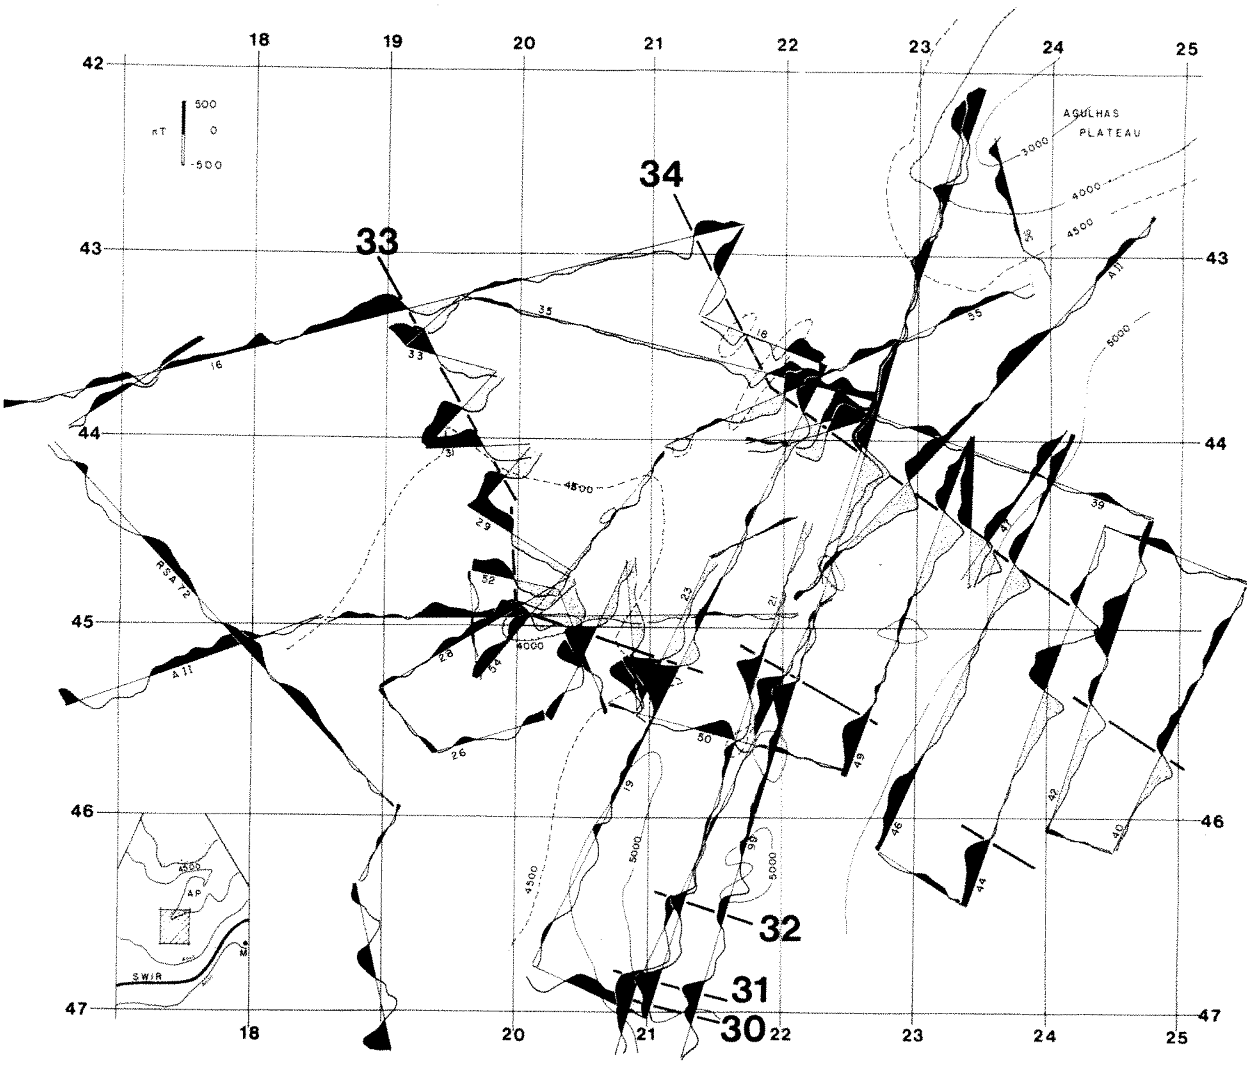

Fig. 1 Magnetic anomalies (total field minus IGRF 1975.0) plotted perpendicular to ship's tracks. Lines marked consecutively from 16 to 56 were run in October 1977 aboard the MV RSA. Lines 99 and RSA 72 were run between Antarctica and South Africa on the RSA in 1977 and 1972 respectively. AII is an Atlantis II track[5]. Positive magnetic anomalies are in black and the lines 34 and 33 refer to the end and beginning of the relevant polarity epochs. The inset shows the survey area in relation to southern Africa, the Agulhas Plateau (AP) and the Southwest Indian Ridge (SWIR). Bathymetry in metres.

poor data coverage but is also probably due to the complications of a westward ridge jump south of the Agulhas–Falkland Fracture Zone soon after anomaly 33 time. Such a jump has been postulated[10,11] to account for the present ridge offset across this fracture zone being ~1,150 km less than its probable offset at the initiation of relative motion between SAM and AF. The timing and nature of this ridge jump, or jumps, are still highly speculative.

Average spreading rates on the two limbs of the bight were determined for the negative polarity interval by projecting the magnetic anomalies perpendicular to their average strike (Fig. 2). In determining the latter parameter, the bight apex portion of anomaly 33 was neglected because it appears atypical of the general trend. We assume here that the anomalies are perpendicular to the spreading direction at their time of formation. This assumption seems to be appropriate[12,13] for spreading half-rates greater than about 30 mm yr^{-1}. Comparison of the projected profiles with suitable simulated profiles (Fig. 2) yields spreading half-rates of 40 mm yr^{-1} for ANT–AF and 55 mm yr^{-1} for SAM–AF.

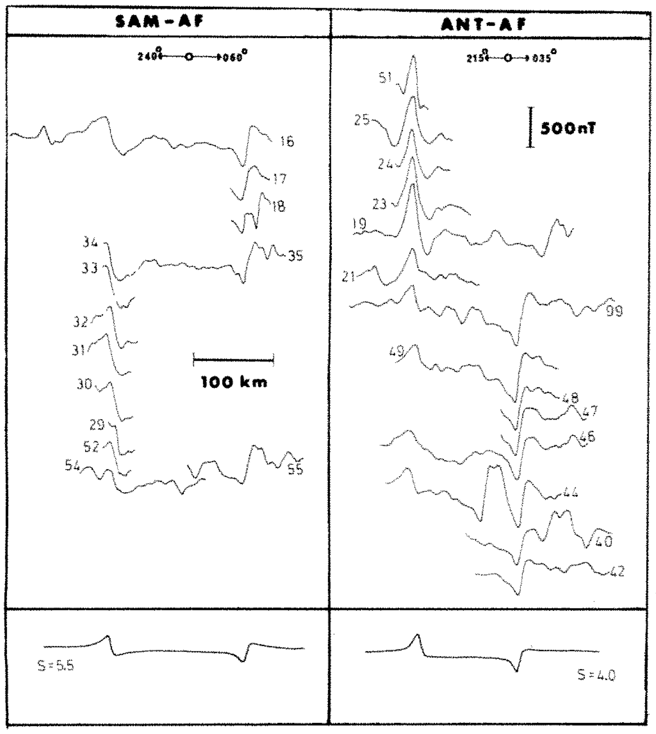

Fig. 2 Magnetic anomaly profiles projected perpendicular to the average strike of anomalies 33 and 34. The simulated profiles at the bottom give the spreading half rates S in cm yr^{-1} for the two plate pairs.

The ridge sections which generated the observed magnetic bight formed two arms of a triple junction at anomaly 34 time. For this junction to be stable the third arm must also have been a ridge. An RRF (ridge–ridge–fault) triple junction could only be stable if the two ridge segments were at right angles[14] or at least one ridge was very oblique to the spreading direction. From the velocity triangle (Fig. 3) we see that the SAM–ANT boundary was a ridge trending slightly east of north (with respect to a fixed AF) and having a half-spreading rate of 25 mm yr^{-1}.

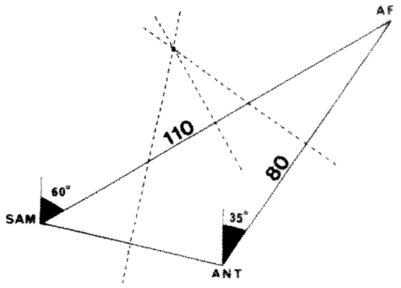

Fig. 3 Velocity triangle for the SAM–AF–ANT triple junction between anomaly 34 and 33 time Angles gives the azimuths of AF–SAM and AF–ANT relative motion and the total separation rate is shown in mm yr^{-1}.

80-Myr reconstruction

Figure 4 is our best reconstruction of the western Gondwana continents at anomaly 34 time. The position of South America relative to Africa differs insignificantly from published palaeolocations[15,16]. Antarctica's palaeoposition has been constrained by our recent findings in the Antarctic Basin and south-west of the Agulhas Plateau and agrees closely with that predicted by Norton and Sclater[17].

With Africa kept fixed, we have rotated South America to the Bullard *et al.*[18] fit and then applied a clockwise rotation of 28°, using the LePichon and Hayes[15] rotation pole at 22 °N, 14 °W. This rotation is only 2° more than theirs and is justified by the excellent matching of previously unpublished magnetic anomaly 34 findings in the Cape Basin with the corresponding anomalies[16] in the Argentine Basin. The Cape Basin anomalies, shown in Fig. 5*a*, are the best evidence we have for the location and strike of anomaly 34 immediately north of the Agulhas–Falkland Fracture Zone.

The Antarctic rotation pole was found by matching of anomalies 34 on either side of the Southwest Indian Ridge.

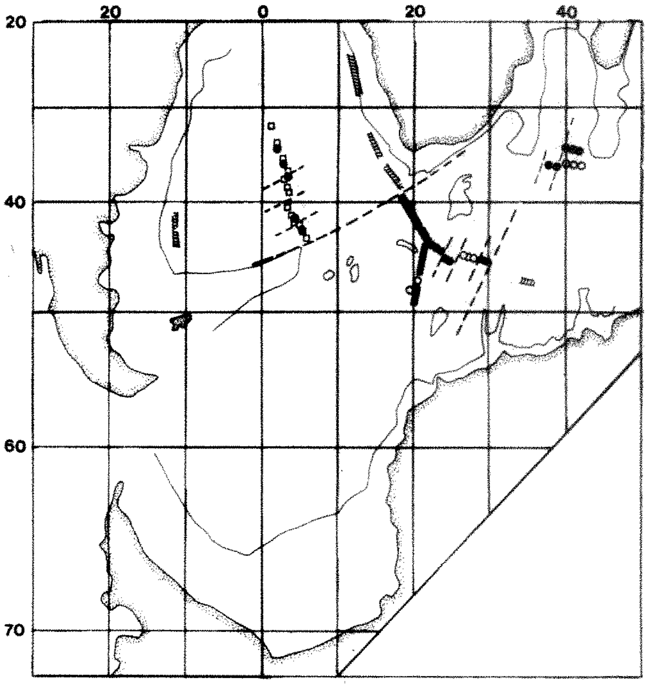

Fig. 4 80-Myr reconstruction of western Gondwana continents. Africa has been kept fixed. Anomaly 34 is shown as: ●, on African plate; ☐, rotated with SAM; ○, rotated with ANT. The rotations are described in the text; ANT has been rotated by 18° about a pole at 10° N, 40° W. Sea floor formed in the Mesozoic interval defined by anomalies M2 to M4 is hatched. Fracture zones are marked by dashed lines, the 3,000-m isobath by a thin solid line. No significance should be attributed to the retention of Madagascar in its present position.

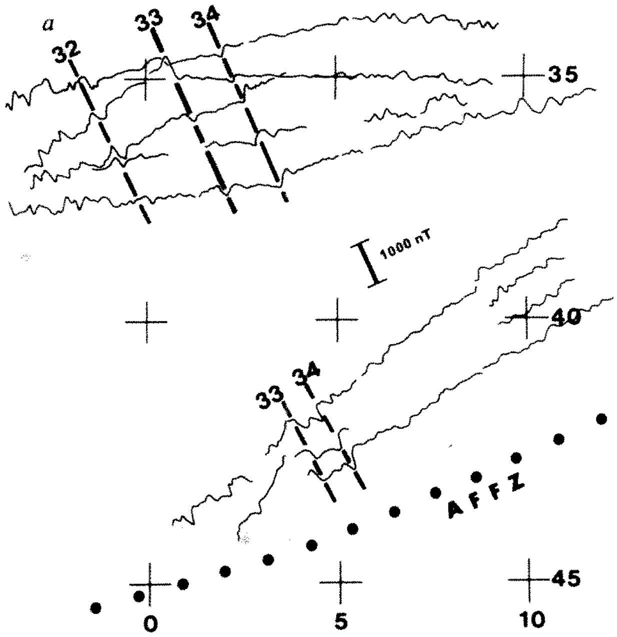

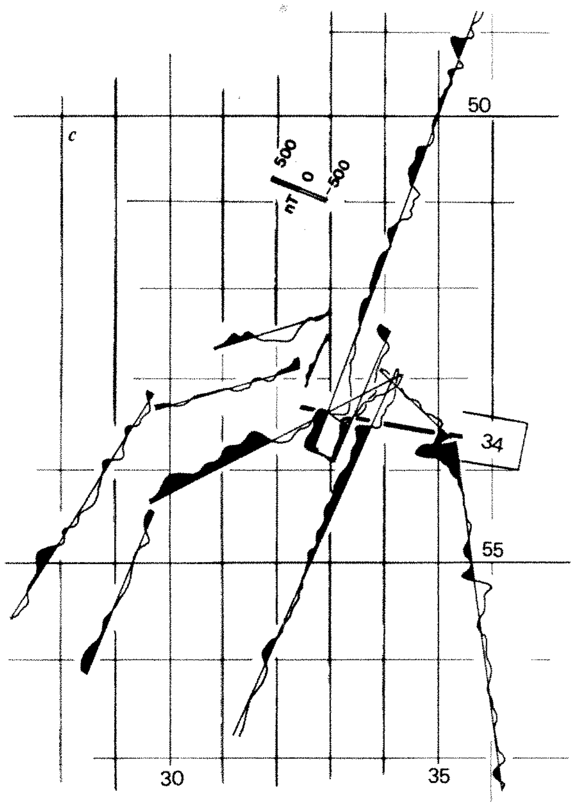

There is uncertainty over whether these conjugate anomaly pairs were formed at exactly the same section of spreading ridge. This need not be too serious a drawback as long as the relevant ridge segments did not have large offsets from one another. We used a very definite anomaly 34 north of Maud Rise (Fig. 5*b*) and a more tentatively identified one at 54 °S, 34 °E (Fig. 5*c*). The pole and angular rotation were adjusted to bring these into best coincidence with, respectively, the anomalies reported here and those in the Mozambique Basin[1].

The pole used for the Antarctic rotation is not much different from the present pole[19] and supports the suggestion[2] that the average ANT–AF pole since the Mesozoic closely approximates the present one. An interesting feature of Fig. 4 is that our questionable SAM–ANT spur of the anomaly 34 bight (Fig. 5*b*) rotates into the predicted position of the SAM–ANT ridge axis at the time of the reconstruction. More intense magnetic surveying is planned near Maud Rise to check on the inferred Antarctic Basin Bight.

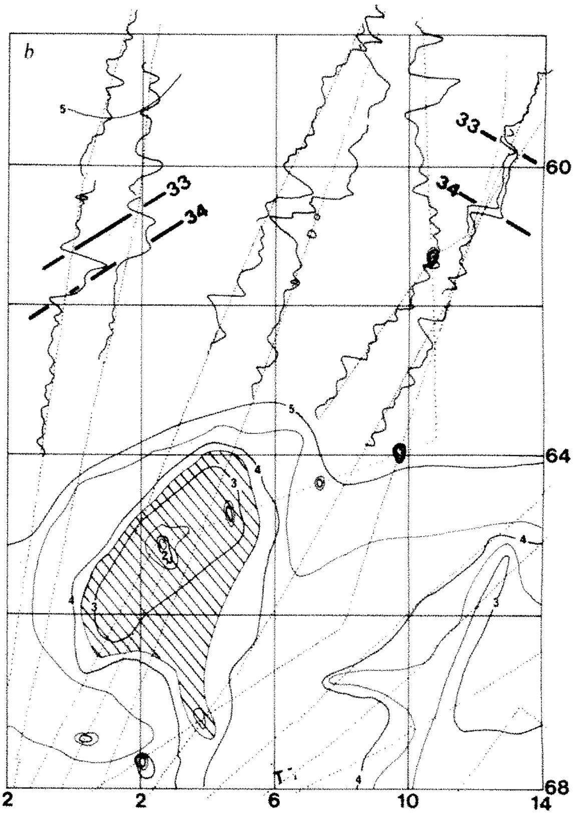

Fig. 5 Unpublished magnetic anomaly profiles obtained during voyages of the MV RSA: *a*, in the South Atlantic immediately north of the Agulhas Falkland Fracture Zone (AFFZ); *b*, north of Maud Rise; *c*, near 54 °S, 34 °E.

Discussion

We confine ourselves here to the evolution of the triple junction between anomaly 34 and 33 time and to possible changes in ANT–AF relative motion immediately after that period. The implications of the striking geometrical relationship between the Agulhas Plateau and the fossil triple junction will be considered elsewhere.

At anomaly 34 time the triple junction was probably a simple RRR with fast orthogonal spreading from all three limbs. By 33 time the ANT–AF half rate had commenced slowing down drastically to ~11 mm yr^{-1}, as determined from the spacing between anomalies 30 and 32. The simultaneous change in SAM–AF relative motion is well documented[16]. Changes in the vicinity of the triple junction seem to be dominated by the removal of the orthogonality constraint as the spreading rates were reduced. Two new transform faults were created and the ridge sections meeting at the triple junction rotated to reduce the lengths of these transforms, as seems to occur generally[12]. The azimuth of the ANT–AF ridge section immediately adjacent to the triple junction is preserved in later linear magnetic anomalies to the south. This incorporation of a persistent oblique spreading regime occurred at the same time in the Mozambique Basin[1] and thus seems to represent a stable mode for slow separation of two plates.

We recognize here that representative spreading rates are imprecisely determined from observations on one plate only of anomalies formed near a rapidly reorientated plate boundary. The problem is more severe near a triple junction, because three relative velocity vectors are changing sympathetically. The

SAM–AF velocity determined from the north-west limb of the bight is based on an assumption of orthogonal, symmetric spreading. The limb strikes very nearly at right angles to the Agulhas–Falkland Fracture Zone (AFFZ). However, assymmetric SAM–AF spreading in the late Cretaceous has recently been proposed[20] immediately south of this fracture zone, and is also apparent when the anomalies in Fig. 5*a* are compared with those near 45 °S on the South American plate[16]. We do not consider the variation in total SAM–AF separation rate to be sufficiently well known at that time to justify much discussion here. The effect of dominant accretion on the AF side of the SAM–AF boundary would have been to increase progressively the obliqueness of the SAM–ANT (ridge) boundary. The ANT–AF velocity seems to be on the high side as the Mozambique Basin half-rate[1] (at 90° from the rotation pole) is 35 mm yr^{-1} using the same time scale[8] as in the present paper. A more consistent half-rate (32 mm yr^{-1}) is obtained using the extreme south-east section of the bight. The effect on SAM–ANT spreading geometry, of taking this possible error into account, would be to make the ridge section more nearly north–south, with a slightly higher spreading rate.

The velocity triangle in Fig. 3 shows that the RRR triple junction will migrate northwards, with respect to ANT, along the SAM–AF rifting margin. Ridge jump proposals[11,20,21] have not considered the proximity of a triple junction to the AFFZ.

A stable RRF junction could possibly be formed if the RRR triple junction reaches this fracture zone. Such a junction with almost orthogonal SAM–ANT and AF–ANT ridges would move away from AF at half the SAM–AF velocity and so would not reduce the active transform length of the AFFZ. If oblique spreading is invoked, it would be possible for the RRF triple junction to migrate towards the SAM–AF ridge section north of the AFFZ, but not at sufficient speed to cause the large reduction in offset since the Cretaceous. Detailed surveying south of the AFFZ is still needed to resolve this problem.

This research was funded by the South African National Committee for Oceanographic Research. The cooperation of the late Captain E. Funk and crew of the MV RSA is gratefully acknowledged. The fine weather and technical expertise of George Knox and Jack Engelbrecht made the survey successful. We thank Frank Anderson, director of the National Research Institute for Oceanology, for equipment and technicians.

X-ray kinetic studies of microtubule assembly using synchrotron radiation

Eva-Maria Mandelkow, Arnold Harmsen & Eckhard Mandelkow
Department of Biophysics, Max-Planck-Institute for Medical Research, Jahnstrasse 29, D-6900 Heidelberg, FRG

Joan Bordas
European Molecular Biology Laboratory, c/o DESY, Notkestrasse, D-2000 Hamburg 52, FRG

The assembly of microtubules has been investigated by time-resolved X-ray diffraction using synchrotron radiation. The small-angle scattering becomes visible within seconds and thus enables study of the structural transitions of the protein aggregates during assembly from their subunits in solution. The X-ray pattern at 4 °C arises from a mixture of tubulin rings, dimers and some other species. Raising the temperature to 36 °C induces the breakdown of rings, followed by the growth of microtubules. The results suggest that microtubules may be formed from tubulin oligomers smaller than rings.

WE report here a study on tubulin polymerization and depolymerization *in vitro*, induced by variation of temperature and monitored by time-resolved X-ray scattering. The aims of our experiments were (1) to establish the usefulness of a new approach to the study of polymerization processes in general, and (2) to understand better the stages of microtubule assembly. We investigated the type of structural entities present in the several stages of assembly and disassembly, their time dependence, their dependence on chemical conditions, and the possibility of detection of intermediate states not previously encountered.

Equipment and method

The technique uses high flux of X-rays available from the positron storage ring DORIS at Hamburg, suitable X-ray optics, detector and data acquisition system[1–3] and offers the advantage of yielding not only the rate constants of the process under study, as for instance light scattering or turbidity measurements might do, but also time-resolved structural detail, comparable and/or complementary to that provided by static X-ray diffraction or electron microscopy. During the measurements the accelerator was running at 5 GeV with currents ranging over 10–25 mA. Typical fluxes on the specimens were of the order of 5×10^{10} photons s^{-1}. The wavelength of the radiation was 1.5 Å. Temperature control was achieved by containing the sample in a thermostatted cell around which circulation of a cold or warm fluid could be quickly selected by a system of switching valves.

The microtubule protein (tubulin and microtubule-associated proteins (MAPs)[4]) was prepared from porcine brain by temperature-dependent cycles of assembly and disassembly without glycerol[5].

0028-0836/80/410595—05$01.00

Experimental results

Figure 1 shows the behaviour of the system and corresponds to a three-dimensional plot, with the scattered intensity in the vertical axis, and the scattering angle and time course in the two horizontal axes.

We used temperature jumps from 4 to 36 °C and vice versa to induce protein assembly and disassembly. The half time of the jump was around 25 s (heating rate 0.6 °C s^{-1}). Two successive cycles of polymerization and depolymerization are depicted. The most prominent changes in the scattering patterns are in the region of the central scatter and in the positions and heights of the subsidiary maxima. The change of one type of scattering pattern into another, following the T-jump, is complete within ~150 s. In spite of the high flux of X-rays the polymerization properties are not affected noticeably by radiation damage during the course of an experiment. Thus the cycles of assembly and disassembly can be repeated several times as long as GTP is in excess of the GDP formed during assembly.

Figure 2 shows four scattering traces selected from Fig. 1. They correspond to the initial scattering from the cold solution, two intermediate states which appear shortly before the onset of microtubule formation, and the final pattern at high temperature. There is an overall decrease of the scattered intensity when going from the initial cold (Fig. 2*a*) to the first intermediate state(Fig. 2*b*). The subsidiary maxima around channels 12, 41 and 65 characteristic of the cold state are reduced. This is followed by a second intermediate state in which the subsidiary maxima are washed out and the central scatter increases again (Fig. 2*c*). The scattering of the final warm state (Fig. 2*d*) shows a marked increase near the origin as well as the appearance of new subsidiary maxima around channels 26 and 72.

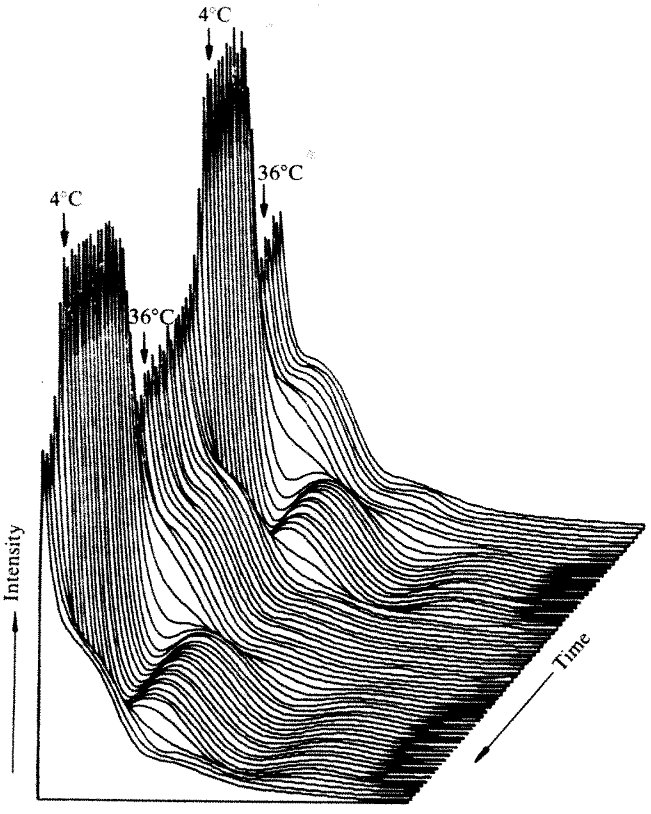

Fig. 1 Composite view of scattering traces obtained during two cycles of polymerization. Intensities were accumulated over time frames of 15 s, but only alternate frames are shown here. Temperature changes are as indicated. The half time of the T-jump is 25 s. Specimen–detector distance 320 cm, detector bin size 0.31 mm (80 mm per 256 channels). Note the changes in the height of the central scatter (left) and in the positions of the subsidiary maxima. The central scatter terminates abruptly due to a lead beam stop in front of the detector. The curves have been corrected for counter response, beam fluctuations, background, and splined to eliminate statistical noise. Microtubule protein was prepared from porcine brain following Borisy *et al.*[5]. The reassembly buffer was usually 0.05 M or 0.1 M PIPES, 1 mM each of GTP, dithiothreitol (DTT), EGTA, and $MgSO_4$, pH 6.94 at room temperature. After the second cycle the protein pellets were stored in liquid nitrogen. They were redissolved in reassembly buffer before use and either used directly or run through one additional cycle. Protein determinations were done by the Lowry assay. The efficiency of assembly was monitored turbidimetrically, and the protein composition was checked by SDS-polyacrylamide gradient gel electrophoresis and analytical ultracentrifugation.

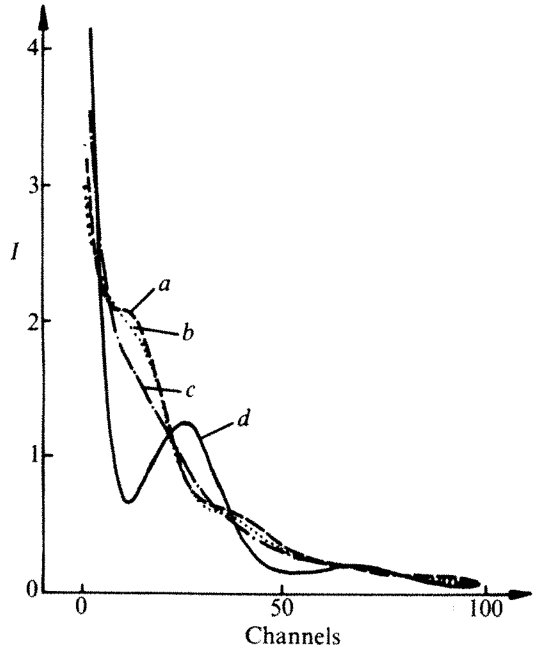

Fig. 2 Selected plots derived from Fig. 1. *a*, Initial cold solution, showing subsidiary maxima around channels 12, 41 and 65. *b*, 45 s after the temperature switch. At this point the temperature in the solution is about 27 °C. It corresponds to the bottom of the undershoot of Fig. 3*b*. The integrated intensity of the central scatter has decreased by about 8%, and the subsidiary maxima are reduced. *c*, 75 s after *T*-jump, corresponding to the recovery of the undershoot of Fig. 3*b*. The central scatter has increased about 8% over its initial value, and the subsidiary maxima have disappeared. *d*, Final warm solution, 225 s after T-jump. The central scatter has increased by 45% over the initial value. New subsidiary maxima appear further away from the origin, around channels 26 and 72.

Figure 3 shows the time course of the temperature in the specimen with the integrated intensities in several regions selected from Fig. 2. The central scatter (Fig. 3*b*) shows an undershoot which reaches its minimum value 45–60 s after the T-jump. This is followed by a sharp increase with a half time of ~100 s. The bottom of the undershoot corresponds to the intermediate scattering pattern shown in Fig. 2*b*. When the temperature is switched back from 36 to 4 °C, a continuous, biphasic, downward trend is observed.

The intensity integrated between channels 11 and 21 (first subsidiary maximum of the cold solution, Fig. 3*c*) decreases in a biphasic manner. The first phase coincides in time with the appearance of the undershoot in the central scatter, the second with its steep increase (Fig. 3*b*). The integrated intensity around channels 22–32 (first subsidiary maximum of the warm solution, Fig. 3*d*) follows a similar trend to the central scatter, but there is an additional lag of 30 s in the polymerization phase. During the depolymerization following the downward T-jump, the intensities return to their approximate initial values, but the lag and half times are shorter than for polymerization.

Figures 1–3 suggest that the assembling system responds to the temperature jump in at least two phases. The first is characterized by a general decrease of intensity throughout the angular range observed. During the second phase the intensity rises again in some regions (Fig. 3*b*, *d*) but continues to drop in others (Fig. 3*c*). This classification is probably oversimplified as the transition between the phases does not occur simultaneously in all parts of the pattern.

The difference between the two main phases may be demonstrated more clearly by reducing the heating rate to about 0.02 °C s^{-1}. In this case the system is much closer to equilibrium than in a T-jump experiment. Nevertheless, the time courses of the intensities are surprisingly similar in both conditions. Figure 4 shows initially a slow drop of intensity in all regions of the pattern with rising temperature. Around 25 °C there is an abrupt transition—the intensity in Fig. 4*b* and *d* rises again while that of Fig. 4*c* drops steeply.

Correlation with physicochemical experiments

The interpretation of X-ray scattering from proteins in solution usually depends on additional experiments to distinguish between different model structures. Gel electrophoresis shows the microtubule protein to consist of tubulin (α and β, $M_r \sim 55{,}000$), high molecular weight-associated proteins [$M_r \sim 270{,}000$ (refs 4, 5)] and several lower molecular weight components, among them the τ factor bands[6] of $M_r \sim 60{,}000$–$70{,}000$ (not shown). Analytical ultracentrifugation of the cold protein solutions yields two main components at 6S and 30S. 6S is the value of the α–β heterodimer of tubulin which constitutes the basic building block of microtubules. 30S is a ring-like structure made up of tubulin and MAPs[5]. The rings may be observed by negative stain electron microscopy (Fig. 4, left). Their apparent diameters vary from 320 to 430 Å. The polymerized microtubules are shown in Fig. 4, right. From the X-ray patterns of oriented gels[7] their mean diameter was determined previously to be ~220 Å.

The process of microtubule assembly is frequently monitored by UV light scattering or turbidity. The increase in the scattered intensity following the temperature jump is usually interpreted as microtubule growth, even though any assembly of tubulin into polymorphic forms produces very similar traces. Thus light scattering by itself is a nonspecific measure of overall aggregation. If the experiment is performed in the conditions of Fig. 1, we observe a decrease in turbidity before the onset of polymerization (not shown). This shows the correspondence between the time dependence of turbidity and the central X-ray scattering and emphasizes the additional information contained in the complete X-ray traces.

Interpretation of scattering curves

The changes in intensity and position of the X-ray scattering peaks could be used simply as indicators of the kinetics of assembly. However, the information above allows a structural interpretation using the theory of small-angle scattering[8]. In the approximation that all particles in solution scatter independently, one can express the intensity as

$$I(h, t) \propto \Sigma x_k(t)^* p_k(t)^* i_k(h)$$

where $h = 4\pi \sin \theta/\lambda$. The sum is taken over all aggregates k in solution. $x_k(t)$ is the fraction of subunits (tubulin dimers) incorporated into aggregate k; mass conservation can be expressed as $\Sigma x_k(t) = 1$. The degree of polymerization $p_k(t)$ expresses the number of subunits per aggregate k, and $i_k(h)$ is the characteristic scattering function of aggregate k normalized to unity at $h = 0$. It contains the structural information. At very small angles $i_k(h)$ approaches 1 so that $I(h, t)$ tends to $\Sigma x_k(t) p_k(t)$. Therefore the central scatter measures the overall aggregation of the system and corresponds to the intensity of scattered UV light. At larger angles the X-ray scattering reflects the overall shape of the aggregates, giving rise to a series of maxima.

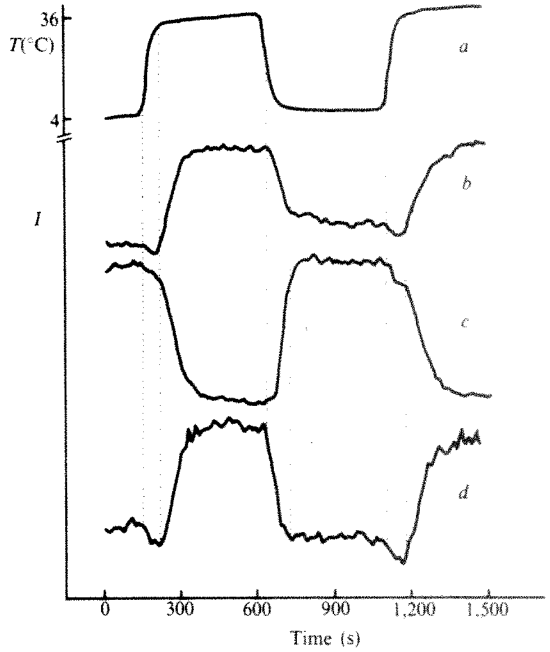

Fig. 3 Time dependence of selected regions of the scattering curves in a temperature jump experiment. *a*, Temperature, measured directly in the protein solution by means of a thermocouple. *b*, Channels 1–5 (central scatter). After the T-jump there is a lag of 45–60 s during which the intensity decreases (undershoot), followed by a sharp rise of half time 100 s. After the reverse T-jump to 4 °C there is a lag of 30–40 s during which the intensity stays constant. This is followed by a biphasic decrease of half times 50 s and 180 s. Depolymerization sets in when the temperature in the solution is about 15 °C. *c*, Channels 11–21 (first subsidiary maximum of the cold solution). The intensity drops steadily in a biphasic manner following the T-jump to 36 °C. The first phase corresponds to the undershoot of curve *b*, the second phase to the rise of *b*. *d*, Channels 22–32 (first subsidiary maximum of the warm solution). The increase in intensity is preceded by an undershoot whose minimum is reached 30–45 s after the one shown by the central scatter. Similarly, the increase in intensity lags behind that of the central scatter. Following the reverse T-jump the intensity decrease is monophasic and coincident with the first phase of the decrease of the central scatter (*b*).

By subtracting the first intermediate scattering pattern, obtained during the undershoot, from the initial cold one (Fig. 2), one obtains the trace of Fig. 5. The comparison with the model calculation shows that it corresponds to the scattering of rings in solution. In this experiment the best fit of the mean diameter is 375 Å. This value is somewhat larger than the mean diameters deduced from published figures based on electron micrographs (~350 Å, see ref. 9). The small discrepancy is probably due to shrinkage on the EM grid. The fact that the difference scattering curves are dominated by the scattering from rings proves that they are dissolved as the temperature is raised, before the formation of microtubules. Within the limits of the instrumental sensitivity the dissolution of rings seems to

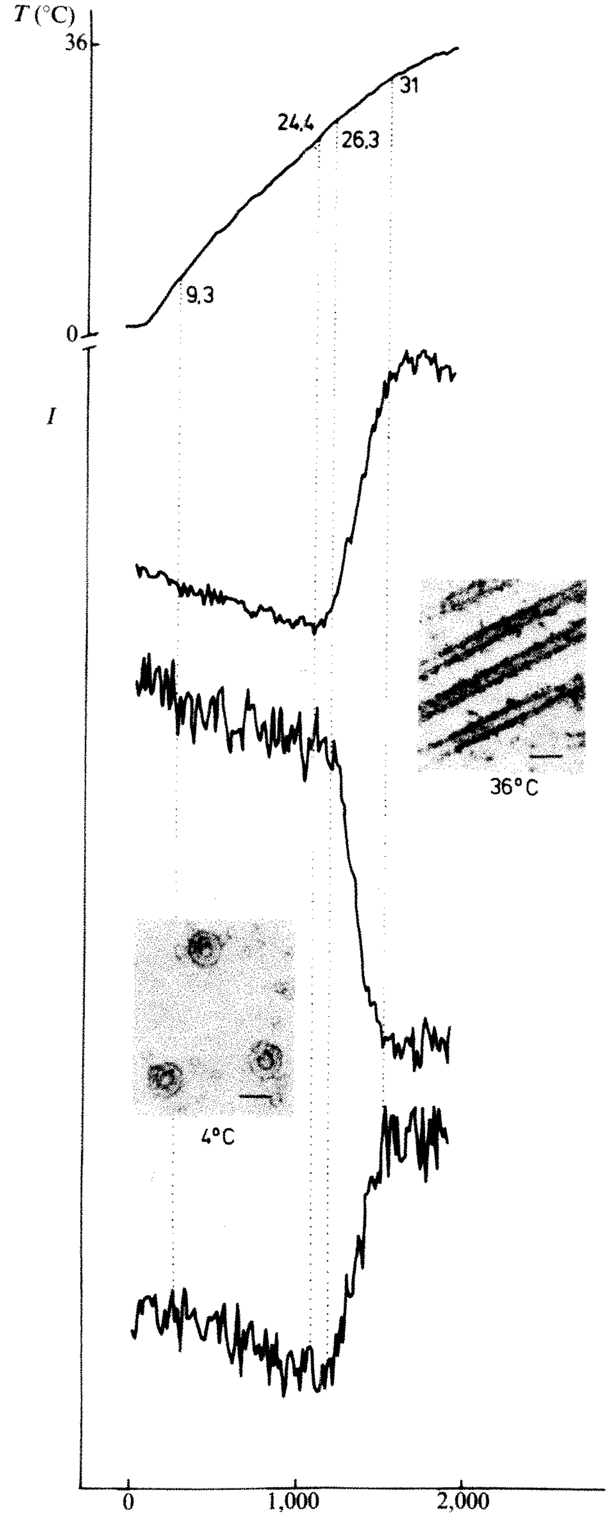

Fig. 4 Microtubule polymerization at a low heating rate. *a*, Temperature. *b–d*, Intensities in the regions corresponding to Fig. 3*b–d*. The central scatter decreases monotonously until 24.4 °C and then rises again (*b*). The region of the first microtubule peak behaves similarly, with the transition temperature displaced towards 26.3 °C (*d*). The region of the first ring peak/first microtubule node decreases monotonously. There is a slight change in rates around 9.3 °C. The second main phase sets in at 26.3 °C. At this point the contribution of rings to the X-ray pattern is below detectability (*c*). Polymerization of microtubules is complete around 31 °C. Insets, Electron images of negatively stained rings (left) and thin sections of microtubules (right). Bar = 500 Å. The cold solution shows single and double rings whose diameters vary between 320 and 430 Å. The warm solution contains microtubules of outer diameters around 250 Å.

be complete by ~60 s after the T-jump (Fig. 2*c*). The processes of ring break down and microtubule formation may be separated particularly well in conditions where the lag time is increased, for instance by raising the temperature slowly (Fig. 4). The transition temperature of about 25 °C coincides with a change in the thermodynamic parameters of the protein[10].

Removal of the contribution of rings from the cold pattern leaves a scattering curve which may be interpreted in terms of scattering from a mixture of dimers and other species smaller than rings. These could be MAPs and/or other tubulin oligomers whose structure is under study.

The scattering pattern of the high temperature state is essentially that of microtubules of mean diameters ~260 Å. We note that their sizes are greater than determined previously in different experimental conditions[7]. This is probably accounted for by the larger contribution of MAPs attached to the outsides of the microtubules (details elsewhere).

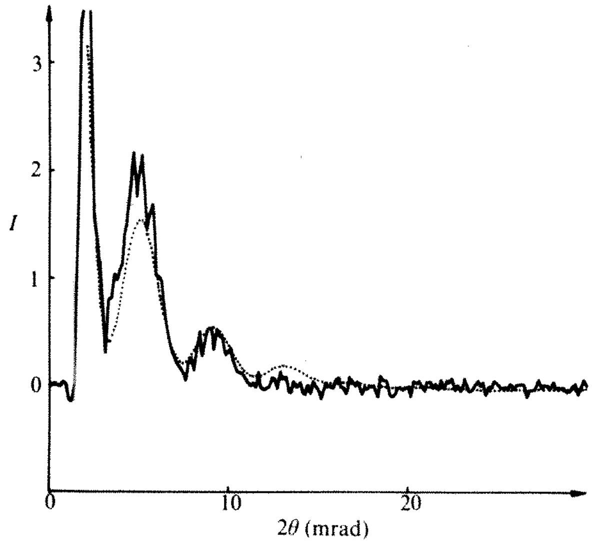

Fig. 5 Difference curve, obtained by subtracting the intensity at 45 s after the T-jump of Fig. 1 from the intensity of the initial cold solution. This plot is representative of the structures that are dissolved. The dotted trace is the calculated small-angle scattering of rings of mean diameter 375 Å, radial width 70 Å, and axial height 50 Å. The positions of the subsidiary maxima are essentially determined by the mean diameter while the width and height modifies mainly the relative amplitudes.

Summarizing the above arguments we may interpret the intensity changes qualitatively as follows: The central scatter ($h \leqslant 0.015$ Å^{-1}) indicates the average degree of polymerization. When rings break down its intensity (and that of the rest of the pattern) decreases. It increases again when microtubules are formed (Figs 3*b*, 4*b*). The region around $h \cong 0.02$ Å^{-1} corresponds to the first subsidiary ring peak. It decreases both absolutely and relative to the rest of the pattern when rings break down. The same region is also near the first subsidiary microtubule minimum. Therefore the intensity decreases even further when microtubules appear (Figs 3*c*, 4*c*). Around $h \cong 0.03$ Å^{-1} we observe the first subsidiary microtubule peak. The intensity decreases during the breakdown of rings and rises sharply with microtubule polymerization. These rules serve as a guide to assess the system's behaviour quickly (for example in Fig. 1), provided that they are backed up by a detailed comparison of the total scattering curves with model calculations such as Fig. 5. The delay between the intensity increases of the central scatter and the microtubule peak (Figs 3*b*, *d* and 4*b*, *d*) suggests that some transient structure is formed around 25 °C between the breakdown of rings and polymerization of microtubules (compare with Fig. 2*b*, *c*). This could correspond to the nucleating centre in the proper sense.

Implications for models of microtubule assembly

Published reports on microtubule polymerization contain a great variety of assembly models (reviewed in ref. 9). Although some of their differences may be due to preparative procedures we suspect that ambiguities inherent in the experimental data play an equally important role. The two main techniques used have been UV light scattering or turbidity and electron microscopy. Turbidity measures only overall polymerization without distinguishing between microtubules and other tubulin aggregates, let alone possible changes of effective diameters due to variations in protofilament number and/or MAP content. Electron microscopy records the structures distorted by drying and staining, it is biased towards large and visible aggregates and provides only snapshot views of the kinetic process. Thus the technique of time-resolved X-ray diffraction helps to bridge the gap between the two conventional approaches as it can be applied to solutions and yet contains structural information on aggregates of all sizes.

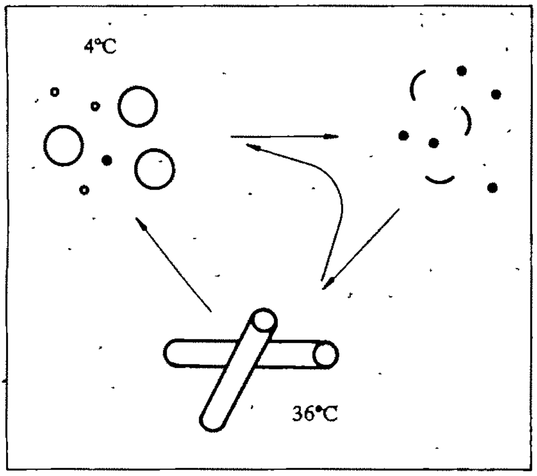

Fig. 6 Possible pathway of tubulin assembly. The initial cold solution contains tubulin dimers, rings, and other entities that are smaller than rings. After the T-jump to 36 °C the rings break apart into fragments which may be involved in the nucleation of assembly. The warm solution consists mainly of microtubules. Depolymerization may proceed either directly to the initial cold state, or via small oligomers.

The assembly models can be placed in three categories depending on the roles assigned to rings. Some assume that opened-up rings are responsible for nucleation and, together with tubulin subunits, contribute to the elongation of microtubules, possibly through intermediates such as sheets or twisted ribbons[11]. Others see a role of rings only in nucleation whereas elongation proceeds by end-on addition of 6S tubulin subunits[12]. Some authors have questioned the role of rings altogether as conditions of microtubule assembly can be found in the absence of rings[13]. There seems to be agreement, however, that brain microtubule assembly is most efficient when starting from a ring-containing solution.

The results presented here favour the view that rings do not directly participate in microtubule nucleation or growth as they tend to break down before microtubules appear. By implication, other intermediates seen in the electron microscope such as sheets or ribbons might also be formed from ring fragments and not by association of opened-up rings. These findings support those of Weisenberg[14] who demonstrated the breakdown of the 30S aggregate into smaller units before microtubule assembly.

During disassembly we observe a smooth transition from the scattering pattern of microtubules to that of rings. This could mean that the rings are formed directly as breakdown products of microtubules. Alternatively, if individual tubulin subunits or small oligomers dissociate from the microtubules they must rapidly reassociate into rings. Whatever the mechanism, the nearly parallel decrease of the central scatter and microtubule maxima (Fig. 3*b*, *d*) suggests that the tubules are largely depolymerized from their ends. The results are summarized in Fig. 6.

Main conclusions and future outlook

The main points to emerge from this study are the following: (1) A cold solution of microtubule protein mainly consists of rings, dimers and other entities made up of MAPs and/or tubulin dimers. (2) When the temperature is raised, either by a T-jump or gradually, rings dissolve into structures of lower degree of polymerization. (3) Within the sensitivity of the method the dissolution of rings is complete before the formation of microtubules. (4) There are at least two intermediate states which differ from both the initial cold and the final warm solution. The first corresponds to the dissolution of rings, the second to the appearance of a new structure just before microtubules begin to form. (5) It is possible to extract accurate sizes for rings and microtubules in solution. (6) Depolymerization is not the exact inverse of polymerization. (7) The cycles of assembly and disassembly can be repeated until the depletion of GTP. These conclusions apply for solutions of microtubule protein prepared in the absence of glycerol, with concentrations around 10–20 mg ml^{-1}

The aim of this experiment, to establish the use of this technique for monitoring the kinetic and structural transitions occurring during the assembly of macromolecules in solution, is fulfilled for microtubule assembly *in vitro*. The structures formed and their kinetics of polymerization do not seem to suffer significantly from radiation damage during the experiment. The extension of the technique to stopped-flow experiments at constant temperature may have a more direct relationship with physiological conditions. This might enable us to investigate the action of factors promoting assembly, especially that of microtubule associated proteins.

We thank Ursula Rühl for technical assistance with the protein preparations, the EMBL staff for help during the experiments, and Michel Koch and Zvi Kam for making available their data analysis and model building programs and for the many stimulating discussions on the subject of small-angle scattering.

Protein-linked RNA of poliovirus is competent to form an initiation complex of translation *in vitro*

Poliovirus RNA that had been labelled with ^{125}I in the 5′-terminal protein (VPg) was found competent to form an initiation complex of translation in a cell-free reticulocyte lysate. In conditions of ribosome binding, no cleavage occurred between VPg and RNA. We conclude that removal of VPg from poliovirus RNA is not a prerequisite for this RNA to initiate translation in vitro.

BOTH *in vivo* and in cell-free extracts, picornavirus RNA is a highly efficient messenger capable of initiating translation at a much faster rate than most host cell mRNAs[1,2]. Evidence from *in vitro* experiments indicates that picornavirus RNA is preferentially translated over cellular mRNAs by virtue of its ability to out-compete host cell mRNA for limiting amounts of a messenger discriminatory initiation factor[3]. The structural feature of picornavirus RNA responsible for its superior translation is not known. Unlike most cellular and viral messengers which require a 5′-terminal 7mG-containing 'capping group' for efficient translation, picornavirus RNA is not capped. Instead, the 5′ terminus of virion RNA is linked to the small virus-encoded protein, VPg (refs 4–8). In contrast, polio RNA isolated from polysomes lacks VPg and is terminated with a 5′ monophosphate[9].

Picornavirus RNA is accurately translated in the messenger-dependent reticulocyte lysate system. Processing of precursor polypeptides occurs to produce proteins which correspond to those seen *in vivo*[10]. Proteinase K treatment of polio virion RNA has been shown to degrade VPg proteolytically, leaving a few amino acid residues linked to the intact RNA molecule[6]. This treatment does not destroy the infectivity of the RNA[11]. Preliminary experiments showed that amino acid incorporation in the reticulocyte lysate was stimulated to the same extent and with identical kinetics by untreated and proteinase K-treated polio RNA. Furthermore, the proteins synthesized in response to both RNAs were indistinguishable when analysed by SDS-polyacrylamide gel electrophoresis (see below). Essentially the same results have been reported for mengovirion RNA treated with proteinase[12].

These results can be interpreted in two ways. In the first case, it may be that the presence or absence of VPg has no effect on the translation of picornavirus RNA. Alternatively, the cell-free system may be able to cleave VPg from RNA so efficiently that no apparent difference is seen in incubations programmed with the two messengers. An activity capable of removing VPg from RNA in extracts prepared from a variety of cells has been described[13]. However, as only a small proportion of the RNA

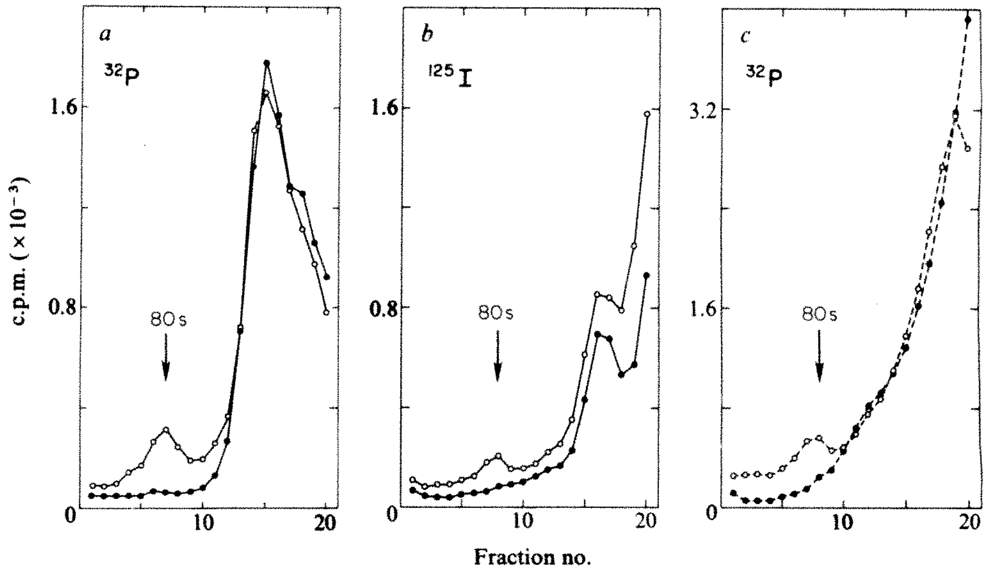

Fig. 1 Binding of polio RNA to reticulocyte ribosomes. Poliovirus ^{32}P-RNA and ^{125}I-VPg-RNA (from type I, Mahoney) were prepared as described previously[9,16]. The messenger-dependent reticulocyte lysate was prepared according to the method of Pelham and Jackson[20]. Incubation mixtures (100 µl) were assembled at 4 °C, containing nuclease-treated reticulocyte lysate (50 µl), creatine phosphokinase (10 µg), 10 mM phosphocreatine, 20 amino acids (0.1 mM each), 20 mM Tris-HCl, *p*H 8.2, 3 mM $Mg(OAc)_2$, 0.13 M KOAc, 2 mM dithiothreitol, reticulocyte ribosomal RNA (1 µg), 0.25 mM NAD, 0.1 mM sparsomycin, and 250 guinea pig L.D. per ml diphtheria toxin. After preincubation at 30 °C for 4 min, 0.1 µg labelled polio RNA was added and incubation continued for 4 min. An equal volume of 1% sodium deoxycholate, 1% Triton X-100 was added and 1 min later the incubation was terminated by chilling to 4 °C. Initiation complexes were resolved by sedimentation at 4 °C on 15–30% w/w sucrose gradients in buffer F (25 mM KCl, 10 mM NaCl, 1.5 mM $Mg(OAc)_2$, 10 mM Tris-HCl, *p*H 7.5 (ref. 14), supplemented with 0.5% sodium deoxycholate and 0.5% Triton X-100. Experiments containing polio ^{32}P-RNA (*a*, *c*) were centrifuged for 10 h at 29,000 r.p.m. in the Spinco SW41 rotor. For *b*, the incubation mixture was scaled up fivefold and programmed with ^{125}I-VPg-polio RNA. Centrifugation was for 10 h at 27,000 r.p.m. in the SW27 rotor. Radioactivity in sucrose gradient fractions was determined in a liquid scintillation counter after addition of one half-volume of H_2O and nine volumes of Biofluor (NEN). ○, Standard conditions; ●, preincubation mixture contained either 5 µg unlabelled polio RNA (*a*) or 10^{-4}M ATA (*b*, *c*). The S value of the ribosome complex was determined by incubating the lysate with ^{35}S-$tRNA^{met}$ and globin mRNA or poliovirus RNA in the same conditions as described for *a*, and sedimenting the initiation complex through a sucrose gradient[21].

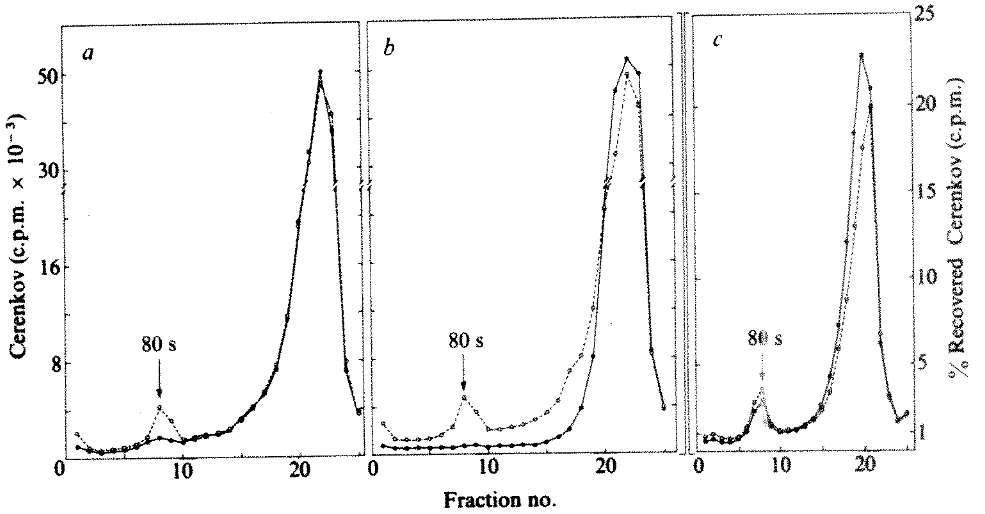

Fig. 2 Binding of polio RNA to reticulocyte ribosomes. Incubation mixtures of the messenger-dependent reticulocyte lysate were prepared as described in Fig. 1 legend. Standard condition reactions were programmed with virion ^{32}P-RNA at a final concentration of 2 μg ml^{-1}. Centrifugation was for 16 h at 21,000 r.p.m. in the SW27 on gradients as described in Fig. 1 legend. Radioactivity in gradient fractions was determined directly by Cerenkov counting. Proteinase K digestion of polio ^{32}P-RNA was done at 37 °C for 1 h[11]. The reaction mixture contained 10 mM Tris, pH 7.6, 100 mM NaCl, 1 mM EDTA, 0.5% SDS, proteinase K (500 μg ml^{-1}) and polio RNA (300 μg ml^{-1}). The mixture was phenol/chloroform extracted after the incubation and the RNA ethanol precipitated before use in the reticulocyte lysate. ○, Standard conditions; ●, preincubation mix contained pactamycin at a final concentration of: *a*, 4×10^{-6} M; *b*, globin mRNA at a final concentration of 400 μg ml^{-1}; *c*, the reaction was programmed with proteinase K-treated ^{32}P-RNA at a final concentration of 2 μg ml^{-1}.

added to *in vitro* cell-free systems is actually translated, the fate of VPg on those molecules which function as messenger was not ascertained. The approach we used to resolve this question was to isolate initiation complexes of ribosomes bound to polio RNA and then determine if VPg was retained on this fraction.

Characterization of initiation complex

Reticulocyte lysates supplemented with sparsomycin and diphtheria toxin allow the binding of ribosomes to mRNA and synthesis of the first peptide bond but block further elongation, permitting isolation of initiation complexes by sucrose gradient centrifugation as shown in Fig. 1 (ref. 14). Due to the large sedimentation coefficient of picornavirus RNA and its nonspecific association with cytoplasmic proteins, separation of ribosome-bound and unbound RNA is difficult. This problem can be overcome by the addition of deoxycholate and Triton X-100 to the incubation and gradient buffer. In the conditions described in Fig. 1 legend, 10% of the polio ^{32}P-RNA is found associated with ribosomes in a peak sedimenting at approximately 80S. The remaining RNA is recovered as a broad peak at 60S with a pronounced shoulder skewed towards the top of the gradient, an observation suggesting that ribonuclease degradation of the unbound RNA occurs. Several criteria have been used to establish that the more rapidly sedimenting peak in Figs 1 and 2 represents a true initiation complex. In control reactions kept at 0 °C, the 80S peak was not seen (data not shown). In Fig. 1*a*, it can be seen that preincubation with excess nonradioactive polio RNA saturates the capacity of the lysate and prevents subsequent binding of ^{32}P-RNA. The same effect was observed when the lysate was preincubated with nonradioactive globin mRNA (Fig. 2*b*). Addition of aurin tricarboxylic acid (ATA), an antibiotic which inhibits association of ribosomes with mRNA, or pactamycin, an inhibitor of initiation of translation[15], both prevent the appearance of the faster sedimenting peak (Figs 1*c*, 2*a*, respectively).

The initiation complex formed with polio ^{32}P-RNA has been further characterized by treatment with ribonuclease T1 and isolation of the ribosome-protected fragment. Analysis by polyacrylamide gel electrophoresis reveals that one major band about 40 nucleotides long is obtained (arrow, Fig. 3*a*, lane 2) together with other RNA bands. This band has been reproducibly observed in several independent experiments using intact virion RNA, or, as shown in Fig. 3*b*, lane 1, using autoradiolysed virion ^{32}P-RNA. The length of the other RNA fragments, however, changes from experiment to experiment (Fig. 3*b*, lane 1). The major band (arrow) is not generated when virion ^{32}P-RNA is bound to ribosomes, isolated without RNase T1 treatment, and analysed by acrylamide gel electrophoresis (Fig. 3*b*, lane 2). The major fragment protected by ribosome binding is capable of rebinding to ribosomes if the mixture of RNA fragments is subjected to a second cycle of ribosome binding (Fig. 3*a*, lane 3). We cannot rule out the possibility that more than one RNA species rebound to ribosomes because the amount of radioactivity in this lane was low.

The VPg moiety of polio genome RNA was specifically labelled with ^{125}I using the Bolton–Hunter reagent[16]. The results of ribosome-binding experiments with this RNA are shown in Fig. 1*b*. Approximately 5% of the labelled RNA is recovered in the initiation complex, showing that VPg is retained on a significant fraction of the polio RNA molecules bound to ribosomes. Formation of the complex is sensitive to ATA. The specific labelling of VPg has been confirmed by releasing ^{125}I-VPg from the initiation complex with RNase T2 and analysing it by gel electrophoresis as published previously[16]. The only radioactive product seen is VPg migrating to the same position as control VPg (data not shown). Unlike the results obtained using ^{32}P-RNA, the peak of unbound ^{125}I-VPg-RNA (in the right half of Fig. 1*b*) is relatively smaller and most of the radioactivity sediments more slowly. The reason for this is not understood.

Table 1 Determination of degree of cleavage of ^{125}I-VPg from ^{125}I-VPg-RNA in various incubations

	No inhibitors			+Sparsomycin +Diphtheria toxin			+ATA		
Time (min)	Aqueous phase (c.p.m.)	Organic phase (c.p.m.)	% Aqueous phase	Aqueous phase (c.p.m.)	Organic phase (c.p.m.)	% Aqueous phase	Aqueous phase (c.p.m.)	Organic phase (c.p.m.)	% Aqueous phase
0	3,473	152	96	3,421	154	96	3,181	125	96
10	3,436	177	95	3,372	192	95	3,253	211	94

Incubation mixtures (500 μl) were prepared as described in Fig. 1 legend with and without the inhibitors as indicated. At the times indicated, aliquots were removed and extracted with an equal volume of phenol/chloroform (1 : 1). Biofluor (NEN) was added to each of the samples and radioactivity was determined by scintillation counting.

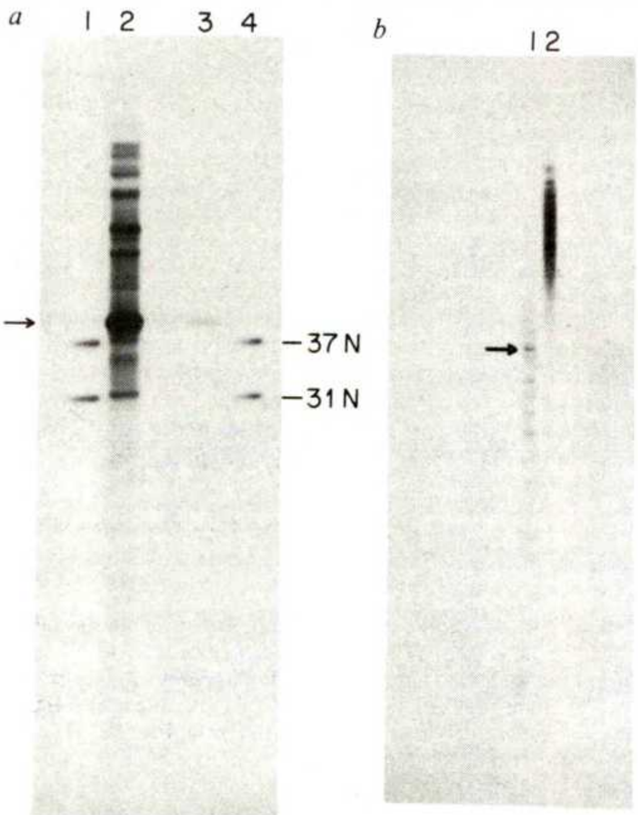

Fig. 3 Acrylamide gel electrophoresis of the ribosome-protected fragment(s) of ^{32}P-RNA from poliovirus. *a*, ^{32}P-RNA from poliovirus was bound to reticulocyte ribosomes as described in Fig. 1 legend. The peak fractions of the sucrose gradient (sedimenting at ~80S) were pooled. RNase T1 was added to 20 units ml^{-1} and incubated at 37 °C for 10 min. The mixture was then chilled on ice and diluted with an equal volume of ice-cold buffer F, containing 0.5% deoxycholate and 0.5% Triton X-100. The sample was pelleted through a 5-ml cushion of 15% sucrose (in buffer F) by centrifugation in the SW27 rotor at 27K r.p.m. (4 °C) for 12–14 h. The pellet was resuspended in 0.5 ml of column buffer (10 mM Tris-HCl, *p*H 7.5, 1 mM EDTA, 7 M urea) containing 0.1% SDS and extracted twice with phenol/chloroform (1 : 1). The aqueous phase was then applied to a small DEAE-cellulose column (0.5 × 4 cm) that had been equilibrated with column buffer. The column was washed with the same buffer containing an additional 0.15 M NaCl (5–10 ml). The presumptive ribosome-protected fragment(s) was eluted with column buffer containing 0.5 M NaCl. The solution containing the fragment(s) was divided. To one half, carrier (either tRNA to 20 μg ml^{-1} or purified oyster glycogen to 200μg ml^{-1}) was added and the sample was alcohol precipitated. This RNA was then analysed by gel electrophoresis on a 20% acrylamide slab gel containing 7 M urea (lane 2). Fragment(s) in the other half were subjected to a second cycle of the same binding and isolation experiments, and analysed by gel electrophoresis (lane 3). Lanes 1 and 4 are marker T1-oligonucleotides 1 and 3 from ^{32}P-RNA of poliovirus, 37 and 31 mucleotides long[22]. N, Nucleotides. *b*, Samples were prepared as described in *a*, except that autoradiolysed virion ^{32}P-RNA was used in the binding experiments and the DEAE cellulose column step was omitted. Lane 1, ribosome-protected fragments corresponding to lane 2 in *a*; lane 2, ribosome-protected RNA isolated without the RNase T1 treatment step.

Retention of VPg on virion RNA after initiation

In view of the activity in uninfected cell extracts that cleaves the linkage between polio RNA and VPg[13], we considered it possible that, by freezing the ribosome on the initiation site, we might prevent the removal of VPg subsequent to the initiation step. Three protein synthesis incubations were prepared containing ^{125}I-VPg-RNA and supplemented with no inhibitor, sparsomycin and diphtheria toxin, or ATA. Aliquots were removed at various times and the unlinking of VPg determined by the phenol extraction assay[13]. Similar results were obtained in the case of all three incubations: little cleavage of VPg from RNA was detected (Table 1). Thus, the retention of VPg on virion RNA reported here is not a consequence of blocking translation at the initiation step. The reason for the apparent discrepancies between our results of release of VPg from RNA and those of Ambros *et al.*[13] may be due to differences in the method of preparation of the reticulocyte extracts and conditions of incubation. A wash of HeLa cell nuclei[13], on the other hand, did remove 90% of VPg from [Tyr-^{3}H,^{32}P]VPg-RNA using the same phenol extraction assay (P. G. Rothberg and E.W., unpublished).

Role of VPg

If the presence of VPg on virion RNA did not prevent ribosome binding, it seemed possible that it might have at least lowered the efficiency of initiation complex formation. Therefore, we compared ribosome binding using VPg-RNA and virion RNA, the VPg of which was degraded proteolytically. As can be seen in Fig. 2*c*, both RNAs form the initiation complex to the same extent. Similarly, translation of VPg-RNA and proteinase K-treated RNA in the reticulocyte lysate leads to the same translat on products with similar yield (Fig. 4).

The role of VPg is not known but the appearance of protein-linked RNA during replication is a general feature of all

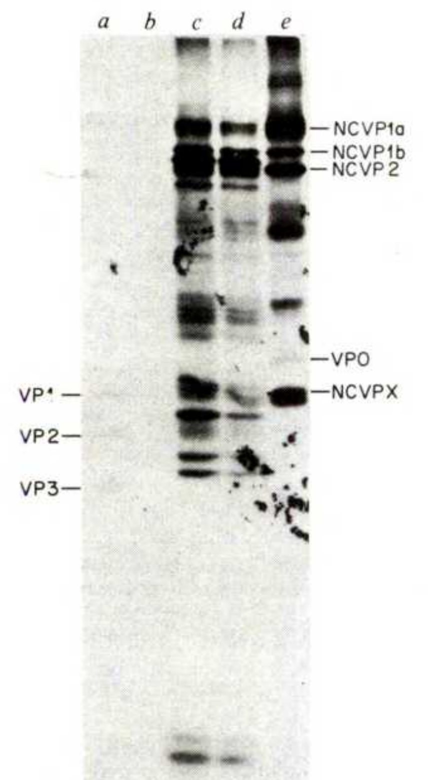

Fig. 4 Acrylamide gel electrophoresis of polio-specific proteins synthesized in the reticulocyte lysate. The messenger-dependent reticulocyte lysate was prepared according to the method of Pelham and Jackson[20]. Reaction mixtures (25 μl) contained 0.5 vol reticulocyte lysate, 20 mM Tris, *p*H 8.0, 2mM dithiothreitol, 100 mM KOAc, 1 mM Mg(OAc)$_2$, 0.5 mM spermidine, 80 μM amino acids except methionine, 50 μg ml^{-1} tRNA, 20 mM creatine phosphate, 100 μg ml^{-1} phosphocreatine kinase, 0.01 μg ml^{-1} rRNA, 60 μg ml^{-1} polio RNA and 400 μCi ml^{-1} ^{35}S-methionine (Amersham). Incubation was for 2 h at 30 °C. Aliquots (1 μl) of the reaction mixture were electrophoresed on 12.5% acrylamide gels containing 0.5% SDS according to the method of Laemmli[23]. The gel was subjected to fluorography according to the method of Bonner and Lasky[24] and exposed at −70 °C. Proteinase K-treated RNA was prepared as described in Fig. 2 legend. Lane *a*, ^{35}S-methionine-labelled capsid proteins isolated from purified virions; lane *b*, without added mRNA; lane *c*, polio virion RNA; lane *d*, proteinase K-treated polio virion RNA; lane *e*, *in vivo* lysate from poliovirus-infected HeLa cells labelled with ^{35}S-methionine. NCVP1a, NCVP1b, NCVP2, VP0 and NCVPX are polio-specific non-copied proteins.

picornaviruses examined[17]. Based on the observations that polio mRNA is infectious and that proteinase K-treated and untreated virion RNAs have equal specific infectivities in transfection assays, it seems that VPg is not essential for early events in replication[6,11]. The identification of VGp on nascent RNA molecules in molar yield implies that it is either a primer for RNA synthesis or is added to all growing chains very soon after initiation has begun[7,18].

We have suggested previously that cleavage of VPg from VPg-RNA may be a prerequisite for this RNA to function as mRNA[7,11]. Our data presented here argue against this hypothesis.

In view of the conclusion reported here that VPg does not interfere with translation *in vitro*, the cleavage of VPg from polysomal RNA *in vivo* is noteworthy. Polio mRNA is not packaged into virions[19]. It is tempting to speculate that retention of VPg may tag those RNA molecules which are to be encapsidated, and thus regulates whether newly synthesized RNA becomes mRNA or enters the pool of progeny genome RNA molecules[7,11,17]. Proof of such a function for VPg clearly awaits further experimental evidence.

We thank Corrado Baglioni for suggestions, Akiko Kitamura for technical assistance, Sandra H. Donaldson for manuscript preparation, Richard J. Jackson for his advice in preparing reticulocyte lysates, R. Hanecak for ^{35}S-methionine-labelled lysate of poliovirus-infected HeLa cells, and R. Rueckert and C. McLean for the gift of pactamycin. This work was supported in part by NIH grant AI 15122. F. G. was recipient of a traineeship from the NCI, grant CA 09176; B. L. S. is recipient of a post-doctoral fellowship, PF-1584, awarded by the American Cancer Society. A. J. D. is a member of the Molecular Biology Program of SUNY at Stony Brook.

Functional and non-functional joining in immunoglobulin light chain genes of a mouse myeloma

Werner Altenburger*, Michael Steinmetz‡ & Hans G. Zachau
Institute für Physiologische Chemie, Physikalische Biochemie und Zellbiologie der Universität München, FRG

Leader, variable (V) and joining (J) gene segments, and adjacent regions of two rearranged alleles of the same κ-chain producing mouse myeloma, comprising approximately 3,200 base pairs, have been sequenced. Sequence comparisons are reported. V–J joining in one of the alleles leads to a reading frame with a stop codon within the J-gene segment. Allelic exclusion is apparently realized in this tumour through the formation of such a non-functional allele.

IN germ-line DNA the information for leader, variable, joining and constant regions of immunoglobulin light chains is located on four separate gene segments called L, V, J and C. In differentiation to an immunocompetent cell, a V- and a J-gene segment are joined by a site-specific recombination process[1,2]. Generally only one type of immunoglobulin is expressed originating from one of the two alleles of the cell[3,4]; this has been termed allelic exclusion. In 15 of 30 mouse myelomas examined allelic exclusion seems to result simply from the fact that only one allele has undergone the V-gene rearrangement whereas the second allele remains in its germ-line configuration[5]. In other myelomas more than one allele was found to be rearranged[5-9]. In some, protein and/or genomic analyses clearly showed that one of the translocations was grossly aberrant[10-13]. However, in other myelomas it was not apparent that one translocation was aberrant or it was even shown that both translocations occurred in the J-gene cluster[14]. Assuming that allelic exclusion operates also in those myelomas one has to search for other reasons either in the translocation step or on the levels of transcription or translation.

Two rearranged κ light chain genes in one mouse myeloma have been previously described[8]. The cloning and restriction mapping of the two rearranged alleles on 14-kilobase[8] and 20-kilobase *Eco*RI fragments[14], respectively, were also reported. We used the myeloma from which the κ chain cDNA clone k38 was derived by Mach *et al.*[15] and which was thought to be identical to MOPC173. However, the sequence analysis described here shows that the V genes on k38 and on the two rearranged *Eco*RI fragments of the myeloma do not correspond to the amino acid sequences of MOPC173 (ref. 16) or other mouse myelomas[17]. Apparently a myeloma other than MOPC173 had been used for the isolation of the mRNA and the subsequent preparation of clone k38 (ref. 15). The same conclusion was reached in independent sequence work on the 14-kilobase fragment and the k38 clone by Fiori, Gorski and Mach (manuscript in preparation). To avoid introducing a new number into the notation before the myeloma is further

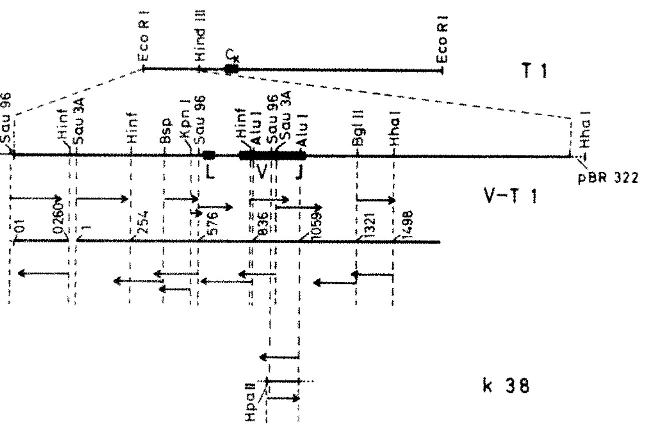

Fig. 1 Localization of the pBR322 subclone V-T1 on the 14-kilobase *Eco*RI fragment T1[14] and partial restriction map of V-T1. Digestions were as previously described[14]. DNA fragments were isolated by *Hha*I (or *Hpa*II) cleavage and separated from the small pBR322 fragments by isokinetic[31] sucrose gradient centrifugation (1 M NaCl, 20 mM Tris-HCl, 10 mM EDTA, *p*H 8.0; $C = 5\%$, particle density 1.89, rotor SW 27.1 for 40 h, 25,000 r.p.m., 20 °C, 1.5–2.0 mg DNA per tube). The fractions (taken from bottom to top) were tested on 1% horizontal agarose gels, pooled, precipitated with ethanol, and washed twice with 80% ethanol. 0.15–0.20 mg of the *Hha*I (or *Hpa*II) fragments (isolated in about 90% yield) were cleaved by one of the nucleases as indicated by dotted lines. Phosphatase treatment (67 °C) and the further steps of sample preparation were as in refs 18 and 32. Labelled fragments were purified by a DE52 step before chemical modification. All 90 °C steps were in siliconized capillaries. Direction and extent of the sequencing are indicated by the arrows. The sequencing strategy of the cDNA clone k38 (see text) is indicated in the bottom line.

characterized we called it tumour T (refs 14, 18, 19). Accordingly the 14- and 20-kilobase fragments are designated T1 and T2, respectively. A 5.3-kilobase *Eco*RI fragment called T3 which was cloned from the same tumour[18] is possibly related to the translocation of immunoglobulin gene segments.

Functional join of V-gene segment to J5-gene segment in one allele of tumour T

Our main interest here was to sequence the V gene segments of the two rearranged alleles and the adjacent L and J regions. We decided to extend the sequencing work both upstream and downstream of these regions for the following reasons. The upstream regions are interesting with respect to possible regulatory sequences and will be even more so as soon as comparison with analogous sequences of other immunoglobulin genes becomes possible. The region downstream of the J segments which extends into the intervening sequence (intron) between J and C_K gene segments is interesting with respect to a search for sites of possible aberrant recombinations[11–13].

As can be seen in Fig. 1, the L-, V- and J-gene sequences of the allele which is found on fragment T1 are located on the previously described subclone V-T1 (ref. 14). 1,800 base pairs have been sequenced (Fig. 2). As a starting point for orientation within the sequence we turn to nucleotides 1,029–1,067 which are identical to those of the J5 gene segment as it was sequenced in germ-line DNA[20,21] (designation as in ref. 20). The junction is within or to the right of the codon CCG, at positions 1,026–1,028. To check whether a V-gene segment is located upstream of the J5-gene segment, the sequence was examined for the presence of codons for the so-called invariant amino acids[17]. All characteristic amino acids were found in the expected positions (6, 16, 23, 26, 35, 44, 57, 59, 61, 62, 63, 64, 65, 73, 75, 86 and 88). The amino acid sequence of the V region as deduced from the nucleotide sequence of fragment T1 is not identical to any of the known[17] sequences of κ light chains. It differs from the published sequences within the 23 amino-terminal amino acids in more than four positions and therefore, by definition[22], cannot be assigned to any one of the known subgroups.

The L-gene segment was localized in fragment T1 at nucleotides 571–621 (Fig. 2) on the basis of the characteristic[23] amino acids at positions 1, 11, 12 and 17 in the leader sequence. Note that there is another possible start codon two codons upstream from the one of amino acid 1 of the leader sequence. The L gene is interrupted by an intron of 113 nucleotides with the probable splice signals AGGT at both ends (positions 618–

Fig. 3 Comparison of leader and intron region sequences of T1 and MOPC41 (upper and lower line, respectively). Numbering is as in Fig. 2. The nucleotide and amino acid sequences of MOPC41 are according to ref. 2. Differences between the sequences are indicated as vertical lines.

621 and 731–734) corresponding to the sequence originally proposed by Breathnach *et al.*[24]. Nucleotides 733–743 downstream of the splice point apparently code for additional amino acids of the leader sequence.

In contrast to the V-gene segment, the L-gene segment on fragment T1 and the small intron show a remarkable similarity to a known sequence, that is, to the leader and intron sequences of the MOPC41 light chain gene (ref. 2 and Fig. 3). While the L-gene sequences are equal in length the optimal alignment of the introns requires the introduction of a few gaps in the first third of the T1 intron sequence. The overall difference is about 15% in the intron and the L-gene sequences of the two tumours, and also in the 75 base pairs upstream of the L genes; further upstream the difference increases to about 30% within the next 50 base pairs. Although according to the V-gene sequences, tumour T and MOPC41 clearly do not belong to the same subgroup, there seems to be a fairly close evolutionary relationship between them on the basis of the sequences of L-gene segments and small introns.

It is interesting that the nucleotide differences or exchanges between the T1 and MOPC41 L gene sequences in positions 611 and 617 seem to be correlated, because only if the nucleotides at these positions are complementary can the inverted repeat structures $\overline{\text{CTGG}}\text{TTT}\overline{\text{CCAG}}^{\downarrow}$ in the T1 and $\overline{\text{CTTG}}\text{TTT}\overline{\text{CAAG}}^{\downarrow}$ in the MOPC41 sequence be formed. Similar repeat structures are seen in an analogous position of fragment T2: $\overline{\text{CTGG}}\text{ATT}\overline{\text{CCAG}}^{\downarrow}$ (positions 846–856 in Fig. 5) and also in the K2 gene sequence[25]. The functional role of such structures on the DNA or RNA level is not known but their location immediately adjacent to a splice point makes it likely that they have one.

The sequences upstream of the L-gene segments of T1 and T2 were screened for the presence of regions similar to the 'Hogness box' TATAAATA which may have a promotor-like function[26]. In fragment T1 sequences centred around positions 0158!, 105, 169, 215!, 236, 264!, 291 and 335 show a fair degree of similarity to the above consensus sequence. The same holds for sequences around positions 215!, 230, 521, 551, 628, 678, 748! of fragment T2. (The exclamation marks indicate the sequences with the highest degree of similarity to the consensus sequence[26].) It cannot be decided at present whether any of these have a functional role. It should be mentioned that remarkably similar T-rich sequences are found in fragments T1 and T2 around positions 225 and 715, respectively, and also in the K2 sequence (around position 172, ref. 25).

To be sure that in myeloma T the T1 allele is transcribed, we sequenced part of the cDNA clone k38[15] (Fig. 1). The clone was found to contain a nucleotide sequence identical to the one of T1 from the middle of the V gene up to the J-gene segment (data not shown). After a stretch of about 30 C's the cDNA insert starts with nucleotide 905 forming a *Hpa*II restriction site; the sequencing was continued until position 1,055 (numbering as in Fig. 2). This proves that the clone k38 is derived from tumour T and that the T1 allele is transcribed into poly-(A) containing RNA.

In the other allele a V-gene segment is joined to J2 in a non-functional way

To sequence the L- and V-gene regions of the second rearranged allele of myeloma T, the previously described subclone V-T2 (ref. 14) was used. A partial restriction map and the sequencing strategy are shown in Fig. 4, the sequence itself in Fig. 5. The V-gene segment could again be identified by the codons for the invariant amino acids and the adjacent J-gene segment was found to be J2. The V-gene segment (nucleotides 1,072–1,358) runs to the codon CCA for Pro 95 but the J-gene segment (nucleotides 1,359–1,396) which is identical to the published one[20,21] does not start with the codon TAC for Tyr 96 but with AC only. Apparently the T has been lost in the V–J recombination event. To exclude experimental error the respective region was sequenced in both directions starting from two different cleavage sites each (Fig. 4). It is clear from the gels (Fig. 6) that between the CCA and the AC neither a T nor another nucleotide has been missed. It is unlikely that this deletion has occurred during the cloning in *Escherichia coli* because the same sequence was found in three independently isolated clones.

The deletion of one nucleotide in the V–J joining region has the important consequence that the reading frame is shifted such that a stop codon is encountered within the J region. In Fig. 5 the amino acid sequence of the presumed translation product, which is terminated after amino acid 105 is shown.

Recombination at the J2 segment may be somewhat more susceptible to mis-pairing than at the other J segments for the following reasons. In J2, but not in the other J's, the 5'-flanking sequence which is thought to pair with the 3'-flanking sequence of a V-gene segment, contains a remarkable stretch of alternating ACs and GTs: ACACCAGTGTGTGTAC[20,21], the terminal

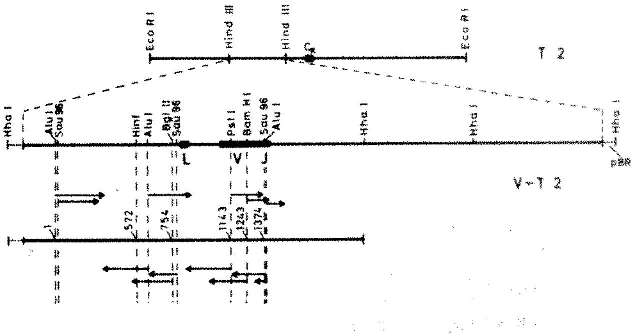

Fig. 4 Localization of the pBR322 subclone V-T2 on the 20-kilobase *Eco*RI fragment T2[14]. Partial restriction map and sequencing strategy. Details as in Fig. 1. For comparison the relevant *Hha*I fragment was also isolated from the fragment T2 containing Charon 4A DNA[14] of two different clones (centrifugation similarly as in the legend to Fig. 1). Sequencing over the V–J junction was from the *Bam*HI site.

Fig. 5 Nucleotide sequence of L, V and J regions of fragment T2. Designations are as in Fig. 2. The position of non-functional joining is marked by an arrow, the respective stop codon in the J segment by underlining. Overlaps with published sequences[20,21] extend from position 1,359 to 1,489 (difference in position 1,403).

TAC being the one which codes for Tyr 96. Such alternating nucleotide sequences may be particularly apt to form stem structures in which non-fitting nucleotides are looped out. In the context of the non-functional joining found in fragment T2 it will be of interest to know the 3′-flanking sequence of the corresponding germ-line V-gene segment.

The amino acid sequence deduced from the V-gene segment of fragment T2 was compared with the known sequences[17] of myeloma light chains. Only one sequence showed a high degree of similarity, that is the one of a light chain from the NZB mouse myeloma PC3858, which was reported[27] up to position 23. The two sequences are identical except for the amino acid at position 10. This similarity bears on the general question of relatedness between BALB/c and NZB myelomas[27].

As on fragment T1, the L-gene segment was identified on fragment T2 by the codons for the four invariant amino acids. It extends from nucleotides 808 to 858 but an initiation at the ATG at position 769–771 cannot be excluded. The L gene on fragment T2, unlike the one on fragment T1, is not interrupted by an intron. Splicing must occur in this case between the 3′ end of the leader and the 5′ end of the V-gene segment, that is in the AGGT sequences at positions 855–858 and 1,070–1,073. Note that there is only about 60% homology with the L segment on fragment T1 and no striking similarities to other leader sequences were found.

Allelic exclusion in myeloma T may operate through non-functional joining on fragment T2

In contrast to the increasing number of reports on myelomas in which more than one allele is rearranged[5–13] Joho and Weissman[28] reported that, in mouse spleen cells, about 50% of the C_κ alleles are unchanged. This suggests that multiple rearrangements may occur in normal lymphoid cells either rarely or not at all. Considering, however, the difficulties in the quantification of blots[28], these experiments do not exclude the possibility that the multiple rearrangements found in myeloma cells occur also in normal lymphoid cells alone. It is possible that myelomas reveal only part of the repertoire of immunoglobulin genes[27] and that this part is enriched with respect to multiply rearranged alleles. It may also be that secondary rearrangements in general are more likely in long-lived or immortal cell lines such as myelomas or hybridomas[29] than in normal lymphoid cells. We believe that allelic exclusion can be effected by various mechanisms and that the mechanisms are basically the same in normal and malignant cells although those involving multiple and nonfunctional rearrangements occur more often in myelomas.

If the rearranged T2 allele of myeloma T is transcribed, translation would be terminated by the stop codon within the

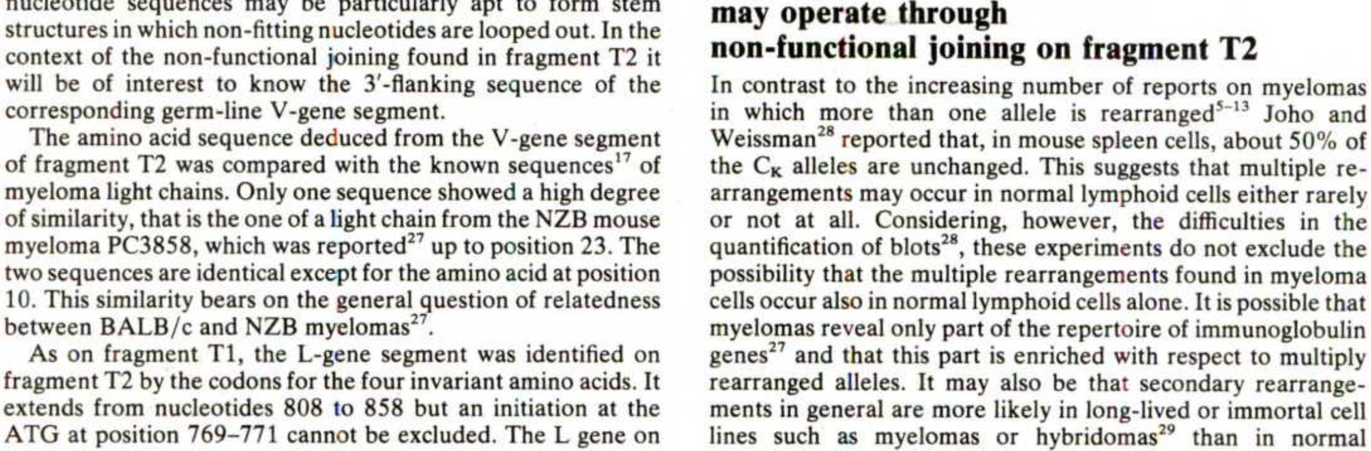

Fig. 6 Junction between the V- and J-gene segments in the V-T2 subclone. The autoradiogram of a 20% sequencing gel (see Fig. 2 legend) of the respective *Alu*I–*Pst*I fragment (Fig. 4) is shown. The complementary sequence to the one of Fig. 5 is indicated.

J-gene segment. Transcription[5] and even translation[10,30] of non-functional immunoglobulin genes have in fact been observed. It has been proposed that the recombination between V- and J-gene segments may occur at slightly different points thereby increasing the diversity of variable regions[20,21]. This flexible recombination mechanism may also lead to non-functionally recombined V-region genes. It is obviously of greater physiological significance to increase antibody diversity by junctional diversification than to generate a functional gene in every V–J joining step by a more stringent recombination mechanism.

Allelic exclusion may be the result of a multi-step process[5,30] with V-gene rearrangements taking place until one functional V–J junction has been formed and further rearrangements are inhibited by an unknown mechanism. The fragment T3 which was found in tumour T and in which 3′-flanking sequences of a V gene and 5′-flanking sequences of a J-gene segment are linked[18] may be the side product of an early translocation step either in the T1 or the T2 allele. Translocation(s) in the T1 allele eventually led to a functional gene while allelic exclusion was realized by a non-functional joining in the T2 allele.

Phorbol esters and vasopressin stimulate DNA synthesis by a common mechanism

Phillip Dicker & Enrique Rozengurt
Imperial Cancer Research Fund, Lincoln's Inn Fields, London WC2A 3PX, UK

The potent tumour promoter 12-O-tetradecanoylphorbol-13-acetate (TPA) acts synergistically with all known mitogens to induce DNA synthesis in 3T3 cells. In contrast, the neurohypophyseal hormone vasopressin, which is mitogenic for 3T3 cells, fails to synergize with TPA to stimulate DNA synthesis, ornithine decarboxylase activity or 2-deoxyglucose uptake. Thus TPA acts through a pathway which converges with that used by vasopressin, and at least some of its biological effects occur through mechanisms normally utilized by specific hormones.

TUMOUR promoters constitute a family of compounds which, although not carcinogenic by themselves, drastically increase the incidence of tumours when applied repeatedly to animals that have received a sub-threshold dose of a carcinogen[1]. Tumour promotion is a phase in the development of many tumours including those that occur in humans[2,3]. Their mechanism of action is of considerable interest, with attention focusing on their biological effects in various types of cultured cells[2,4].

Studies of the cellular actions of 12-*O*-tetradecanoyl-phorbol-13-acetate (TPA), the most potent tumour promoter of the phorbol ester family[2], suggested that these compounds regulate a complex array of cellular activities, including mitogenesis, by using receptor–effector systems for a physiologically occurring material[5,6]. It has been suggested that the biological effects of TPA are mediated by the epidermal growth factor (EGF) receptor–effector system[7–9], but although TPA inhibits the specific binding of EGF to the cell, phorbol esters and EGF do not compete directly for the same receptors[10–12]. Further, TPA synergistically stimulates DNA synthesis when added in combination with most known mitogens including unfractionated serum[4,13,14], plasma[15], platelet-derived growth factor[15], multiplication-stimulating activity[15], fibroblast-derived growth factor (FDGF)[16], fibroblast growth factor[15], insulin[16] and EGF[6,10,15,16], indicating that TPA does not act identically to any of these growth factors. At least two alternative mechanisms of action of TPA can be envisaged. It may act in a fundamentally different way from hormones and growth factors by increasing cellular sensitivity to any growth factor in a non-selective fashion[15], or it may regulate biological activity through a specific hormonal pathway not yet identified[5,6].

We have found that the neurohypophyseal nonapeptide arginine vasopressin is a potent mitogen for Swiss 3T3 cells[17]. We were led to this finding when testing whether hormones and ionophores able to stimulate ion fluxes[18–20] could also regulate cell proliferation. The effect of vasopressin on DNA synthesis is synergistically potentiated by insulin, EGF and FDGF[17]. Similarities in the mitogenic properties of vasopressin and TPA prompted us to suggest that these chemically diverse factors stimulate DNA synthesis through an identical mechanism[6]. Based on the evidence presented here, we propose that the actions of TPA and vasopressin converge into a common

0028–0836/80/410607—06$01.00

pathway to stimulate DNA synthesis, 2-deoxyglucose uptake and ornithine decarboxylase activity in quiescent cultures of mouse Swiss 3T3 cells.

Equivalent mitogenic properties

A series of experiments demonstrated the equivalence of the mitogenic properties of TPA and vasopressin. Addition of saturating levels of either vasopressin or TPA to quiescent cultures of Swiss 3T3 cells stimulated identical increases in DNA synthesis when tested in combination with EGF, insulin, FDGF or low concentrations of serum (1.5–2.5%, Table 1), when DNA synthesis was measured either by ^{3}H-thymidine (^{3}H-TdR) incorporation into acid-insoluble material (Table 1) or by the percentage of labelled nuclei after autoradiography (results not shown).

We have found that exposure of cell cultures to vitamin A derivatives such as retinoic acid[21], or disruption of the microtubular network by colchicine[22], enhances the stimulation of DNA synthesis induced by growth factors in quiescent cells. To ascertain whether the mitogenic equivalence of vasopressin and TPA holds under those conditions of increased cellular responsiveness, cultures of quiescent 3T3 cells were exposed to vasopressin plus EGF or TPA plus EGF and to different concentrations of retinoic acid or colchicine. The dose-dependent enhancement of DNA synthesis produced by retinoic acid or by colchicine in the presence of TPA plus EGF is identical to that obtained in parallel cultures exposed to vasopressin plus EGF (Fig. 1). Thus vasopressin and TPA can substitute for each other in stimulating DNA synthesis in Swiss 3T3 cells in the presence of various agents, including EGF, FDGF, insulin, unfractionated serum (Table 1), retinoic acid and colchicine (Fig. 1).

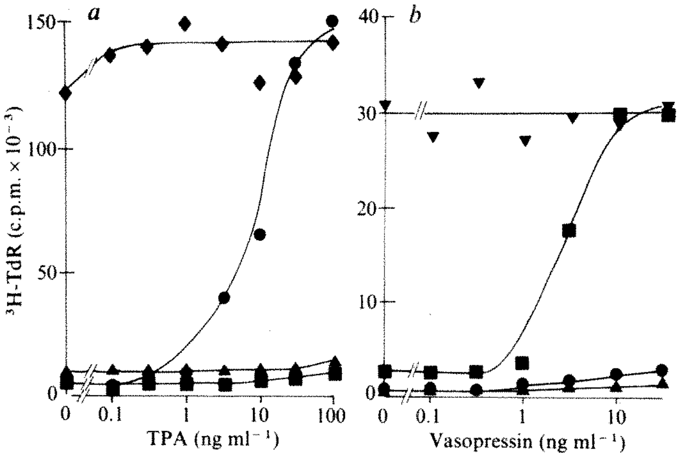

Fig. 2 Absence of synergistic interactions between the mitogenic effects of vasopressin and TPA, in the presence or absence of insulin or EGF. Cultures produced as in Fig. 1 legend were washed twice in DMEM, and incubated in 2 ml of a 1 : 1 mixture of DMEM: Waymouth medium containing ^{3}H-TdR plus the mitogens as indicated. After 40 h at 37 °C, cumulative ^{3}H-TdR incorporation into acid-insoluble material was measured. Conditions and measurements of ^{3}H-TdR incorporation were as in Fig. 1. Fetal calf serum (10%) induced incorporation of 156 × 10^3 and 105 × 10^3 c.p.m. in the experiments in *a* and *b*, respectively. Concentrations of mitogens were 1 μg ml^{-1}, 100 ng ml^{-1}, 10 ng ml^{-1} and 10 ng ml^{-1} for insulin, TPA, EGF and vasopressin, respectively. *a*; ◆, TPA plus insulin plus vasopressin; ●, TPA plus insulin; ▲, TPA plus vasopressin; ■, TPA only. *b*; ▼, vasopressin + TPA + EGF; ■, vasopressin plus EGF; ●, vasopressin plus TPA; ▲, vasopressin only.

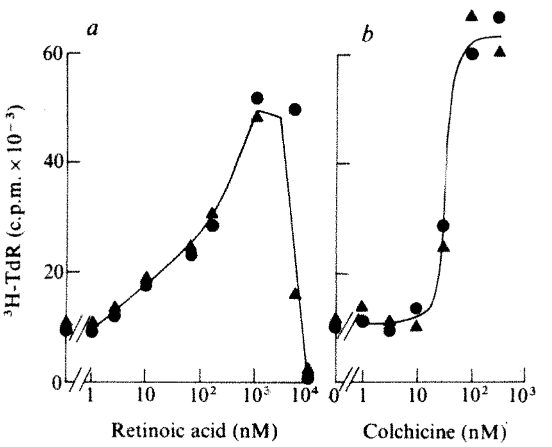

Fig. 1 Enhancement by retinoic acid and colchicine of ^{3}H-TdR incorporation induced by TPA plus EGF (●) or vasopressin plus EGF (▲) in Swiss 3T3 cells. Confluent and quiescent cultures of 3T3 cells were washed twice with Dulbecco's modified Eagle's medium (DMEM) at 37 °C to remove residual serum, then incubated in 2 ml of a 1 : 1 mixture of DMEM: Waymouth medium[43] containing ^{3}H-TdR (0.5 μCi ml^{-1}; 1 μM, Amersham) and mitogens as indicated. After 40 h at 37 °C ^{3}H-TdR incorporation into acid-insoluble pools was assayed as follows. Cultures were washed twice with ice-cold phosphate-buffered saline (0.15 M NaCl in 0.1 M K_2PO_4 buffer, *p*H 7.4) and acid-soluble radioactivity was removed by a 20-min treatment with 5% trichloroacetic acid (TCA) at 4 °C. Cultures were then washed twice in ethanol, cells were solubilized by a 30-min incubation with 0.1 M NaOH and 2% Na_2CO_3, and the radioactivity in the acid-insoluble pools was determined. Fetal calf serum (10%) induced incorporation of 155 × 10^3 and 198 × 10^3 c.p.m. when retinoic acid and colchicine (Sigma) were involved, respectively. TPA (Consolidated Midland, Brewster, New York), EGF or vasopressin (Sigma) alone induced incorporation of less than 2 × 10^3 c.p.m. Concentrations of mitogens were 10 ng ml^{-1}, 10 ng ml^{-1} and 100 ng ml^{-1} for vasopressin, EGF and TPA, respectively. All points are the average of duplicate plates. Stock cultures of Swiss 3T3 cells were maintained in DMEM plus 10% fetal calf serum, penicillin (100 U ml^{-1}), and streptomycin (100 μg ml^{-1}), in a humidified atmosphere of 10% CO_2 : 90% air at 37 °C. Cells were subcultured in 30- or 90-mm Nunc Petri dishes with medium containing 10% fetal calf serum, refed with the same medium after 2 d and used 5 d after the last change of medium. These cells were arrested in G_1 as judged by cytofluorometric analysis (Table 2) and by the fact that less than 1% of cells are autoradiographically labelled after a 40 h exposure to ^{3}H-TdR. Retinoic acid was dissolved in ethanol. Equivalent concentrations of ethanol were added to all controls and never exceeded 0.5% which was not toxic to our cells. Stock solutions of TPA (10 mg ml^{-1}) were made up in acetone and kept at −20 °C.

No additive or synergistic stimulation of DNA synthesis

The striking similarity in the mitogenic properties of TPA and vasopressin in Swiss 3T3 cells raises the possibility that they act through a common mechanism. If they stimulate DNA synthesis by an identical pathway, these chemically diverse factors should not interact either additively or synergistically in stimulating DNA synthesis when tested at saturating concentrations. We therefore tested their combined effect.

TPA caused a potent dose-dependent stimulation of ^{3}H-TdR incorporation into acid-precipitable material when tested in the presence of insulin (Fig. 2*a*). In contrast, addition of different concentrations of TPA in the presence of a fixed and saturating concentration of vasopressin (10 ng ml^{-1}), in either the absence

Table 1 Identical mitogenic properties of saturating concentrations of vasopressin and TPA

EGF (ng ml^{-1})	Insulin (μg ml^{-1})	FDGF (μg ml^{-1})	Serum % vol. : vol.	^{3}H-TdR (c.p.m. × 10^{-3}) No other addition	Vasopressin	TPA
—	—	—	—	1	1	1

Cultures produced as for Fig. 1 were washed twice in DMEM and incubated for 40 h at 37 °C in 2 ml of a 1 : 1 mixture of DMEM : Waymouth medium containing ^{3}H-TdR (0.5 μCi ml^{-1}; 1 μM) plus mitogens as indicated. Cumulative incorporation of ^{3}H-TdR was measured as in Fig. 1. Fetal calf serum (10%) induced incorporation of 208 × 10^3 c.p.m. Concentrations of vasopressin and TPA were 10 ng ml^{-1} and 100 ng ml^{-1}, respectively, which are saturating under these conditions (Fig. 2). FDGF was prepared as before[46].

or presence of insulin, did not alter stimulation of DNA synthesis (Fig. 2*a*). This lack of synergistic interaction between TPA and vasopressin was confirmed when both were added at submaximal concentrations together with insulin (results not shown).

Because the stimulation of DNA synthesis by saturating levels of TPA plus insulin or vasopressin plus insulin was frequently comparable to that promoted by fresh medium containing 10% serum (that is, maximal response), the possibility remained that a synergistic effect between TPA and vasopressin could be revealed in the presence of a third mitogen if DNA synthesis was stimulated submaximally. Figure 2*b* shows that in the presence of EGF the stimulation of DNA synthesis induced by saturating levels of TPA (a submaximal response) was not enhanced by increasing concentrations of vasopressin. Thus, vasopressin and TPA do not interact synergistically or additively in the presence or absence of a third mitogen.

The conclusions drawn from Fig. 2 are further substantiated by flow cytofluorometric analysis (Table 2). Vasopressin or TPA alone caused little increase in the percentage of the cell population moving from G_1 to $S+G_2+M$. Vasopressin and TPA together did not interact to increase cell exit from G_1. However, the addition of vasopressin or TPA together with insulin caused a striking increase in the proportion of cells in $S+G_2+M$ which was not further increased when the three mitogens were added together in the culture. These results agree well with those in Table 1 and Fig. 2.

Table 2 Equivalence of mitogenic effects of TPA and vasopressin demonstrated by cytofluorometry

Vasopressin	TPA	Insulin	Serum	Percentage of cells in $S+G_2+M$
−	−	−	−	9
+	−	−	−	13
−	+	−	−	12
+	+	−	−	14
−	−	+	−	12
+	−	+	−	78
−	+	+	−	76
+	+	+	−	71
−	−	−	+	87

Cell cultures (90-mm) produced as for Fig. 1 were washed twice in DMEM and incubated for 40 h at 37 °C in 10 ml of a 1:1 mixture of DMEM:Waymouth medium containing 2 μM colchicine (to arrest cells at mitosis) plus mitogens as indicated. Cells were then detached by minimal treatment with 0.025% trypsin and EDTA (0.16 mg ml^{-1}), suspended in DMEM containing 10% bovine serum, centrifuged at 1,000 r.p.m. for 2 min, washed twice with phosphate-buffered saline, suspended in 1 ml of saline and squirted rapidly through a 25-gauge needle into 3 ml of ethanol:saline (70:30). This suspension could be stored at 4 °C for 1–2 weeks. Immediately before a cytofluorometric assay, the ethanolic suspension was centrifuged at 1,000 r.p.m. for 2 min and the pellet was resuspended in 0.5 ml of a mixture containing mithramycin (50 μg ml^{-1}) in ethanol:H_2O (25:75) plus 15 mM $MgCl_2$. After 30 min DNA histograms were obtained with a fluorescence activated cell sorter. Two 90-mm cultures were used for each condition. Concentrations of mitogens were 10 ng ml^{-1}, 100 ng ml^{-1}, 1 μg ml^{-1} and 10% (volume:volume) for vasopressin, TPA, insulin and fetal calf serum, respectively.

In all the above experiments, cumulative DNA synthesis was measured after a 40-h exposure of cultures to mitogens. It is possible that vasopressin or TPA, in the presence of insulin and other agents, induce identical amounts of DNA synthesis but with different kinetics. The experiment shown in Fig. 3 rules out this possibility. Both the lag period preceding the onset of DNA synthesis (14 h) and the rate of entry into S phase were the same regardless of whether the cultures were exposed to TPA plus insulin, vasopressin plus insulin or TPA plus vasopressin plus insulin. Thus, with respect to the kinetics of stimulation of DNA synthesis as well as cumulative DNA synthesis, the effects of vasopressin and TPA are neither additive nor synergistic. Note that serum-stimulated cells enter S phase more rapidly than the parallel cultures treated with the tumour promoter and the hormones, indicating that potential additive or synergistic effects could be detected under our experimental conditions.

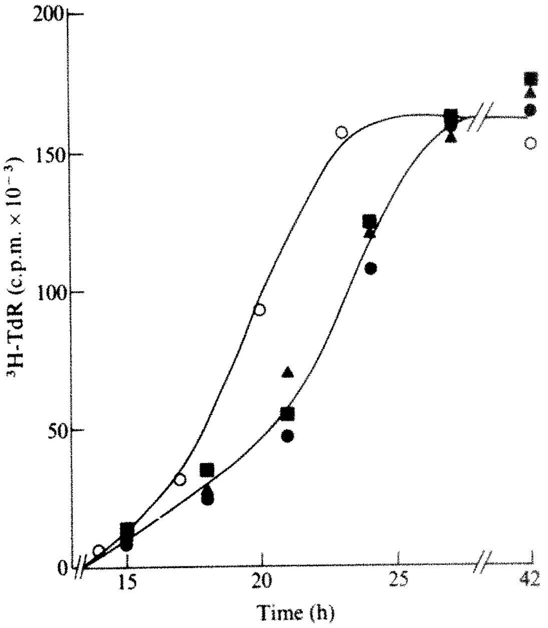

Fig. 3 Time course of ^{3}H-TdR incorporation into Swiss 3T3 cells stimulated by different combinations of TPA, vasopressin and insulin. Cultures produced as in Fig. 1 legend were washed twice in DMEM. Then 2 ml of a 1:1 mixture of DMEM: Waymouth medium containing ^{3}H-TdR plus mitogens as indicated was added (time 0), and the cultures were incubated at 37 °C. At the times indicated on the abscissa the incubation of duplicate cultures for each condition was stopped. The cumulative incorporation of ^{3}H-TdR into the acid-insoluble pools of these cultures was then determined. Conditions and measurements of incorporation were as for Fig. 1. Insulin, TPA or vasopressin alone induced incorporation of less than 15×10^3 c.p.m. of ^{3}H-TdR. Concentrations of mitogens were 10% (volume:volume), 10 ng ml^{-1}, 1 μg ml^{-1} and 100 ng ml^{-1} for fetal calf serum, vasopressin, insulin and TPA, respectively. ●, Vasopressin plus insulin; ■, TPA plus insulin; ▲, vasopressin plus TPA plus insulin; ○, serum.

The above evidence shows that vasopressin and TPA stimulate DNA synthesis by a common mechanism in Swiss 3T3 cells. However, TPA is a potent mitogen for several cell lines in which vasopressin is not active. For example, TPA stimulates DNA synthesis in quiescent 3T6 and hamster Nil-8 cells and synergistically stimulates DNA synthesis in the presence of other growth factors in BALB 3T3 cells[16,21]. Vasopressin when added to these cells fails to enhance DNA synthesis or elicit any early biological response either in the presence or absence of other growth factors (unpublished data). It seems likely that these cell lines possess receptors for TPA (see below) but not for vasopressin, which in turn suggests that TPA and vasopressin interact with distinct receptors in Swiss 3T3 cells.

Stimulation of ornithine decarboxylase activity and 2-deoxyglucose uptake

Do the actions of TPA and vasopressin converge before the initiation of DNA synthesis? When quiescent cultures of 3T3 cells are stimulated by serum or by defined growth factors, a complex array of biochemical events precedes the onset of DNA synthesis[23]. Two of these events—the induction of ornithine decarboxylase activity and of 2-deoxyglucose uptake—both of which peak 6 h after stimulation, are synergistically increased by combinations of growth factors. These events provide useful markers to determine whether the actions of TPA and vasopressin converge before the initiation of DNA synthesis, which occurs 14 h after mitogenic stimulation.

The activity of ornithine decarboxylase, a key enzyme in the biosynthesis of polyamines, rises markedly in different cell types stimulated by TPA[24–26] and the induction of this enzyme has been proposed as essential for tumour promotion[27].

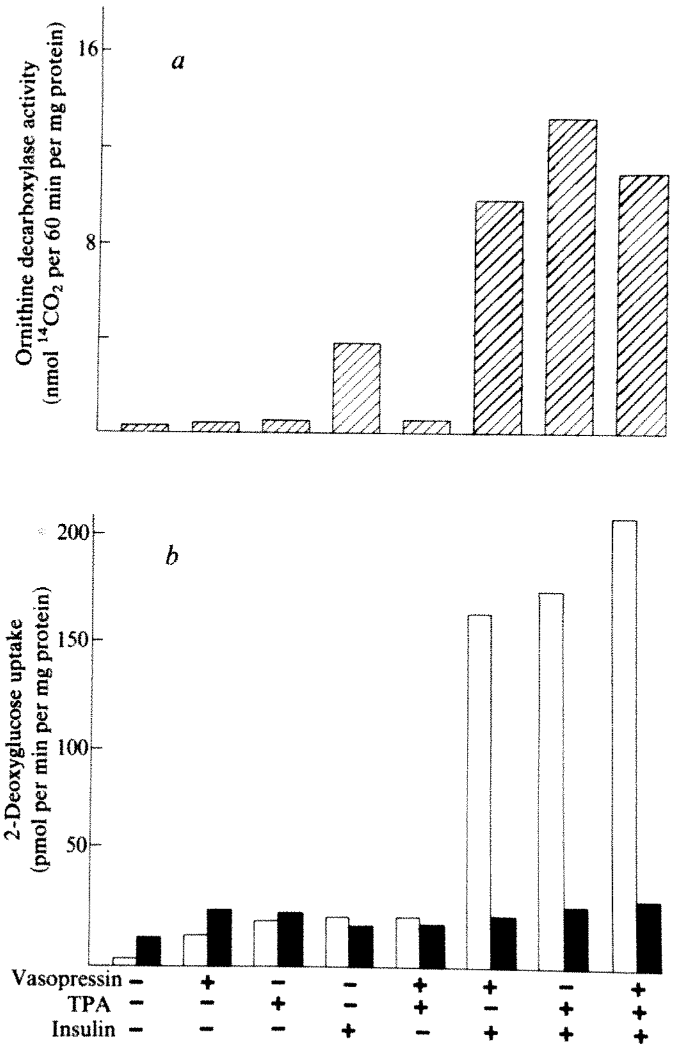

Fig. 4 Effect of TPA and vasopressin on ornithine decarboxylase activity (*a*) and ^{3}H-2-deoxyglucose uptake (*b*) in the absence and presence of insulin. *a*, Quiescent 90-mm cultures of Swiss 3T3 cells produced as for Fig. 1 were washed twice in DMEM and incubated for 6 h in 10 ml of a 1 : 1 mixture of DMEM : Waymouth medium plus TPA or the hormones as indicated. Cultures were then washed three times in ice-cold saline and cells were scraped off the dish with a rubber policeman. For each experimental condition, cells from three separate cultures (about 10^7 cells in total) were pooled, spun down, resuspended in 1 ml of saline, then spun down once more and stored at −40° until assayed. The assay used was similar to that of Hogan[44]. The cell pellet was frozen and thawed three times in 200 µl of the assay mixture. The final concentration of the various components in the enzyme assay was 0.1 mM EDTA, 0.05 mM pyridoxal phosphate, 5 mM dithiothreitol, ^{14}C-ornithine (0.2 µCi; 0.2 mH, Amersham) and 50 mM of HEPES, *p*H 7.1. The release of radioactive CO_2 in the assay was linear for at least 60 min of incubation at 37 °C and was also proportional to the amount of cell extract used. The amount released did not vary by more than 10% in duplicate samples and the values presented are the average of duplicate determinations. To ensure that the release of $^{14}CO_2$ from 1-^{14}C-ornithine was a valid measure of enzymatic activity, the formation of ^{3}H-putrescine (Amersham) from [5-^{3}H]ornithine was determined. Labelled putrescine was isolated from the reaction mixture and analysed by the method of Inoue and Mizutoni[45]. The amount of ^{3}H-putrescine formed was proportional to the amount of $^{14}CO_2$ released. Concentrations of mitogens were 10 ng ml^{-1}, 100 ng ml^{-1} and 1 µg ml^{-1} for vasopressin, TPA and insulin, respectively. *b*, Confluent quiescent 30-mm cultures produced as for Fig. 1 were washed twice in DMEM and incubated for 5.5 h in 2 ml of a 1 : 1 mixture of DMEM : Waymouth medium with the mitogens as indicated in the presence (black bars) or absence (plain bars) of 10 µg ml^{-1} cycloheximide. The cultures were then washed three times in DMEM minus glucose and incubated in DMEM minus glucose plus the mitogens as indicated with or without cycloheximide. After 30 min the cultures received ^{3}H-2-deoxyglucose (2.5 µCi ml^{-1}; 0.2 mM Amersham). After 15 min at 37 °C, cultures were washed rapidly four times with ice-cold saline. Acid-soluble radioactivity was measured by extracting for 20 min with 5% TCA at 4 °C. All values are the mean of duplicate determinations. Concentrations of mitogens were as for *a*.

Vasopressin, like TPA, increases the activity of ornithine decarboxylase[26]. Figure 4*a* shows that whereas addition of TPA or vasopressin to quiescent 3T3 cultures in the absence of other mitogens caused little increase in the activity of this enzyme, in the presence of insulin saturating concentrations of TPA or vasopressin synergistically induced identical levels of ornithine decarboxylase. When added together, the promoter and the hormone did not act synergistically in increasing enzyme activity in either the absence or presence of insulin. Thus the actions of vasopressin and TPA converge before the initiation of DNA synthesis.

The uptake of 2-deoxyglucose increases in a biphasic fashion[23,28–30] in quiescent fibroblasts stimulated to divide. In various types of cells TPA induces an increase in 2-deoxyglucose uptake[31,32]. In 3T3 cells TPA and insulin added together synergistically induced the cycloheximide-sensitive (second) phase of deoxyglucose uptake (Fig. 4*b*). Vasopressin could replace TPA in inducing the activity of this uptake system, acting synergistically with insulin. However, TPA and vasopressin together failed to act either synergistically or additively in the absence or presence of insulin. Thus, as with ornithine decarboxylase induction, TPA and vasopressin induce the second phase of 2-deoxyglucose uptake by a common mechanism.

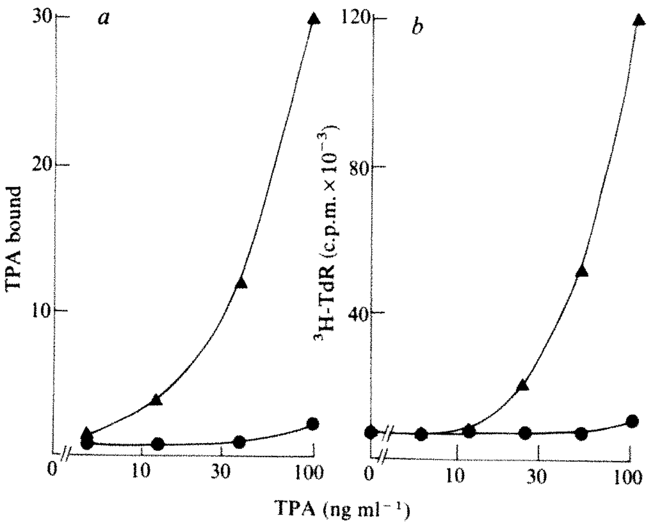

Fig. 5 Physical persistence of TPA (*a*) and the persistence of its mitogenic actions (*b*) are eliminated in parallel by BSA. *a*, 30 mm cultures produced as for Fig. 1 were washed twice in DMEM and incubated for 1 h at 37 °C in 2 ml of a 1 : 1 mixture of DMEM : Waymouth medium containing insulin (1 µg ml^{-1}) plus [20-^{3}H(N)]TPA (0.15 µCi ml^{-1}, NEN) at various specific activities. Cultures were then washed twice with DMEM at 37 °C and the amount of TPA bound (ng per culture) was determined from the remaining radioactivity extracted as described below (▲). Parallel cultures were exposed three successive times (45 min each) to 2 ml of recrystallized defatted BSA (10 mg ml^{-1}, Sigma) in a 1 : 1 mixture of DMEM : Waymouth medium supplemented with insulin (1 µg ml^{-1}), followed by three 10-min washes with the same medium without BSA (●). Radioactivity was extracted from the dish after two rapid washes with ice-cold 0.15 M saline followed by a 30-min incubation at 37 °C with 0.1 M NaOH and 1% SDS. Insulin was present in these incubations to maintain cell attachment. The number of cells per culture was the same after either treatment. The ^{3}H-TPA was dissolved in ethanol at a final concentration of less than 0.2% which had no effect on the cell cultures. *b*, Cultures were washed twice in DMEM and incubated for 1 h at 37 °C in 2 ml of a 1 : 1 mixture of DMEM : Waymouth medium containing insulin (1 µg ml^{-1}) plus various concentrations of TPA. Cultures were washed twice in DMEM and 2 ml of a 1 : 1 mixture of DMEM: Waymouth medium containing insulin (1 µg ml^{-1}) and ^{3}H-TdR (0.5 µCi ml^{-1}; 1 µM) was added either immediately (▲) or after the cultures had been washed with BSA solutions as above (●). After 40 h at 37 °C cumulative incorporation of ^{3}H-TdR into acid-insoluble pools was assayed as for Fig. 1. Addition of TPA (100 ng ml^{-1}) and insulin (1 µg ml^{-1}) to cultures pretreated with BSA or with cultures not pretreated with BSA, induced incorporation of 118×10^3 and 142×10^3 c.p.m. of ^{3}H-TdR, respectively, after a 40-h incubation. Thus treatment with BSA does not cause cells to become less responsive to the mitogenic actions of TPA plus insulin. Fetal calf serum (10%) induced incorporation of 185×10^3 c.p.m. in this experiment.

Table 3 TPA acts synergistically with each of a wide range of mitogens except vasopressin

Mitogens acting synergistically with TPA	Reference

Transient exposure to TPA

The mitogenic effects of TPA persist after the removal of the TPA-containing medium (refs 15 and 16 and our unpublished data), but vasopressin must be in contact with cells continuously to stimulate DNA synthesis synergistically with insulin[17]. It has been suggested that mitogens such as TPA, which exert biological effects that persist after the medium containing the mitogen has been removed, act by inducing a cell to become 'competent'[33]. Mitogens such as vasopressin, which must be present throughout G_1 to cause entry into S phase[17], are postulated in this model to act in a fundamentally different fashion: they are said to allow a 'competent' cell 'to progress' through G_1 and into S phase[33]. According to this model TPA and vasopressin act by separate paths. This contradicts the evidence reported here. However, although the biological effects of TPA may be mediated by specific receptors (see below), it is also known that TPA associates tightly but nonspecifically with cell membranes[34], a phenomenon which may account for its persistent biological effects and has impeded the detection of specific binding of the molecule. The following experiments show that the mitogenic effects of TPA persist after the removal of the TPA-containing medium, merely because it binds tenaciously to cell cultures. Figure 5*a* demonstrates that the phorbol ester remains bound to cell cultures even after multiple washes with Dulbecco's modified Eagle's medium. About 30% of the ^{3}H-TPA added in a 1-h incubation remained attached to the culture after washing and this was not reduced by adding a vast excess of unlabelled TPA (that is, binding was nonspecific). TPA binds with high affinity to bovine serum albumin (BSA)[34], and the level of TPA remaining bound to cell cultures could be reduced considerably by repeated incubation with solutions of BSA (Fig. 5*a*). If the ability of TPA to exert its mitogenic effects after removal of the TPA-containing medium is due merely to its remaining bound to the cell culture, incubations with BSA solutions should prevent the persistence of the mitogenic effects of TPA. Figure 5*b* shows that this is indeed the case. The removal of TPA from cell cultures by BSA (Fig. 5*a*) parallels the elimination of the persistent mitogenic effects of TPA (Fig. 5*b*). Thus, as with vasopressin, a transient exposure to TPA is not sufficient to render the cells responsive to insulin in stimulating DNA synthesis. This is consistent with our data showing that vasopressin and TPA act as mitogens by identical mechanisms.

Conclusions and implications

Our study demonstrates that (1) TPA and vasopressin can substitute for each other in stimulating DNA synthesis, ornithine decarboxylase induction and 2-deoxyglucose uptake under various experimental conditions; (2) TPA and vasopressin added at saturating concentrations do not have additive or synergistic effects in eliciting these responses in either the absence or the presence of other factors such as EGF or insulin. The lack of synergistic interaction between TPA and vasopressin sharply contrasts with the synergistic interaction of TPA with practically all known growth-promoting polypeptides as summarized in Table 3. These findings indicate that vasopressin and TPA control cellular responses in mouse 3T3 cells by a common mechanism.

The effects on the induction of ornithine decarboxylase activity and 2-deoxyglucose uptake suggest that the common step occurs rapidly after TPA and vasopressin interact with the cell, possibly at the level of the cell membrane. There is considerable evidence that the membrane is an important target for the biological actions of TPA[31,35,36]. TPA can rapidly trigger ion fluxes in responsive cells (ref. 35 and our unpublished data) and similar findings have been made with vasopressin[37]. Another rapid and striking effect of TPA on the cell membrane is an alteration in the receptors for ^{125}I-EGF, which results in a profound inhibition of growth factor binding[8,10-12]. Recently we have found that vasopressin induces a potent, reversible and temperature-dependent change in the affinity of cellular receptors for EGF, again suggesting that the biochemical effects of TPA and vasopressin converge at the level of the plasma membrane[47].

Vasopressin and TPA could bind to specific receptors in 3T3 cells because their effects are elicited at low concentrations, are saturable and exhibit remarkable stereospecificity[16,17]. Indeed, specific binding of phorbol dibutyrate (a tumour-promoting phorbol ester) to membrane preparations of chick fibroblast has recently been reported[38] and there is physiological evidence for at least two classes of vasopressin receptors[39]. In theory, the lack of additive or synergistic interactions between saturating concentrations of TPA and vasopressin may result from (1) both agents binding to an identical cellular receptor; (2) both compounds binding to separate sites but interacting with a common effector system, or (3) TPA directly modulating the activity of a coupling protein[40] or an effector system that can interact with vasopressin receptors in those cells which possess such receptors. The lack of apparent chemical analogy between these agents and the fact that in several cell types TPA is mitogenic whereas vasopressin is biologically inactive (presumably because these cells do not express vasopressin receptors) renders the first possibility unlikely. More data are required to distinguish between the second and third alternatives, although it is interesting that TPA uncouples β-adrenergic receptors from adenyl cyclase in mouse epidermis[41,42]. Regardless of the specific details, the recognition that the phorbol ester tumour promoters act at least in part through a specific hormonal pathway is a prerequisite to understanding the mechanism of action of these important molecules.

Is PKS1921−29 a quasar with correlated radio and optical variations?

Gerard Gilmore

Royal Observatory, Blackford Hill, Edinburgh EH9 3HJ, UK

Although many quasars and related objects are variable at both optical and radio frequencies, the relationship, if any, between these variations is unclear. In particular, only three objects, OJ287 (ref. 1), 0235+164 (ref. 2) and 0420−01 (ref. 3), have shown well correlated radio–optical variability. The first two are BL Lac objects and showed little or no time delay between the radio and optical variations. The last object is a quasar, and underwent a radio flare some 2 years after a significant optical outburst. Optical observations of another quasar, PKS1921−29, which may also show correlated radio and optical variability are reported here.

Quasar PKS1921−29 has been monitored since 1975.6 at Mount John University Observatory of the University of Canterbury, New Zealand, as part of a larger quasar patrol programme[4,5]. All 27 observations available were taken with an unfiltered S20R photocathode image intensifier camera (effective $\lambda \approx 550$ nm). The plates were measured on a Becker iris photometer at the Royal Observatory, Edinburgh, and data reduced as described elsewhere[4]. The results are shown in Fig. 1. The object is also visible on two ESO Blue Sky Survey plates (fields 459, 460) and five UK Schmidt Telescope plates (IIIaJ+GG395). Magnitudes for the object and the comparison stars used in the iris photometry were visually estimated on these plates, and are also shown in Fig. 1. The fortuitous presence of the globular cluster NGC6809 near the centre of ESO/SRC Survey field 460 allowed the magnitude scale to be calibrated by comparison with the photometry of Harris[6]. Because of the different bandpasses, however, the possibility of both zero point and scale differences between the two data sets remains, and care should be taken in applying the magnitude scale of Fig. 1 to the Canterbury results.

The significant features of these results are the large flare($\gtrsim$1.5 mag) beginning near 1977.4, lesser amplitude activity in 1978, and the very bright state recorded during the single observation in 1979. By comparison, the object appears both fainter and less active during 1974–77, although few observations are available, and this may simply represent a sampling effect. Additionally, photoelectric observations on 9 May 1980 (UT) (not shown in Fig. 1) showed the object to have returned to near minimum level at $m_B = 16.8$ (P. Brand and C. Impey, personal communication).

Dent and Balonek[7] have recently reported radio flux observations from 1972 to 1980 at four frequencies between 7.9 and 89.6 GHz. These show a steady decline in radio flux from 1972 to 1976, a more rapid increase to 1979.4, and then a very rapid increase continuing at least to 1980.0. Superimposed on these trends are small (±25%) flares near 1975.3 (predominantly seen at 15.5 GHz) and 1977.5 (seen only at 31.4 and 89.6 GHz). Landau *et al.*[8] report 90 GHz data and note a factor of 2 decline in flux in only 2 days in December 1978 (see also ref. 9).

The coincidence of the increasing high frequency variability, and the optical variability may be evidence for a common origin of all activity. The significance of this cannot, however, be evaluated until the frequency of optical flaring, such as that in 1977, is better determined.

The optical burst beginning near 1977.4 is also significant. This may be correlated with the maximum of the high frequency activity (31.4 GHz and 89.6 GHz) reported by Dent and Balonek during 1977. In this case, however, the optical flare began near the maximum of the radio activity, and lasted for a significantly shorter time than the radio flare. Similar behaviour in the BL Lac type object AO0235+164 has recently been reported by Balonek and Dent[10].

Note that two possible identifications for this radio source have been published. Radivich and Kraus[11] suggested a 16.5 mag red star, while Peterson *et al.*[12] give a different identification. The Radivich and Kraus identification has shown no statistically significant variability on any of the plates measured here. The light curve in Fig. 1 refers to the Peterson *et al.* identification, and supports that object as the correct optical counter part to OV236. Final confirmation is provided by optical spectroscopy (ref. 13 and J. G. Bolton, personal communication) which provides a redshift $z = 0.352$ from two lines.

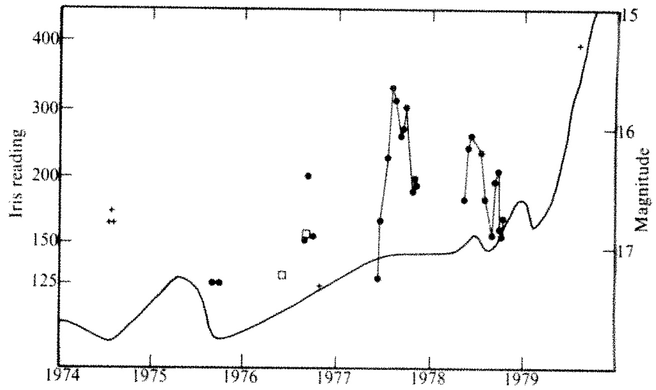

Fig. 1 Optical observations of PKS1921−29 at Mt John University Observatory (●, iris readings scale), on ESO B Survey plates (□) and UK Schmidt Telescope plates (+, magnitude scale). The magnitude scale is not accurately tied to the iris readings scale (see text). Photometric uncertainty is typically ±0.1 mag. The solid line is a smoothed representation of the 15.5 GHz radio data reported by Dent and Balonek[7].

Star formation in a galactic wind

A. C. Fabian, P. E. J. Nulsen & G. C. Stewart

Institute of Astronomy, Madingley Road, Cambridge CB3 OHA, UK

Malin and Carter[1] have discovered giant shells of faint optical emission around several normal elliptical galaxies. We suggest here that these shells are composed of stars formed in shocked galactic wind material. Shocks might arise from relatively gradual increases in wind velocity, or from the collision of the wind with a tenuous intergalactic medium, and need not imply that cataclysmic events have occurred within the galaxy.

The evolution of the stars in an elliptical galaxy should produce a few $M_\odot\,\mathrm{yr}^{-1}$ of gas[2], mostly from giant stars and planetary nebulae. The lack of observable gas in most ellipticals has led to the suggestion[3,4] that the gas produced there is driven out of the galaxy in a wind powered by supernovae. Typical wind velocities are estimated to be several hundred kilometres per second.

The wind expands freely beyond the edge of the galaxy, so that its temperature falls rapidly and the flow becomes highly supersonic. Thus when it passes through a shock of velocity $v_s = 10^7 v_7\ \mathrm{cm\ s^{-1}}$ the gas is heated to a temperature

$$T_s = 1.3\times10^5 v_7^2 \quad \mathrm{K} \qquad (1)$$

The shocked gas is compressed to a density n_e electrons cm^{-3} and cools to $\lesssim 10^4$ K on a time scale

$$t_c = 1.4\times10^3 T^{1.6} n_e^{-1} \quad \mathrm{s} \qquad \text{(ref. 5)}$$

that is

$$t_c = 1.5\times10^8 R_{50}^2 \dot{M}^{-1} v_7^{4.2} \quad \mathrm{yr} \qquad (2)$$

behind a stationary shock at $R_s = 50\ R_{50}$kpc in a (spherical) wind of $\dot{M}M_\odot\ \mathrm{yr}^{-1}$. The pressure of the shocked gas is maintained at

$$n_e T = 8.4 R_{50}^{-2} \dot{M} v_7 \quad \mathrm{cm^{-3}\ K} \qquad (3)$$

by the ram pressure of the wind. The shock is easily confined by a very tenuous intergalactic (or circumgalactic) medium[6] (for example, at a temperature $\sim10^7$ K and density $\sim 8\times10^{-7}\ \mathrm{cm^{-3}}$, which is much less than the closure density of the Universe).

The total power in the wind is only $\sim 3\times10^{39}\ \dot{M}v_7^2\ \mathrm{erg\ s^{-1}}$ and will be converted into optical (mostly line) radiation with an efficiency which decreases with increasing v_7. Thus the cooling gas is unlikely to be visible.

The emission seen by Malin and Carter[1] is easily provided by $\sim 10^8 M_\odot$ of stars, each of $\sim 1 M_\odot$. Star formation can occur in the cooled gas if it is unstable to self-gravitation, that is Jeans unstable. To estimate whether this is possible we identify the likely length and mass scales that occur. The dense cooled gas is supported over lighter and more recently shocked gas against the pull of the galaxy. This situation is subject to the Rayleigh–Taylor instability which causes the shell to break into clouds of size r_c in a time

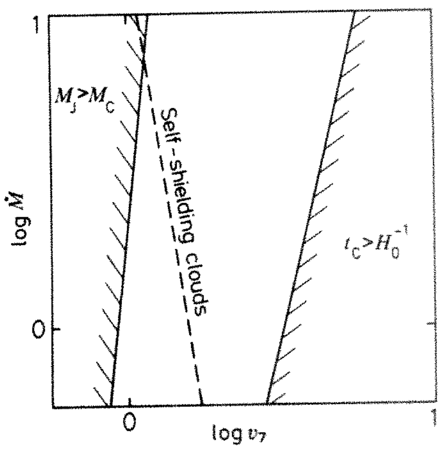

Fig. 1 $\dot{M}$ and v_7 are the mass loss rate and velocity of a galactic wind in $M_\odot\ \mathrm{yr}^{-1}$ and $10^7\ \mathrm{cm\ s^{-1}}$ respectively. Gas behind a shock in a wind at a radial distance of 50 kpc can cool within the age of the Universe provided that $\dot{M}$ and v_7 lie to the left of the rightmost line. The Rayleigh–Taylor instability causes cooled gas to form clouds of mass M_c, which exceed the Jeans mass M_J at 100 K and can thus collapse to form stars, if $\dot{M}$ and v_7 are to the right of the leftmost line. External shielding of quasar ionizing UV radiation is required if stars are to form below the dashed line.

$$t_{\mathrm{RT}} \simeq t_{\mathrm{ff}}(2/\pi)^{3/2}(r_c/R_s)^{1/2} \qquad (4)$$

where the free-fall time into a galaxy of mass $5\times10^{11}\ M\,M_\odot$,

$$t_{\mathrm{ff}} = 2.6\times10^8 R_{50}^{3/2} M^{-1/2}\ yr \qquad (5)$$

This fragmentation cannot proceed before the shocked gas has begun to cool, and leads to the size of a typical cloud forming at t_c being similar to the thickness of the shell of shocked gas (see ref. 7);

$$\begin{aligned}\Delta R &= \tfrac{1}{4} v_s t_c \\ &= 4 R_{50}^2 \dot{M}^{-1} v_7^{5.2} \quad \mathrm{kpc}\end{aligned} \qquad (6)$$

The corresponding cloud mass is then

$$M_c \simeq 1.6\times10^5 R_{50}^4 v_7^{14.6} \dot{M}^{-2} M_\odot \qquad (7)$$

The Jeans mass in neutral gas at a pressure given by equation (3) and a temperature $10^4\ T_4$ K is

$$M_J \simeq 5.0\times10^8 R_{50} \dot{M}^{-1/2} v_7^{-1/2} T_4^2 M_\odot \qquad (8)$$

which is less than M_c provided that the gas can cool still further to $T_4 \sim 10^{-2}$ and that

$$\dot{M} \lesssim 2.2 R_{50}^2 v_7^{10} M_\odot \quad \mathrm{yr}^{-1} \qquad (9)$$

The steep dependence on shock velocity means that gravitational collapse, and we presume star formation, can occur for almost any $\dot{M}$, provided that $v_7 \gtrsim 1$ (see Fig. 1).

An important step in the above process is the cooling of clouds from 10^4 K to $\sim 10^2$ K, so that the Jeans instability can occur. In the absence of any heat source in the clouds, this further drop in temperature can occur by radiative cooling due to the presence of heavy elements in the wind material. The only obvious heat source is ionizing UV radiation from quasars[8,9], which is poorly determined and may be shielded by gas at larger distances than are considered here. If no such external shield is present, the clouds at 10^4 K must shield themselves against the ionizing UV flux, assumed to be $10^4\ \Phi_4$ photons $\text{cm}^{-2}\ \text{s}^{-1}$, where $\Phi_4 \sim 1$ (refs 8, 9). This requires a cloud radius

$$r_{\text{UV}} \geqslant 39\ \Phi_4 R_{50}^4 \dot{M}^{-2} v_7^{-2}\ \text{kpc} \tag{10}$$

and we obtain $r_{\text{UV}} < r_c$ if

$$\dot{M} \geqslant 18 R_{50}^2 v_7^{-6.5} \Phi_4 M_\odot\ \ \text{yr}^{-1} \tag{11}$$

(Fig. 1).

The details of the process of star formation are not well understood. However, there is a substantial range in $\dot{M}$ and v_7 (Fig. 1) for which Jeans unstable clouds can arise. We propose therefore that shells of $\geqslant 10^8\ M_\odot$ of stars can sometimes form from galactic wind material at large distances from elliptical galaxies. The approximate spherical symmetry of the wind will be reflected in the distribution of the stars. To form a thin shell, the star formation must occur on a time scale which is short relative to the free-fall time. Patches of stars may form at several different radii following thermal instabilities in a thick region of shocked gas ($\Delta R \sim R$) or from velocity changes in the wind. These changes could be due to a cooling instability in the core of the galaxy[4], or to more dramatic events such as the accretion of a gas-rich companion or an outburst of the nucleus. Continuous star formation at a fixed radius gives the appearance of a thin shell, as the acceleration of the stars from rest under the influence of the galaxy gives a density profile $\rho_* \propto (R_s/R - 1)^{-1/2}$. Localized bursts of star formation in more peculiar galaxies might lead to small-scale wind shocks. The loop structures seen in Fornax A (NGC1316) could, in part, be due to this mechanism.

Star shells produced at large distances from a parent galaxy may remain roughly spherical for a reasonably long time scale $\sim t_{\text{ff}}$. This will be the approximate age of the component stars. We therefore expect the shells to appear bluer[11] than the parent galaxy (up to ~0.5 mag in $U-B$ and $B-V$) if the initial mass function is similar to that in the solar neighbourhood. Thereafter these high-velocity stars may contribute to the outer galactic envelope. Shocks in denser galactic winds at earlier epochs could have created substantial isothermal stellar envelopes to galaxies.

Volcanic material from Mount St Helens in the stratosphere over Europe

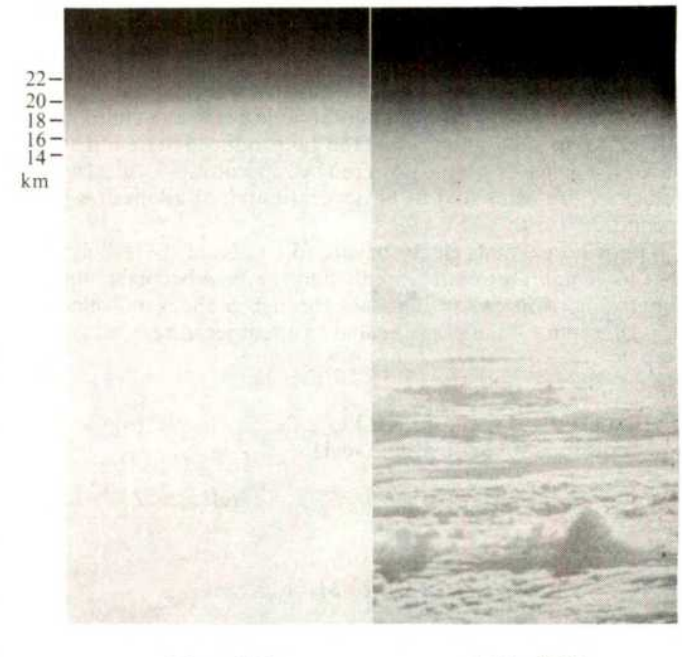
M. Ackerman, C. Lippens & M. Lechevallier*

Institut d'Aéronomie Spatiale de Belgique, 3, Avenue Circulaire,
B-1180 Brussels, Belgium
*E.T.C.A., 16 bis, Avenue Prieur de la Côte d'Or,
F-94114 Arcueil, France

The two most recent balloon flights devoted to studying the stratospheric aerosol vertical structure by comparison with winds, temperature and ozone vertical structures took place on 7 May and on 5 June 1980. At 15.23 h GMT on 18 May Mount St Helens volcano (46 °N, 122 °W) erupted with a tremendous explosion, projecting ash into the stratosphere. An explosion of this size occurs only about once a decade[1]. This sudden introduction of material into the atmosphere offers the opportunity to study air motions both horizontally and vertically. The last such large-scale opportunity was offered by the Mount Fuego eruption which took place in 1974. In this latter case, the enhancement of stratospheric aerosols was observed by means of ground-based lidars and of balloon-borne particle counters. The time development of the aerosol event in 1974 and 1975 has been described elsewhere[2–4]. Mount St Helens material can now also be traced by various satellite-borne instruments. This new stratospheric aerosol event appears to be spectacular. As shown by the photographs discussed here, it leads in its early stage of development to an increase by a factor of three of the Earth limb reflectivity at 15-km altitude after a period of several years of low stratospheric aerosol content.

The new method[5] is based on the photographic observation from balloon altitude of the Earth limb in the azimuthal direction of the Sun at low solar elevation angles. Aerosols are known to scatter light mostly at small angles whereas, comparatively, Rayleigh scattering by air molecules occurs almost evenly at all angles. Our observational geometry favours aerosol detection.

At balloon altitude the camera lenses view the Earth limb below the horizontal line directly and the Sun above it through a neutral optical density ($D \cong 4$) screen which serves several purposes. It avoids penetration of straylight in the optics to obtain clean pictures of the Sun at various elevation angles providing an angular scale. It puts both the Sun and the Earth limb in the sensitive dynamic range of the film calibrated in relative units by means of a step wedge photographed before flight. The solar images provide the absolute scale. The gondola is Sun oriented so that the cameras have the Sun in the middle of the horizontal field of view. Colour (Kodak EPR 475) and black



5 June 1980 7 May 1980

Fig. 1 Photographs of the Earth limb taken with identical exposure settings in the azimuth of the Sun at low solar elevation angles from balloon gondolas on 7 May and on 5 June 1980. The gondolas were at 37- and 35-km altitude respectively. An altitude scale of the grazing line of sight is shown in kilometres. Below the dark blue sky horizontally stratified aerosol layers are revealed by scattered sunlight. In the 5 June case, material from the Mount St Helens volcano has spread in the low stratosphere over a large horizontal extent. It enhances the brightness of the limb so that the cloud cover in the foreground can hardly be seen through the whitish veil. In contrast, the cloud cover is well visible on 7 May. Note that the grazing point at 16-km altitude is some 500 km away from the camera. An altitude difference of 1 km at that altitude corresponds to 7 arc min.

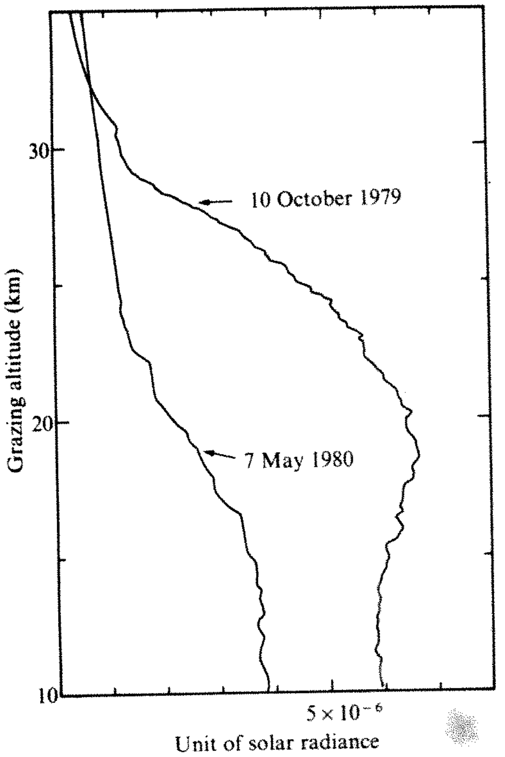


Fig. 2 Earth limb radiance in the azimuth of the Sun versus grazing altitude of the line of sight. The solar elevation angles were respectively 6.18° and 6.94° on 10 October 1979 and on 7 May 1980. The variation of the limb radiance versus altitude is relatively smooth in both cases. As most of the radiance observed is due to scattering by particles, their amount in the low stratosphere appears larger in October than in May where a low aerosol background had been reached. The situation at higher altitudes seems to be reversed. However, these aspects require confirmation from other flights and further interpretation of these raw data where ozone and air absorption should be taken into account. The uncertainties due to difficulties of the photographic photometry have also to be considered.

and white (Kodak Plus X Pan) 70-mm films are used. The results reported here were obtained in the red using Wratten filters nr. 25 set in front of the 80-mm focal length lenses of the Hasselblad EL500 cameras and without filter. The cameras are remotely operated from the ground. The telemetry return signal allows us to check their operation.

Three flights are considered here. The first two took place on the afternoons of 10 October 1979 and 7 May 1980 from Aire sur l'Adour in south-west France. To determine the geographical coordinates as accurately as possible, the tracking was performed by the CNES telemetry station and by radars located at the Centre d'Essais des Landes (Biscarosse). The altitude, longitude and latitude of the gondola at the time that the picture was taken were respectively 37 km, 1° E and 44° N. The third flight took place on 5 June 1980 from the other CNES range in the Alps. Radar tracking was performed in this case from Ile du Levant on the edge of the French Riviera. The coordinates were 35.2 km, 2° E and 44° N.

Inspection of limb pictures such as those shown in Fig. 1 reveals the presence of aerosol layers with a thickness ranging from 100 metres to several kilometres. The latter layers extend horizontally over the whole field of view whereas the thinner layers may have a smaller extension. The black and white photographs are analysed using a Jarrell–Ash densitometer. Grazing altitudes in the stratosphere are determined using the tables of Link and Neuzil[6], taking refraction into account.

The Earth limb radiance is deduced from the densitometric measurements. The radiance vertical profiles observed on 10 October 1979 and on 7 May 1980 in white light are compared in Fig. 2. These profiles are similar showing mostly smooth vertical structure. Figure 3 shows the vertical radiance profiles observed in red light on 7 May and on 5 June 1980. The abrupt radiance increase observed on 5 June between 15- and 16-km altitude is similar to the increase of particle amount observed shortly after the Fuego eruption[2–4]. The very sharp cutoff at the upper boundary of the layer is typical.

On the other hand, satellite-borne instruments have tracked at 16-km altitude material from the volcano crossing the east coast of the US on 23 May and moving towards Europe above the Atlantic Ocean on 27 May (M. P. McCormick, personal communication). The observation reported here is likely to have occurred shortly after the arrival over Europe.

Theory[7,8] predicts that a stratospheric aerosol increase reduces the amount of solar energy reaching the troposphere and the ground. Two main processes are involved: absorption in the aerosol layer and reflection to space of solar energy flux leading to small average temperature decreases in the troposphere[4,9]. The reflectivity data reported here will be augmented by further flights and together with other absorption data will hopefully improve the understanding of the problem and help to evaluate more precisely the possible impact of stratospheric aerosol events.

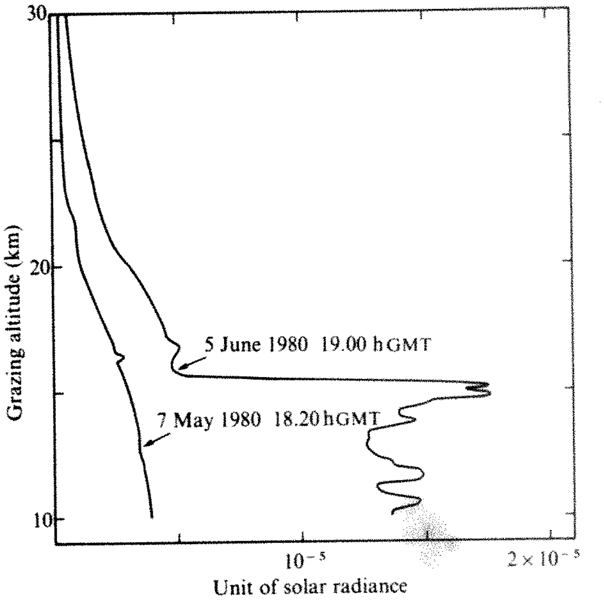

Fig. 3 Earth limb radiance in the azimuth of the Sun and in units of solar radiance versus altitude of the grazing line of sight. The solar elevation angles were respectively 6.94° and 6.26° on 7 May and on 5 June. The large and sharply cut radiance increase between 15.6 and 15.2 km is due to the stratospheric loading of volcanic material. The radiance increase at higher altitudes is thought to be partly due to the illumination increase of the upper levels by the lower levels. The thin layers (some 300-m thick) at some 16.5-km altitude seems to be a frequent feature of the mid-latitude stratosphere and is thought to be related with the height of the tropical tropopause.

We thank the French Centre National d'Etudes Spatiales balloon launching range for launches, tracking and recovery of the gondolas.

Magnetic activity and variations in solar luminosity

E. A. Spiegel

N. O. Weiss*

Harvard-Smithsonian Center for Astrophysics, Cambridge,
Massachusetts 02138

Attempts to detect changes in the solar luminosity suggest that the solar constant has been misnamed[1-4]. Although the Nimbus satellite data[4] show no significant fractional variations above 5×10^{-3} during the period 1975–78, results from recent balloon[5] and rocket[6] flights show changes of 4×10^{-3}. Intense magnetic fields in sunspots hamper convection locally[7] but active regions are believed not to be directly responsible for long term variations in luminosity of the Sun[8] or of RS CVn and BY Dra stars[9]. The cause of luminosity variations over spot cycles should be sought in more deep-seated global features. Here we indicate how strong magnetic fields at the base of the convective zone can alter the local convection. The resulting changes in thermal energy are large enough to produce variations of order 0.1% in the solar luminosity over the 11-yr sunspot cycle.

The magnetic field in the solar envelope is believed to be predominantly toroidal and generated by differential rotation[11,12]. Flux expulsion and magnetic buoyancy[11,12] will quickly sweep toroidal fields from the convective zone. Moreover, the observed large scales of coronal holes and complexes of solar activity point to a confinement of the toroidal field in the lower part of the convective zone[13]. We are led to a model in which the toroidal field is concentrated into a boundary layer at the base of the convective zone where there is relatively little motion. Flux expulsion and topological pumping[11] compress the fields into such a layer, and any flux tubes that stray into the main body of the convective zone will be brought up to the surface by magnetic buoyancy. Such a magnetic layer is deeply implicated in the solar cycle and is accordingly time dependent. We shall explore its influence on convective heat transfer.

Let T be the local temperature and $\bar{T}$ be its average over an equipotential surface, presumed spherical. Then $\bar{T}$ depends only on radius, r, and time. In the mixing-length treatment of stellar convection the heat flux is determined by the gradient of potential temperature,

$$G_p = \partial\bar{T}/\partial r - (\partial\bar{T}/\partial r)_{ad} \tag{1}$$

The adiabatic temperature gradient is given by

$$G_a = (\partial\bar{T}/\partial r)_{ad} = (\partial\bar{T}/\partial\bar{p})_{\bar{S}}\partial\bar{p}/\partial r = (\bar{\rho}C_p)^{-1}\partial\bar{p}/\partial r \tag{2}$$

where $\bar{S}$ is the horizontal average of the specific entropy. The radiative flux is fixed by the mean temperature gradient, $\partial\bar{T}/\partial r$.

From equation (2) and the hydrostatic relation,

$$\partial\bar{p}/\partial r = -g\bar{\rho} + \hat{\mathbf{r}}\cdot[\overline{(\boldsymbol{\nabla}\wedge\mathbf{B})\wedge\mathbf{B}}/(4\pi) - \overline{\boldsymbol{\nabla}\cdot(\rho\mathbf{uu})}] \tag{3}$$

where $\mathbf{u}$ is velocity and $\hat{\mathbf{r}}$ is a unit radial vector, it follows that G_a is directly affected by magnetic fields. Because the field $\mathbf{B}$ is solenoidal,

$$G_a = -g/C_p - (\bar{\rho}C_p)^{-1}\partial[\overline{(B_h^2 - B_v^2)}/(8\pi) - \overline{\rho w^2}]/\partial r \tag{4}$$

where B_h and B_v are the horizontal and vertical components of $\mathbf{B}$, and w is the vertical component of $\mathbf{u}$. In the nether regions of the convective zone $G_p \sim 10^{-6}$ K km^{-1} (ref. 10). The magnetic correction produced by a toroidal field occupying a layer of thickness d is

$$\delta G_a \sim \overline{B^2}/(8\pi\bar{\rho}C_p d) \tag{5}$$

with $\bar{\rho} \sim 0.1$ g cm^{-3} near the bottom of the solar convective zone. To estimate the variation in G_a during the solar cycle that results from the reversal of the toroidal field at sunspot minimum and the subsequent growth of magnetic flux with the approach of sunspot maximum, we need to focus on the magnetic layer that is formed between the radiative and convective zones by flux expulsion.

In standard mixing length theory, the bottom of the convective zone is well defined: motion is assumed to stop at the depth where $G_p = 0$. In reality, fluid slows down as it approaches this depth from above; then it overshoots and goes below it. A sublayer of mild convection forms in the lower part of which the toroidal field develops and whence it intrudes into the stably stratified radiative zone. In this magnetic intrusive region, $\partial B^2/\partial r > 0$. Hence the adiabatic gradient is modified in a way that causes the bottom of the convective zone slowly to recede. This helps stabilize the layer in which magnetic field is building up.

The field grows more rapidly than the stable layers can admit it by diffusion. Flux expulsion drives the magnetic energy density up to values comparable with the kinetic energy density at the base of the convection zone. Hence, in the reclaimed part of the convective zone, fields will grow to values comparable with the equipartition value of 10^4 G. Hydromagnetic convection theory indicates several possible instabilities, both linear and nonlinear, involving magnetic buoyancy. These will be of the 'double diffusive' type, with stable temperature gradient and unstable magnetic gradient. According to the rough criteria available these instabilities occur when d, the thickness of the magnetic layer, approaches the pressure scale height, $H_p \sim 5\times10^4$ km.

Instabilities driven by magnetic buoyancy produce ropes of magnetic flux, which rise up through the convective zone and emerge into the photosphere. As the subconvective fields become unstable, therefore, active regions appear more frequently at the surface and the sunspot cycle approaches a new maximum. The magnetic flux of a field of 10^4 G in a layer whose depth is of the order of H_p should, in this picture, be comparable with the flux that protrudes from the solar surface near sunspot maximum. This conclusion accords with observation[14].

The onset of the instability affects the toroidal field strength and hence modifies the adiabatic gradient. Thus it is accompanied by an increase in the convective intensity in the lower convective zone. We suggest that these changes will give rise to variations in the solar luminosity. To gauge their amounts we may use our estimates of $\overline{B^2}$ and d and find from equation (5) that $\delta G_a \sim 10^{-6}$K km^{-1}, which is comparable with G_p. Other terms of like magnitude also occur in the heat equation, through which G_p has a central role in the theory. None of these terms is included in the usual mixing length theory of stellar convection and their precise relative magnitudes and phases are not known. Moreover, fields of 10^4 G must exert dynamical effects on the motion. From the rate of work done against the Lorentz force we estimate that the potential temperature gradient may increase by as much as

$$\delta G_p \sim \overline{B^2}\,\bar{T}/(4\pi\bar{\rho}gd^2) = [\overline{B^2}/(4\pi\bar{\rho}\mathscr{R}d)](H_p/d) \tag{6}$$

where $\mathscr{R}$ is the gas constant. When $d \sim H_p$ this is comparable with the estimate of δG_a obtained above. Thus the alteration of the adiabatic gradient is one of several competing mechanisms which modify convective transfer through the action of strong magnetic fields arising at the base of the convective zone. These mechanisms have comparable numerical significance and we focus on one to estimate the order of magnitude of the resultant luminosity variation.

The convective zone itself adjusts to mild changes within a few turnover times of the largest eddies, that is months, but the underlying radiative zone requires much longer. In 11 yr thermal diffusion affects only a thin skin at the top of the radiative zone, whose thickness is 1,000 km and whose heat capacity is far smaller than that of the convective zone. Fluctuations in the convective zone do eventually influence a deeper region having a heat capacity comparable with its own, but that process takes

---

0028–0836/80/410616—02$01.00

10^5 yr (refs 15, 16). On the other hand, hydrostatic adjustments of the whole Sun occur within a few hours. We may therefore regard the convective zone as receiving a fixed flux from below, which it modulates during the 11-yr time scale of solar activity.

Whatever the precise dynamical details of such a modulation, its magnitude may be gauged from our estimate of δG_a. While the thermal state of the underlying radiative zone does not change much in the time of interest and the radiative flux from below remains nearly constant, the change in G_a must result in a change in convective flux in the deep convective zone as soon as the instability develops. This will be accompanied by a slight change in temperature at the base of the convective zone of the order of $\delta T \sim \delta G_a d \sim 0.05$K. The thermal energy involved in this change is of magnitude

$$\delta U \sim C_p M_c d\, \delta G_a \qquad (7)$$

where M_c is the mass of the convective zone. For the Sun, $M_c \sim 0.03 M_\odot$ and so $\delta U \sim 10^{39}$ erg. Locally the toroidal field rises from zero at reversal to its peak value in a time τ during which, by equations (5) and (7), the change in magnetic energy is comparable with δU. In the same period, there are slight changes in the Sun's structure, for even adiabatic processes allow exchanges among the potential, thermal and magnetic energy reservoirs.

These fluctuations affect the rate at which convection removes energy and conveys it to the solar surface. Such modifications of the convective flux reach the surface in a few months with consequent changes in the upper transition layer of the convective zone. Here, radiative transfer becomes the dominant heat transport mechanism. The energy carried up by convection is converted into local thermal energy and radiated into space, hence the temperature of this layer must be close to the effective temperature, T_e. We wish to estimate the amplitude of temperature variations in this layer that result from convective changes and to infer the magnitude of concomitant changes in solar luminosity.

Solar models, based on mixing length theory, indicate that the transition layer is quite thin: its depth is about one local scale height and its mass $m \sim 10^{-9} M_\odot$. Its thermal response time, $m C_p T_e/(4L)$, where L is the luminosity, is ~ 5 min. On this time scale this crucial layer adjusts itself to accommodate changes in the rate at which convection carries energy outward. The changes of interest here are of magnitude $\delta U/\tau$, and they are directly reflected in fluctuations in T_e and L. The former are given approximately by

$$\delta T_e \sim \delta U T_e/(4L\tau) \qquad (8)$$

and, for $\tau \sim 6$yr, this yields $\delta T_e \sim 2$K. Then, from equations (6) and (7), we find that

$$\delta L \sim M_c \overline{B^2}/(8\pi\bar{\rho}\tau) \qquad (9)$$

which does not depend on the thickness, d, of the magnetic layer. This gives a luminosity variation, $\delta L \sim 10^{-3} L_\odot$.

As we do not have an independent estimate of the radius variation, we cannot be explicit about the phases of the various changes. These enter through the familiar relation

$$\delta L/L = 4\, \delta T_e/T_e + 2\, \delta R/R \qquad (10)$$

In agreement with our estimates, a change of 0.1% in luminosity requires that $\delta T_e \simeq 1.5$K if R remains constant. The relevant measurements have been discussed elsewhere[17]: the best data indicate that T_e decreases[8] by about 6K from sunspot minimum to sunspot maximum and that R increases[19] by about 0.015% in the same time. These observations together with equation (10) point to the value $\delta L/L \simeq 4 \times 10^{-3}$, which agrees with the above estimate.

Magnetic corrections to G_a and G_p have therefore to be included in studies of variations of solar luminosity over the solar cycle. Although we cannot reliably predict the phases of such variations, application of the viral theorem[20], modified to allow for the fluctuations we are discussing here, suggests that an increase in luminosity accompanies a decrease in solar radius and *a fortiori* an enhancement of effective temperature. Livingston's measurements show a decrease in surface temperature as the sunspot cycle approaches maximum[18]; hence the solar luminosity ought to decrease in the intervals preceding sunspot maxima.

Seasonal variation of oriental sunspot sightings

D. M. Willis & M. G. Easterbrook*

An important, though inexact, index of past solar activity[1–3] is the frequency of unaided-eye sunspot sightings in the Orient[1,3–7]. When the glare of the Sun is reduced by a natural atmospheric filter, a single sunspot or compact group of sunspots located within the central part of the solar disk can be seen with the unaided eye if its area exceeds 0.5‰ of the Sun's visible hemisphere[8]. The oriental sunspot records represent one of the few available sources of solar data before the invention of the telescope[4,5]. The abundance of historical sunspot records from China and Korea must be attributed partly to the regular occurrence of atmospheric conditions suitable for the detection of sunspots[4–6]. Considerably diminished solar brightness, caused by, for example, atmospheric haze, dust storms, severe atmospheric absorption (for example, near sunrise or sunset) or reflection off still waters, is necessary to render sunspots visible to the unaided eye. Indeed, many of the oriental sunspot records explicitly mention reduced solar brightness[6] compatible with these conditions. We discuss here what information the dates of the oriental sunspot sightings provide on past atmospheric conditions in the Orient and hence on past solar activity.

Figure 1 shows the number of sunspot sightings that have been recorded in each month of the year according to a catalogue of pre-telescopic sunspot sightings (139 in all)[6] which is based on an independent search of official oriental dynastic histories. These sightings have been used to obtain the seasonal variation in the occurrence of atmospheric conditions favourable to the detection of sunspots with the unaided eye. Three sightings have been discarded because only the year of the sighting is known; a fourth has been omitted because it is the sole sighting recorded in Japan, where such phenomena seem to have attracted less attention.

The shaded part of the histogram in Fig. 1 shows the distribution of those dates (year, month and day) in the catalogue[6] that are specified without reservation. The unshaded part includes 12 dates for which either the day or month is uncertain; in such cases the most plausible historical date is used. In addition, each of the intervals within which the dates of eight other sightings lie has been contracted (from ~60 to 30 days) after re-examining the historical records. In these latter cases, which also contribute to the unshaded part of the histogram, the median day has been adopted as the date of the sighting. The probability of obtaining the shaded histogram by chance is less than 1 in 25,000, according to the χ^2 test[9] with the theoretically expected frequencies assumed to be proportional to the number of days in the month. If the unshaded part of the histogram is included, this probability is still smaller. Therefore the seasonal variation of oriental sunspot sightings is highly significant statistically and should not be affected appreciably by the sporadic nature of the sightings. A similar seasonal variation exists in the data before (70 sightings) and after (65 sightings) AD 1150, a convenient date that divides the data into two subsets containing approximately the same number of sightings. The seasonal variation also exists separately in the Chinese (103 sightings) and Korean (32 sightings) observations.

Figure 1 presents the composite seasonal variation of sunspot sightings arising from a combination of various atmospheric conditions occurring at different geographical locations. The probable places at which most of the oriental sunspot observations were made are shown in Fig. 2. Despite the diversity of locations, the main features of the seasonal variation can be explained in terms of known characteristics of the general climate of much of East Asia. Thus the marked spring maximum can be ascribed to the fact that dust storms and sand storms ('yellow winds') originating over central China occur most frequently during late winter and early spring, when aridity due to low winter rainfall and increased surface winds associated with cold fronts contribute to their occurrence[10–13]. The source of atmospheric dust and sand is the vast barren land comprising the Takla Makan, Gobi and Ordos Deserts and the Chinese loesslands[12]. Dust and fine sand carried into the lower troposphere by strong winds can be transported down-wind several thousand kilometres[12,13,15]. The resultant haze often obscures the horizon and causes deep red sunsets throughout China as far south as Hong Kong[16]. Airborne dust and fine sand over China and Korea acts as a natural filter that reduces the glare of the Sun, thus allowing fine detail to be perceived on the solar surface. Ho Peng Yoke[15] suggested that such atmospheric dust would produce favourable viewing conditions at sunrise and sunset, thereby making direct observations of the Sun possible. Furthermore, those sunspot sightings for which the oriental records quote a duration of several days[5] mostly occurred during winter or spring, which also supports the suggestion that dust storms produce favourable atmospheric viewing conditions.

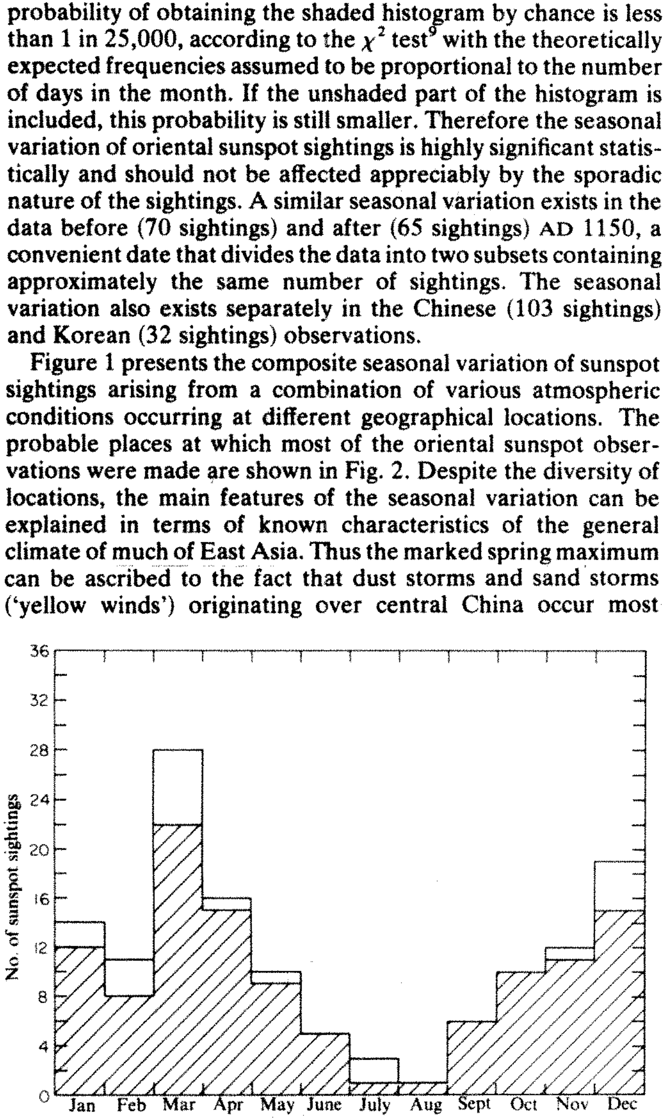

Fig. 1 Number of unaided-eye sunspot sightings recorded in each month of the year according to a catalogue of pre-telescopic sunspot sightings[6]. The date of the first sighting is 28 BC 10 May (Julian calendar) and that of the last sighting is AD 1604 25 October (Gregorian calendar). All dates have been corrected to the Gregorian calendar to allow for the gradual change in the dates of the seasons in the Julian calendar. The shaded part of the histogram refers exclusively to reliable dates, whereas the unshaded part includes dates for which the day or month is uncertain (see text).

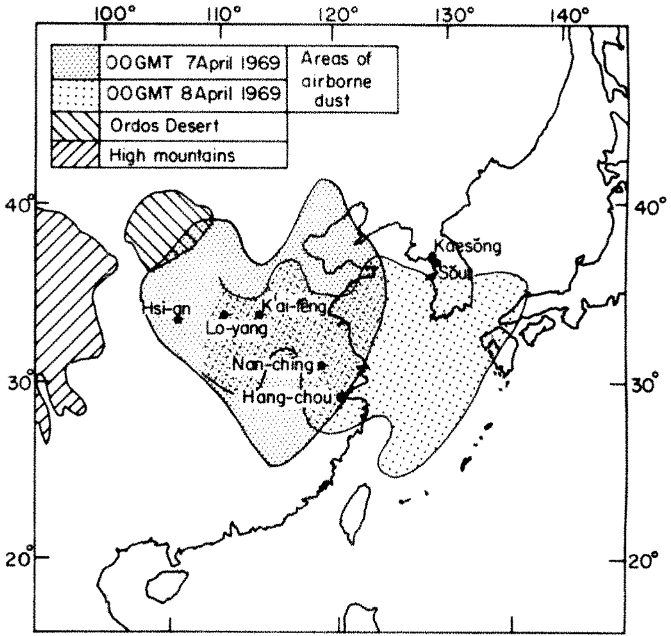

Fig. 2 The sites at which most of the ancient oriental sunspot observations were made. The areas affected by airborne dust or sand on two consecutive days during the large dust storm in April 1969 are shown for comparison. This storm was initiated by the passage of three successive cold fronts over the loesslands and Ordos Desert. The stippled areas define the regions within which meteorological stations reported blowing dust or sand: ESSA 9 satellite photographs confirm the large extent of this dust storm (after Ing[12]).

Colleagues who have travelled extensively in China have noted that a typical dust storm dims the Sun considerably but does not blot it out and may well provide the conditions necessary for observing fine detail on the solar surface with the unaided eye. During a typical dust storm the Sun appears a deep yellow colour. Several oriental sunspot records specifically mention that "the Sun was orange and had no brilliance"[6] and thus it seems likely that atmospheric dust in the lower troposphere was responsible for many of the oriental sunspot sightings.

An optically dense volcanic dust veil in the stratosphere would also dim and redden the Sun[17], but the residence times for such volcanic dust (or 'ash') are too long for the seasonal variation shown in Fig. 1 to be attributed to stratospheric dust. Although long-lived changes in atmospheric viewing conditions, resulting from changing amounts of volcanic dust in the stratosphere, may possibly have contributed to long-term changes in the frequency of oriental sunspot sightings, we show below that transient changes of dust in the lower atmosphere can probably account

Table 1 Number of severe winters per century in China (after Lamb[22]) and the corresponding number of oriental sunspot sightings (from Clark and Stephenson[6])

Century (AD)	6	7	8	9	10	11	12	13	14	15	16	17	Average	s.d.*
Severe winters	19	11	9	19	11	16	24	25	35	10	14	21	17.8	7.7
Sunspot sightings	12	0	0	6†	3	5	32	13	32	1	1	12‡	9.8	11.4

The correlation coefficient, $r = 0.89$, is significant at the 0·1% level§

* Standard deviation.

† The single Japanese sighting (AD 851 22 December, Julian calendar) has been omitted, as in Fig. 1.

‡ As Clark and Stephenson's catalogue[6] is confined to pre-telescopic sunspot sightings (sightings before AD 1611), the entry for the seventeenth century is based on the table presented by Cullen[25], which includes 12 Chinese sightings recorded in standard histories (*cheng shih*). If the 21 Chinese sightings found in local records (*fang chih*) are included, this number becomes 33. The correlation coefficient is then 0.83, but the significance level is unchanged.

§ According to Student's t-test[9]; the correction for autocorrelation is negligible.

for much of the variability in the number of sunspot sightings per century.

As an example, Fig. 2 shows the large area affected by airborne dust and sand for the dust storm generated over central China in early April 1969[12]; ESSA 9 satellite photographs have been combined with surface data from meteorological stations to track and identify the synoptic features of this dust storm. This particular storm was associated with the passage of three successive cold fronts over the loesslands and Ordos Desert. Such a large dust storm can obviously dim the Sun considerably and perhaps create propitious atmospheric conditions for viewing sunspots at all of the ancient observing sites. Smaller dust storms might produce the right atmospheric viewing conditions in more limited geographical regions.

The broad summer minimum shown in Fig. 1 can be attributed to greater cloudiness and precipitation during the rainy season[13]. The number of overcast days is highest in summer in both the Yellow River Basin (Hsi-an, Lo-yang and K'ai-fêng) and the Yangtze Basin (Nan-ching and Hang-chou)[18]; a similar situation prevails at the two observing sites in Korea (Kaesŏng and Sŏul)[19]. This explanation relies mainly on optically thick clouds obscuring the Sun and hence reducing the likelihood of sunspots being detected, particularly at sunrise or sunset, although optically thinner clouds or fog may occasionally favour the detection of sunspots. Heavy summer rainfall also washes dust out of the lower atmosphere, which results in maximum glare from the Sun on clear days. Owing to the greater cloudiness in summer[18,19], however, this 'clear sky' situation occurs on relatively few days per month. The small number of sunspot sightings recorded in July and August (see Fig. 1) can therefore be regarded as a summer base level determined by a combination of greater obscuration of the Sun on cloudy days and greater glare from the Sun on clear days, with the cloudy days outnumbering the clear days. The above discussion indicates that the detection of sunspots with the unaided eye depends sensitively on local atmospheric viewing conditions involving several meteorological variables. There are, however, considerable regional differences in climate within a geographical area as large as that shown in Fig. 2 and further research is required to clarify the seasonal variations of sunspot sightings in different localized regions.

Needham[4] has suggested that the Chinese may have viewed the Sun through pieces of semi-transparent jade, mica or smoky rock crystal. Further, Chu Wên-hsin[20] has described a method of observing solar eclipses and sunspots by looking at the reflection of the Sun in a basin of water blackened with Chinese ink, and very similar methods of observing the reflection of the Sun are actually mentioned in ancient Chinese astrological literature[21]. However, there is no convincing evidence that efficient artificial aids were used to dim the Sun systematically; indeed, from the viewpoint of the ancient observers, the use of such optical aids might negate any astrological predictions. Also, although many more sunspot sightings would have been recorded if an efficient artificial aid had been used, the seasonal variation might then be expected to depend on the duration (hours) of bright sunshine[18,19]. This inference is not substantiated by the seasonal variation shown in Fig. 1.

We conclude that atmospheric viewing conditions complicate the interpretation of the oriental sunspot sightings as an index of past solar activity. In particular, as dust storms in East Asia are associated with the passage of cold fronts over deserts and loesslands, more sunspot sightings should have been noted during cold winters and springs. Most of the oriental sunspot sightings were indeed recorded during those centuries for which the number of severe winters in China was above average[22], as indicated in Table 1; this association seems to be meaningful whatever the cause of the climatic changes in China. As the detection of sunspots with the unaided eye depends significantly on local atmospheric viewing conditions, the number of sunspot sightings in the Orient should not be compared with the severity of winters in geographical areas remote from China (such as Europe). However, if the frequency of the oriental sunspot sightings is still regarded as an approximate measure of past solar activity, rather than just an indicator of favourable atmospheric viewing conditions, the correlation ($r = 0{\cdot}89$) between severe winters and sunspot sightings presented in Table 1 conflicts with Eddy's claim[2] that cold climate coincides with low solar activity. It now seems more likely that the oriental sunspot records provide merely circumstantial evidence for excursions in solar activity[23] and that the radioactive isotope ^{14}C, preserved in the annual growth rings of trees , should be used as the prime guide to past solar activity. Nevertheless, the association between severe winters and sunspot sightings may help to elucidate the discovery in Chinese provincial historical records of six sunspot sightings during the 'Maunder minimum'[24,25], as the seventeenth century was one of the coldest in China[22].

Frequency sensitivity of the deep-sea climatic record

Thomas J. Goreau

Center for Earth and Planetary Physics, Harvard University,
Cambridge, Massachusetts 02138

Attempts to explain quasiperiodic glacial/interglacial transitions[1] in the Pleistocene ^{18}O deep-sea stratigraphic record have focused on spectral analysis of palaeoclimatic data and comparisons with Milankovitch-type calculations of variations in isolation caused by periodicities of the Earth's orbit around the Sun[2–6]. Periods close to those of orbital eccentricity (100 kyr), obliquity (41 kyr), and precession (22 kyr) can be identified in deep-sea cores, but their relative strengths are very different from those of solar insolation and other peaks are also present. Mixing of sediment by deposit-feeding infauna significantly perturbs stratigraphic boundaries in deep-ocean sediments[7]. Although mixing models[8–11] have been proposed to describe quantitative effects of bioturbation no formulation of the effect of this process on the spectrum of the climatic record has been presented. Using the signal processing model[11], the suppression of recorded climatic variation over the past 700 kyr is estimated. In the frequency range where changes in the Earth's orbital path affect incident solar radiation the results support an appreciably larger role for astronomical 'forcing' of climate than previously estimated.

Mixing is treated here as a process which filters input information arriving at the surface of the sediments from the overlying water. The mixing function, operating on the input, is the spatial distribution of an impulse input to the sediment surface after some period of mixing. Mixing proceeds by a series of stochastic events in which organisms overturn, ingest and excrete sediment while in search of food. On a sedimentation time scale huge numbers of such events occur.

The model evaluates the evolution of the profile through numerical solution of equations like:

$$O_\tau(x) = F_\tau(x)\frac{I_\tau}{S_\tau} + \int_0^{L_\tau} F_\tau(x) O_{(\tau-\Delta\tau)}(x - x'')\,\mathrm{d}x''$$

where x is the depth in the core at time τ; x'' a dummy variable; Δt the time integration step; L_τ the maximum mixing depth; S_τ the sedimentation rate; I the input time series; F the spatial mixing function; and O the distribution of the output in the mixing zone. Mixing functions, as shown in Fig. 1, were chosen to simulate the range of bioturbation patterns inferred from stratigraphic, geochemical and benthic ecological studies, as well as functions used in simple models[8,9]. The curves at the left of Fig. 1 show mixing functions of varying concavity and convexity, whereas those at right indicate the output following a long period of continuous mixing and burial following a pulse input. Profiles of deep-sea ash layers[18] and microtektites[19] resemble those of curve 3 (right) with maximum mixing depth of around 10 cm, whereas short-lived radionuclides have profiles peaked at the surface like Fig. 2*b* left, and a similar maximum depth. The impulse response displays transient behaviour until the input has been buried to a depth of ~4*L*, after which change in the shape of the output is negligible. This is convenient as deep downcore the output is a simple convolution integral of the input and asymptotic mixing function response[11], but it requires that treatment of recent inputs such as pollutants, ^{14}C, U–Th series daughter products, and even the last glacial–interglacial transition use the full recursive model. Mixing models lacking 'memory' of previous outputs applied to the glacial meltwater 'spike'[12,13] produce numerically unstable results which 'blow-up' the data (see, for example, ref. 14). The programme for recursive unmixing will be discussed elsewhere.

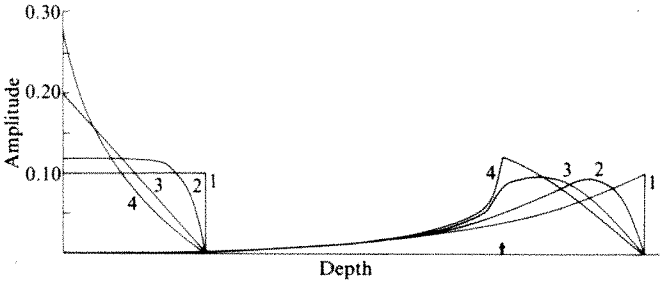

Fig. 1 Impulse response functions for mixing functions with the same maximum mixing depth but differing degrees of convexity and concavity. The curves at left show the 'instantaneous' (on a sedimentation time scale) response to a unit input at the top of the sediment, before burial. The curves at right show the output for unit inputs which have been delivered at the point shown by the arrow and subsequently mixed and buried. The impulse response function changes shape with increasing burial, but approaches asymptotic form after burial to about four mixing depths has occurred: only the initial and final shapes are shown. Amplitude reduction of unit inputs is sensitive to the shape of the mixing function near the surface, but almost insensitive to it after sufficient burial. Phase shifts between output and input are very sensitive to the shape of the mixing function. Deep-sea ash layer stratigraphy[18] and microtektites[19] give profiles of class 3, as do radionuclides such as ^{14}C. The first are deeply buried and the last are near surface inputs. Simulations using ^{14}C profiles show that they do not strongly constrain the shape of the mixing function.

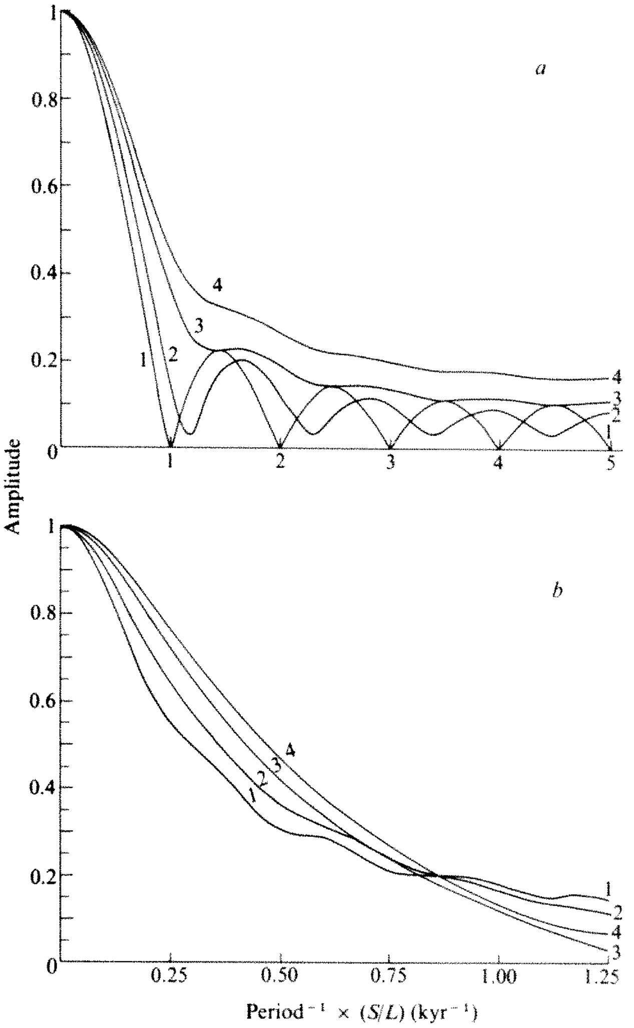

Fig. 2 *a*, The frequency response ('transfer') function for inputs to the surface before burial, calculated from the Fourier transform of the curves at the left of Fig. 1. Using curve 1 as a base for inverse filtering is numerically unstable because of the zeros in the curve. Frequency is scaled by the ratio of the sedimentation rate to the maximum mixing depth; a shape-dependent factor allows transformation to scaling by mean mixing depth, a convenient procedure when dealing with noisy data. *b*, Transfer functions following burial to asymptotic output shape under continuous mixing and burial. The curves of the right of Fig. 1 have been Fourier transformed as in *a* but note that the horizontal scales differ. The frequency band width of the bioturbation low-pass filter is about twice as wide before burial than after it so that high frequencies are somewhat better preserved at the very top of the core.

0028–0836/80/410620—03$01.00

Figure 1 shows the impulse response in the spatial domain. In the frequency domain the mixing transfer function, which indicates the fraction of input at any frequency seen in the output, can be obtained by Fourier transform of the curves of Fig. 1. This has been done by calculating the coefficients of the Fourier Series expansions. Figure 2*a* shows the frequency transfer functions for inputs before burial, and Fig. 2*b* shows the transfer functions of inputs so deeply buried that their transients have relaxed. For an input of known power spectrum, the power spectrum of the output is derived by multiplying the input power spectrum by the square of the transfer function at each frequency[15].

Climatic and other controls on local sedimentation rates introduce a non-linear filter that in the space domain is a measure of the uncertainty in the true age at each depth caused by variable sedimentation. This effect is particularly severe for high frequencies as small shifts in sedimentation alter apparent periodicities and suppress power. Present data on fluctuations of sedimentation rates are inadequate for quantitative treatment, although they limit the reliability of the record.

Curve *c* of Fig. 3 shows the power spectrum of Emiliani's[16] composite ^{18}O chronology for the past 730,000 yr (the late Pleistocene since the Brunhes–Matuyama magnetic reversal) computed from the periodogram determined by FFT[4]. Curve *b* shows the power spectrum of this climate record corrected for mixing by function 3 of Fig. 1 and appropriate values of L and S.

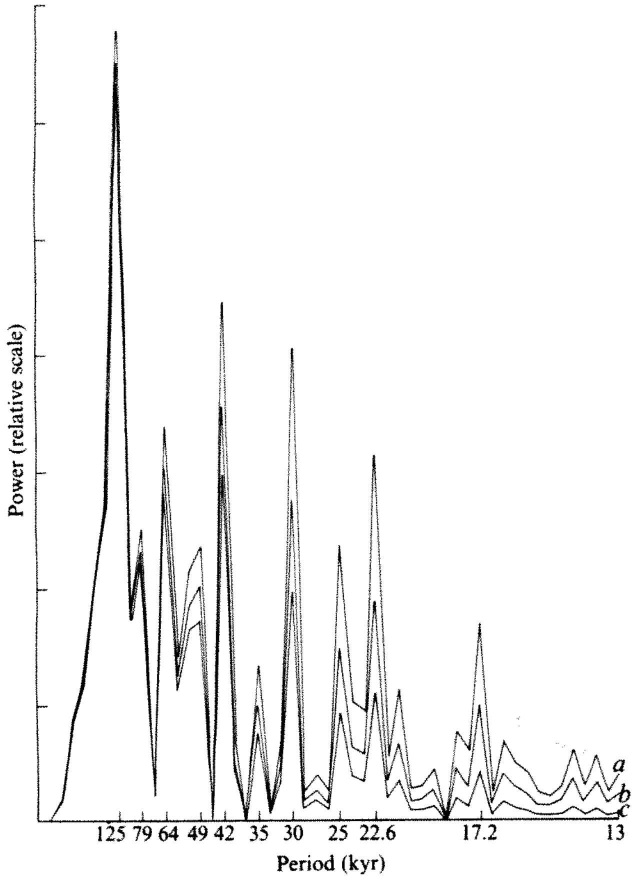

Fig. 3 Periodogram of observed climate variability of Emiliani's composite ^{18}O curve for the past 730 kyr (ref. 16) computed by FFT[4] (curve *c*). Curve *b* is the power spectrum unmixed by curve 3 and curve *a* for unmixing by curve 1 (note that the asymptotic form has been used, thus avoiding the numerical instability caused when the surface response is used to deconvolve the input). Bioturbation decreases the power at the precession frequency by a factor of two or more with respect to the power of the fundamental frequency, dependent on the shape of the mixing function. The non-Milankovitch frequencies at 64, 30, and 17 kyr^{-1} could be odd harmonics of the 125-kyr period produced by non-linear interactions but data are insufficient for statistical tests of this hypothesis without an underlying physical model (C. Wunsch, personal communication). The doublet at around 23 kyr results from splitting of the precession frequency by eccentricity modulation.

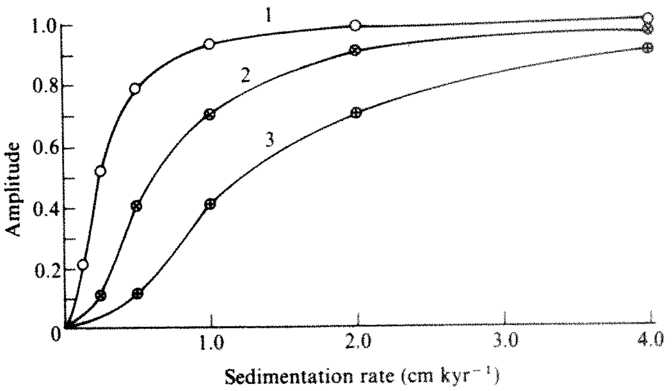

Fig. 4 Signal amplitude reduction at periodicities corresponding to those of the Earth's orbital eccentricity, obliquity, and precession for various sedimentation rates. These were calculated using curve 3 of Fig. 2*b* and S/L of 5 kyr^{-1}, a value consistent with the apparent sedimentation rates and mixing profiles of many deep-sea cores used in palaeoclimatic work. ○, 100 kyr; ⊗, 40 kyr; ⊕, 20 kyr.

Curve *a* shows the spectrum after correction for mixing pattern 1 of Fig. 1. Although such a pattern is atypical of deep-sea ash layers[18], it is similar to that assumed in most mixing models. These calculation suggest that the observed power at frequencies corresponding to orbital precession has been suppressed by a factor of about two. The actual amount may be greater because of possible variability in sedimentation rate. No attempt was made to 'tune-up' the record by making features cohere with expected precession and obliquity peaks as done by some workers without markedly changing the spectra[3,6].

Figure 4 shows the effect of sedimentation rate on amplitude suppression at 20, 40, and 100 kyr periodicities for a mixing curve of type 3 and a mixing depth of 10 cm. Increased depth of mixing shifts the curves to the right (greater attenuation of input), and reduced depth shifts them to the left. Analogous curves for attenuation and phase shift for mixing functions of differing shapes and S/L ratios are readily computed. Events of less than 10-kyr duration (such as the last glacial–interglacial transition) are strongly attenuated in all but very rapidly accreting cores. These results support Erez's suggestion that differences in glacial–interglacial ^{18}O amplitudes observed in cores from different oceans are greater than would be expected from mixing alone and are likely due to dissolution effects[20] or growth rate-dependent biological kinetic isotope fractionation during calcium carbonate deposition[21,22] superimposed on ice-cap volume and local temperature signals.

Energy-balance models have been developed to explain climate changes[23,24]. However, uncertainties in parametrizing atmospheric and oceanic heat transport, cloudiness, precipitation, albedo, and ice-cap growth as functions of insolation highlight the alternative approach: that of extracting as much information as possible from the historical record to estimate empirically climatic responses[3–6,16]. It has recently been suggested[5] that the observed climate spectrum is 'red' (power varying as the inverse square of frequency) in accordance with a climate model in which stochastic forcing at much higher frequency drives the lower frequencies seen in the deep-sea record[25]. When bioturbation is taken into account this interpretation is weakened: the astronomical frequencies explain a larger portion of the observed variance (as the coherence with insolation is proportional to responses at 20 and 40 kyr), and the spectrum is no longer 'red', dropping off as approximately the $-1/2$ power of frequency.

Deriving climate transfer functions for the astronomical theory of climate is made difficult by the narrow bandwidth of the forcing frequencies. At the high frequency end bioturbation limits the response, and at low frequencies it is uncertain whether the 100-kyr period is a sharply peaked or a non-linear response to eccentricity, an artefact of short data length, or generated by another process[3,4,23,24]. A linear climate model would require long response times: crustal rebound time scales[26] are too short, but some highly parameter-sensitive models have generated appropriate time constants for polar ice-cap growth[23,24,27]. The two processes are probably coupled[28]. Whatever mechanisms regulate climate on these time scales, detailed understanding of bioturbation is needed to estimate response time scales to external and endogenous forcing from the deep-sea record. This record contains more information than is apparent once the rules for its encoding are understood. Further work on particulate and chemical tracers of mixing[29–33] is needed to quantify the effects of bioturbation. Recent work on deep-sea ash layer stratigraphy[29,30] will further constrain the mixing function's spatiotemporal patterns in the deep sea and allow improved understanding of climate change.

I thank Cesare Emiliani and Henry Poor for data, discussion and encouragement; Carl Wunsch for stimulating comments; W. F. Ruddiman and W. H. Hutson for constructive suggestions.

Dolomite formation in the seawater–freshwater interface

M. Magaritz & L. Goldenberg

Isotope Department, Weizmann Institute of Science, Rehovot, Israel

U. Kafri & A. Arad

Geological Survey of Israel, Jerusalem, Israel

The 'dolomite problem' long defied solution by geologists largely because it could not be resolved in experiments or by comparative studies with Recent sediments. Most of the known Pleistocene dolomites are from evaporative environments, whereas most of the ancient ones occur in rocks which show no evidence of intertidal or supratidal evaporative conditions. A possible environment for Recent formation of dolomites is the mixing zone between freshwater and seawater. We consider here dolomite formation in the interface mixing zone between freshwater and seawater and suggest that this type of dolomite formation is much more common than was previously indicated.

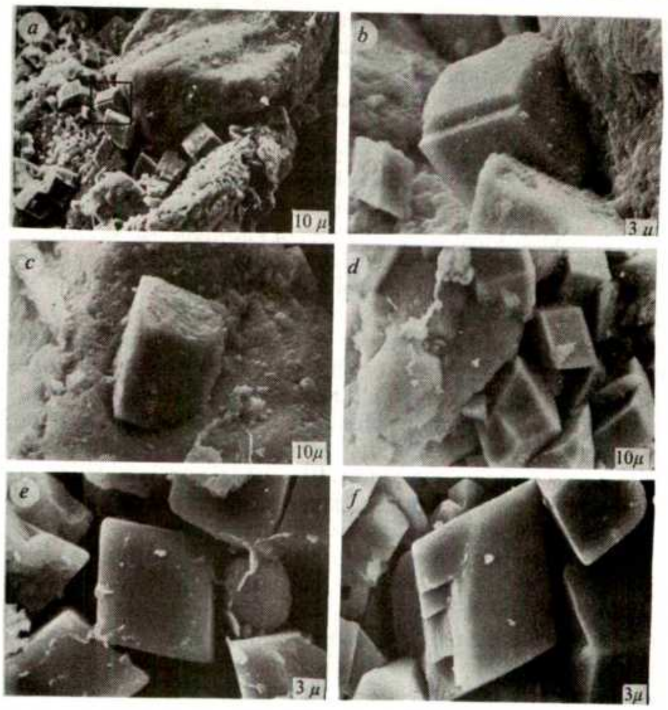

Fig. 1 *a*, Protodolomite rhombs cementing calcareous sandstone. Inset square is enlarged in *b*. *b*, *c*, Protodolomite rhombs attached to the surface of a quartz grain showing euhedral growth into the void. Imperfection of the euhedral form is found at the contact with the quartz grain. *d*, Protodolomite rhombs and calcite scalenohedron attached to bioclasts. Neither crystal shows evidence of replacement. *e*, Protodolomite cement and an unaltered coccolith. *f*, Subhedral protodolomite crystal.

Pleistocene to Recent dolomitization in hypersaline, evaporative environments has been reported by several authors[1–4]. In addition, dolomitization and precipitation of dolomite has been noted from freshwater karst systems[5]. Recent dolomite formation in brackish waters of the mixing zone between freshwater and either hypersaline or seawater has been postulated and described[6–8], particularly from carbonate coastal aquifers of the Caribbean region[8–10].

It seems that the latter phenomenon is more abundant than was previously recognized, little attention having been given to this process taking place in the diffusion zone between freshwater and seawater in coastal aquifers. This is probably partly related to the fact that most wells in coastal aquifers did not penetrate the diffusion zone.

Fortunately, the Mediterranean coastal aquifer of Israel is densely drilled and has been well sampled and documented to depths below the freshwater–seawater interface. This Quaternary coastal aquifer consists mainly of alternating calcareous sandstones (eolianites), claystones and siltstones[11,12]. The eolianites consist mainly of detrital quartz grains, transported from the Nile by longshore currents, together with 10% calcareous skeletal fragments. During exposure to meteoric water the bioclasts were recrystallized to coarse low Mg–calcite and calcitic cement was formed in the vadose zone[13,14].

Two groups of brackish water springs along the Coastal Plain of Israel, in the Zevulun Plain and southern Mt Carmel, were interpreted as mixtures of fresh aquifer water with intruding seawater[15,16]. Carbonate concretions which were precipitated from these brackish waters in the upper soil sequence were found to consist of magnesian calcites and some authigenic dolomite[17]. The ^{14}C age determination of the concretions from the Zevulun Plain was 3,200 ± 1,730 yr BP. (The age determination was carried out on magnesium-bearing calcite nodules which contain some protodolomite in the inner parts. The lack of

0028–0836/80/410622—03$01.00

available material meant that the gas for the counting had to be diluted, a process which increased the uncertainty of the age.)

Dolomite has been found in cores from the central and southern coastal aquifer of Israel, forming at the freshwater–seawater interface. Two horizons of protodolomite were detected in the cores, the upper one coinciding with the diffusion zone of the present-day freshwater–seawater interface and the lower one at a deeper level[18]. Note that the protodolomite occurrences were found only in these two specific horizons and not throughout the sequence.

Protodolomite which forms up to 90% of the total carbonate (sample 3K 108–109) has been studied using scanning electron microscope (SEM) (Fig. 1). Crystal size reaches 50 μm (Fig. 1*c*). Samples with a low protodolomite content are typically composed of smaller (1–15 μm) crystals. Some protodolomite rhombs form a cement around detrital grains (Fig. 1*a*), being attached to the grain at one point and showing euhedral growth into the intergranular void (Fig. 1*b*, *c*). This results in subhedral crystals (Fig. 1*f*). The protodolomite was formed in voids and is not pseudomorphing pre-existing $CaCO_3$. It precipitated directly from the solution and the sources of the Ca^{2+} and part of the CO_3^{2-} could be from dissolution of $CaCO_3$ somewhere in the aquifer. This can be seen in Fig. 1*a*, *b* where unaltered carbonate bioclasts are cemented by protodolomite. The crystals resemble closely the limpid protodolomites reported from schizohaline environments[8,19].

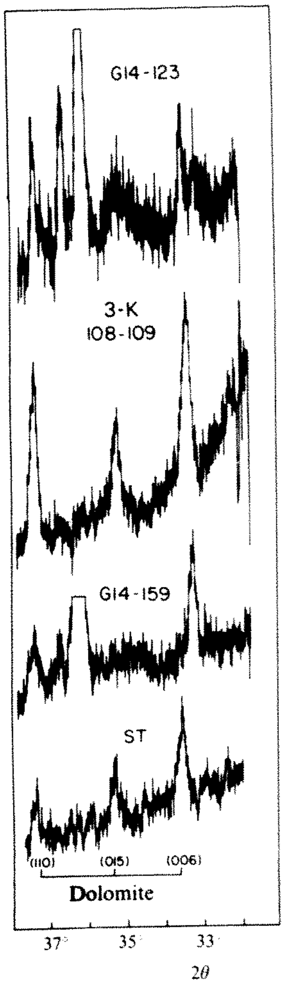

Fig. 2 X-ray diffraction traces showing variation in dolomite reflections in the studied samples compared to a standard ideal dolomite (ST). The ordering (015) reflection is broad and less intense than the non-ordering (110) peak. The 36.2° and 36.7° 2*θ* peaks are those of calcite and quartz.

All $CaMg(CO_3)_2$ minerals discussed here can be defined by X-ray diffraction and EDAX analyses as protodolomites[20]. The outer surfaces of the crystals are deficient with regard to Mg^{2+} compared with ideal dolomites. The EDAX analysis shows a Ca^{2+}/Mg^{2+} ratio between 6 and 7 (peak height) similar to some Florida limpid protodolomites[19], whereas this ratio in a normal dolomite is around 4. In addition, the X-ray diffraction (112) peak is shifted to the lower 2*θ* values typical of protodolomites with excess Ca^{2+}.

The degree of ordering of the protodolomites was determined by measuring the (015) ordering peak height and comparing it to another peak not directly associated with these alternating cation planes[21]. In the samples discussed the (015) ordering peak is either small (sample 3K 108–109) or almost non-existent (sample G 14-159) compared to the (110) non-ordering peak. The basal reflection (006) is slightly shifted compared to standard dolomite (Fig. 2).

The $\delta^{18}O$ and $\delta^{13}C$ values obtained for sample 3K 108–109 are $-1.3 \pm 0.1‰$ (ref. 22) and $-9.6 \pm 0.05‰$ respectively. These are similar to the results from Jamaican protodolomites precipitated from a mixture of seawater and CO_2 oversaturated groundwater[7]. The $\delta^{13}C$ values of these samples are similar to those obtained for the low Mg-calcite cement (−9 to −11‰) formed from meteoric water in the Israel Pleistocene coastal aquifer[14]. The $\delta^{13}C$ values of the dissolved carbonate in the aquifer near the coastline range between −10 and −12‰ and ^{14}C concentration range between 55 and 60 PMC (A. Kaufmann personal communication) indicating a mixed source for the dissolved carbonate (soil CO_2 and carbonate mineral dissolution). The $\delta^{13}C$ values of the protodolomite is −9.6‰ indicating an equilibrium between the protodolomite and the dissolved carbonate in the groundwater. The $\delta^{18}O$ of the protodolomite, however, differs by 4‰ from the calcitic cement. The same difference of 3–4‰ was experimentally obtained and has been attributed previously to isotopic fractionation between calcite and protodolomite[23].

The basic requirement for the dolomite depositing solution is that $[Mg^{2+}]/[Ca^{2+}] > 1$, and this ratio is reached at a chlorinity level[17] of 1,000 mg l^{-1}. As the cementing calcite and the protodolomite of the coastal aquifer discussed here are in isotopic equilibrium (having the same source of CO_3^{2-}) the solution must constitute more than 95% of the fresh groundwater. Dolomite formation is apparently proceeding in the subsurface of the Israeli Coastal Plain in a calcareous sandstone aquifer where the Mg^{2+} is mainly derived from seawater and where an isotopic equilibrium between calcite and protodolomite is reached.

We can now demonstrate that in addition to Recent dolomitization of an evaporative (supratidal) type, a non-evaporative dolomite precipitation is also currently occurring. This process seems to be more widespread than considered before, as it exists in a wide region where the mixing zone between fresh groundwater and intruding seawater occurs. In most of the known coastal aquifers, the contact between the two water bodies does not appear as a sharp interface, but as a wide diffusion zone occupied by brackish waters.

The existence of more than one level of dolomite precipitation in the sequence arises from the fact that the interface is not necessarily stationary. It moves vertically, shrinks and spreads with corresponding eustatic changes of sea level and seasonal fluctuations of the water table. Therefore, dolomites below the present-day interface might indicate 'palaeo-interfaces' or 'palaeo-diffusion zones' which were stationary during certain periods when lower sea levels prevailed, and are in agreement with the Quaternary history of the Mediterranean sea levels.

This continuous process of dolomite precipitation in the diffusion zone is responsible for the reported reduction of $[Mg^{2+}]/[Ca^{2+}]$ ratio[24] and it might also affect the reduction of permeability of some of the coastal aquifers by reducing their pore space.

We thank Dr A. Kaufmann for the ^{14}C age determination and M. Dvorachek and R. Knafo, for the SEM-EDAX analyses, and Dr D. J. J. Kinsman for his helpful comments.

^{243,244}Cm in Columbia River sediments

T. M. Beasley & L. A. Ball

School of Oceanography, Oregon State University,
Marine Science Center, Newport, Oregon 97365

Holm and Persson[1] have described the presence in lichens of ^{244}Cm resulting from the testing of nuclear devices. As the retention of transuranic radionuclides by lichens differs markedly as discussed by the above authors, integrated inventories of ^{244}Cm (mCi km^{-2}) resulting from fallout were not computed, nor were samples earlier than 1961–62 analysed to determine possible curium isotope production during testing in 1952–58. We have now measured ^{243,244}Cm as well as ^{238}Pu, ^{239,240}Pu and ^{241}Am in sediments from the Columbia River which show that (1) ^{243,244}Cm was produced in weapons tests before 1961, and (2) the total ^{243,244}Cm activity produced during testing was 1–3% that of ^{239,240}Pu. Even though the Columbia River received large amounts of radioactivity as a consequence of the operation of plutonium production reactors on the Hanford Reservation[2], we believe that the ^{243,244}Cm reported here is entirely derived from fallout and that our ability to detect these isotopes in river sediment is due to the concentrating effect of erosional processes on land which mobilize material containing ^{243,244}Cm (and other transuranic radionuclides) to the river, where they are subsequently sedimented.

The data presented here were derived from a sediment core raised from McNary Reservoir in August 1977. McNary Reservoir is located approximately 100 km downstream from the Hanford Reservation in Washington State and is formed by waters held by McNary Dam. It represents the first major accumulation site of fine-grained sedimentary material transported by the Columbia River after its confluence with the Snake, Yakima and Walla Walla rivers. On retrieval of the core, the sediment was extruded, sectioned and 0.5 cm trimmed from the outer rim to remove down-trained material. Each section was subsequently weighed, dried, homogenized and an aliquot dissolved in HNO$_3$ and HF. Calibrated amounts of ^{242}Pu and ^{243}Am were added before processing to quantify the recovery of Pu, Am and Cm isotopes. We have determined that our chemical procedures do not fractionate Am from Cm and therefore ^{243}Am can be used as a tracer for Cm isotopes. Our radiochemical procedures have been tested in blind intercalibration exercises[3] with excellent results. Except for the mass spectrometry data discussed below, all activities were determined by α spectrometry using silicon surface barrier detectors. Because the energies of the α particles emitted by ^{243}Cm and ^{244}Cm (5.79 and 5.82 MeV, respectively) are nearly identical, the relative percentages of the two isotopes cannot be distinguished by present-day α-spectrometry techniques. This becomes moderately troublesome where decay corrections are required owing to the different half lives of the two isotopes (^{243}Cm, $t_{1/2} = 28$ yr; ^{244}Cm, $t_{1/2} = 17.9$ yr). Therefore, the data reported here and those of Holm and Persson must be viewed with this constraint.

We will consider in turn our contention that curium isotopes were produced in weapons tests before 1961, that the curium isotopes we measure are derived from fallout rather than from the Hanford reactors and by inference, must be accumulating in environments similar to McNary Reservoir, and finally that by assuming identical mobilization from land for both Pu and Cm isotopes the total amount of curium isotopes deposited globally from weapons testing is 3–10 kCi.

Table 1 lists the activity concentrations of the transuranic radionuclides measured over the core length. The Pu and Am activities represent values at the time of collection; column 5 shows the curium isotope activities at the time of measurement (mid-1979) and column 6 the year represented by the respective sediment horizons. The sedimentation rate at this coring site ($\sim$1.8 cm yr^{-1}) was determined from the position of the ^{239,240}Pu subsurface maximum (identical to the subsurface maximum for ^{137}Cs) and the abrupt change in the ^{238}Pu/^{239,240}Pu ratio at 21 cm indicating the arrival of SNAP-9A ^{238}Pu in the Northern Hemisphere in mid-1966 (ref. 4). Our attempts to describe geochronologies using ^{210}Pb have been unsuccessful in McNary Reservoir because of the rapid sedimentation rates occurring there (2–5 cm yr^{-1}), the varying within-core textural qualities of the sediments, and the low activities of ^{210}Pb present (1–2 d.p.m. per g dry wt). All these conditions preclude the use of ^{210}Pb for establishing reliable sedimentation rates[5].

From the data of Table 1, we conclude that ^{243,244}Cm was produced in devices tested before 1961; unfortunately, low levels of activity present at depths >40 cm in our core prevented us fixing earlier production dates precisely. For the following reasons we do not believe the ^{243,244}Cm we measured in this core was derived from the operation of the various single-pass plutonium production reactors located at the Hanford complex which were in operation in 1944–71. First, from mass spectrometry measurements (T. M. Beasley, L. A. Ball and B. A. Blakesley, unpublished data), we have determined that the mean ^{240}Pu/^{242}Pu ratio observed in several cores raised from McNary Reservoir is 41 ± 9. Krey *et al.*[6] have reported a mean ^{240}Pu/^{242}Pu ratio of 40 ± 10 for global fallout on land. We consider that the agreement between these data sets suggests that release of Pu isotopes with mass numbers greater than 239 from the reactors did not occur and therefore the presence of their decay products (Am isotopes) could not have served as parent isotopes of ^{243,244}Cm through neutron capture and subsequent β decay.

Mass spectrometry results have also shown that approximately 25% of the ^{239,240}Pu radioactivity in McNary Reservoir sediments is reactor-derived. The mean ^{241}Am/^{239,240}Pu ratio from the data of Table 1, when corrected for this contribution, is 0.29. This is only slightly higher than the measured range of 0.22–0.25 characteristic of fallout-derived material as measured in the early to mid-1970s (refs 6, 7). Our values are somewhat higher due to the further decay through 1979 of ^{241}Pu ($t_{1/2} =$ 14.9 yr), the parent isotope of ^{241}Am. As the most probable event leading to direct introduction of ^{243,244}Cm to the river would have been fuel element rupture in the reactors, such events would most certainly have been accompanied by release of Pu isotopes and ^{241}Am. Because no excess ^{240}Pu appears in the sediments and because our ^{241}Am/^{239,240}Pu ratios are very near those of fallout, we think direct release of curium isotopes by the reactors unlikely.

To calculate integrated inventories of transuranics at the coring site (activity per unit area) the activity per g dry wt of sediment and the measured bulk dry density (g cm^{-3}) of each

0028-0836/80/410624—02$01.00

56–57	ND	0.16±0.08	ND	ND	

ND, not detectable. Errors represent 1 s.d. of the measurement determined from propagated counting errors.

section were plotted against depth through the core. The product of the mean activity per g dry wt and the mean bulk dry density over each 2.5 cm of core length was then summed to give the total activity per unit area. Errors through the summation process were propagated by standard techniques (1σ). We calculate integrated inventories of 19.4±0.5, 4.3±0.5 and 0.21±0.07 mCi km^{-2} for ^{239,240}Pu, ^{241}Am and ^{243,244}Cm, respectively, as of May 1979. Subtracting a 25% reactor contribution from the total ^{239,240}Pu activity gives a fallout-integrated inventory for these isotopes of 14.5 mCi km^{-2}, which is seven times the cumulative deposition that has been measured in undisturbed soils at 45° N latitude[8]. We have observed even higher cumulative deposits within the reservoir (>50 mCi km^{-2}), where both sedimentation rate and sediment texture lead to more rapid accumulation of fine-grained material. Clearly, erosional processes have mobilized the transuranic radionuclides from the landscape where they are then sedimented to the reservoir floor. Although the description of such processes is not novel, the degree of enrichment seen here for transuranic radionuclides is, we think, instructive.

Assuming ^{239,240}Pu and ^{243,244}Cm are mobilized by erosional processes to the same degree (a reasonable assumption based on our Am/Pu ratios measured), the amount of ^{243,244}Cm in our core was 1.4% that of the fallout ^{239,240}Pu in May 1979; considering the errors involved with individual inventory estimates, this percentage could be as low as 0.9% or as high as 1.9%. Were all the curium isotope activity due to ^{244}Cm (as was assumed by Holm and Persson for lichen), we calculate a decay-corrected total deposition of ^{244}Cm over the 14–40-cm interval of our core of 0.34±0.12 mCi km^{-2}, a value representing 2.3% of the total ^{239,240}Pu deposited (range 1.5–3.2%). As the half life of ^{243}Cm is significantly longer than that of ^{244}Cm, this latter calculation represents the maximum curium activity which could be present, and therefore we estimate that curium isotope deposition from fallout lies between 1 and 3% that of ^{239,240}Pu. As the ^{239,240}Pu inventory for global fallout has been reported at some 325 kCi (ref. 9), between 3 and 10 kCi of curium isotope activity has resulted from weapons testing.

We acknowledge support for this research from a contract with the Office of Health and Environmental Research, US Department of Energy.

Lower Cretaceous sediment from the East Antarctic continental shelf

Eugene W. Domack*, William W. Fairchild† & John B. Anderson*

* Department of Geology, Rice University, Houston, Texas 77001
† International Biostratigraphers Inc., 5933 Bellaire Blvd, Suite 108, Houston, Texas 77036

Except for a few localities along the Antarctic Peninsula, on Alexander and Livingston Islands (Fig. 1), there are no known outcrops of Cretaceous sedimentary rocks in Antarctica[1]. Thus, little is known concerning the palaeogeography and palaeoclimatology of Antarctica during the Cretaceous period. During Operation Deep Freeze 1979 to the George V–Adelie coast East Antarctica, a 40-cm long piston core, DF 79-38, was recovered which contains abundant palynomorphs of early Cretaceous age. Core 38 is an organic-rich siltstone believed to have been deposited in a non-marine setting. It represents the oldest known sediment recovered from the Antarctic continental margin and the first evidence for Cretaceous strata in East Antarctica. In addition, its exact location and sedimentary characteristics suggest an important correlation with similar sediments from the South Australian continental shelf.

Based on structural considerations, the probable existence of Cretaceous strata in Marie Byrd Land, West Antarctica (Fig. 1), was suggested by geologists of the New Zealand Antarctic Survey of 1958–59 (ref. 2). Cretaceous deposits are widespread on the South Australian continental shelf[3,4] and Kemp[5] discovered 'reworked' Lower Cretaceous palynomorphs in surficial glacial marine sediments collected off the West Ice Shelf, East Antarctica (Fig. 1). From this she suggests the local presence of sedimentary rock sequences of approximate Albian age. Reworked Cretaceous foraminifera have also been reported in Quaternary deposits from Taylor Valley, Transantarctic Mountains[6].

Core 38 penetrated a mono-lithological breccia which contains clasts of grey, organic-rich siltstone. Small flecks of carbonized organic matter and whispy laminations are conspicuous. Clasts are 0.5–4 cm in size and are highly angular. The breccia is clast-supported except for the upper 5 cm which contains a muddy matrix. Core 38 was taken at a depth of 1,407 m along the seaward flank of the George V Basin (67°44′ S, 146°51′ E Fig. 2). Based on available core coverage this unit is probably overlain by a relatively thick section of glacial and glacial marine sediments, some of late Quaternary age[7] (Fig. 2).

Five samples from the depths 8–10, 15–18, 24–29, 30–33, and 37–40 cm in Operation Deep Freeze Core DF 79-38 were processed for palynological study using standard maceration techniques. Each sample yielded abundant palynomorphs, comprising mainly spores with smaller amounts of saccate pollen. No significant differences were noted from top to bottom of the interval studied, suggesting that the entire interval was deposited in a single environment. The absence of marine microplankton (dinoflagellates) in these assemblages indicates deposition in a non-marine environment. Twenty-four species, listed in Table 1, were identified from core 38 samples, but the assemblages are so diverse and well preserved that many additional forms could undoubtedly be recognized with detailed study.

Table 1 Palynomorphs recognized from DF 79-38

Aequitriradites spinulosus (Cookson and Dettmann) Cookson and Dettmann 1961
Alisporites grandis (Cookson) Dettmann 1963
Ceratosporites equalis Cookson and Dettmann 1958
**Cicatricosisporites australiensis* (Cookson) Potonie 1956
Classopollis classoides Pflug emend Pocock and Jansonius 1961
**Crybelosporites stylosus* (?) Dettman 1963
Cyathidites australis Couper 1953
**Cyclosporites hughesi* Cookson and Dettmann 1959
Foraminisporis wonthaggiensis (Cookson and Dettman) Dettmann 1963
Ischyosporites punctatus Cookson and Dettman 1958
Klukisporites scaberis (Cookson and Dettmann) Dettmann 1963
Stoverisporites lunaris (Cookson and Dettmann) Norvick and Burger 1975
Leptolepidites verrucatus Couper 1953
Lycopodiumsporites austroclavatidites (Cookson) Potonie 1956
Lycopodiumsporites circolumenus Cookson and Dettman 1958
Microcachrydites antarcticus Cookson 1947
**Murospora florida* (?) (Balme) Pocock 1961
Cepulina truncata (Cookson) Scultz 1967
Osmundacidites wellmanii Couper 1953
**Pilosisporites notensis* Cookson and Dettmann 1958
Schizoporis parvus Cookson and Dettmann 1959
Schizoporis reticulatus Cookson and Dettmann 1959
?*Trilobosporites trioreticulosis* Cookson and Dettmann 1958, maybe *T. purverulentus* (Verbitskaya) Dettmann 1963
Velosporites triquetrus (Lantz) Dettmann 1963

* The most stratigraphically useful species according to Dettmann and Playford[8].

An extensive review of Cretaceous palynology in Australia was presented by Dettmann and Playford[8]. They recognized four distinct spore–pollen zones as well as two subzones within the early Cretaceous. The oldest, *Crybelosporites stylosus* zone, was considered to be Neocomian; the *Cyclosporites hughesi* subzone as Neocomian to Aptian; the *Crybelosporites striatus* subzone as Aptian; and the youngest, *Coptospora paradoxa* zone, as Aptian to Albian. These zones have since been stratigraphically used in palynological studies in southern and eastern Australia. Most recently, Burger[9] found the zonation scheme of Dettmann and Playford[8] a workable one for Lower Cretaceous sediments of the Surat Basin in East Central Australia. In addition, Burger was able to correlate with faunal evidence and fix the age of his *Osmundacidites dubius* zone as Aptian[9]. Burger equates this zone with the middle and upper part of the *C. hughesi* subzone of Dettmann and Playford[8,9].

Many species identified in core 38 range throughout the Lower Cretaceous in Australia and elsewhere, and are thus of little value for precise age determinations. Five species in Table 1 are considered important stratigraphic indicators by Dettmann and Playford[8], most of these were also recognized by Burger[9]. A single specimen questionably identified as *C. stylosus* was noted in the sample from 37–40 cm. According to Dettmann and Playford this species is restricted to the *C. stylosus* zone, although Burger lists it as ranging up into the *O. dubius* zone[9]. *Murospora florida* and *C. hughesi* are found both in the *C. stylosus* zone and the *C. hughesi* subzone. *Pilosporites notensis* is also present in the *C. hughesi* subzone but ranges up into the *C. striatus* subzone as well. Comparison of the species identified in core 38 samples with those discussed by Dettmann and Playford[8] suggests that the assemblage present correlates fairly well with the *C. hughesi* subzone or the *O. dubius* zone of Burger[9], and that it is of early Cretaceous, Aptian age.

The continental margins of South Australia and East Antarctica, between 90° E and 150° E, represent classic passive-rifted margins[10,12]. The best morphological fit of the two continents before break-up seems to be that of Sproll and Dietz[10]; see also Weissel and others[13]. This fit is consistent with subsequent reconstructions of Australia–Antarctica with New Zealand, the Cambell Plateau, and other continental crust regions of the South-West Pacific margin of Gondwanaland[14]. According to their reconstruction, the continental shelf off the George V Coast, where core 38 was taken, lay directly south of the city of Adelaide and west of the Otway Basin, Australia (Fig. 3). Recent seismic profiling and exploratory drilling on the continental shelf of Australia has revealed a series of east–west trending normal faults[4,15]. Faulting occurred in the latest Cretaceous to earliest Tertiary, was associated with early rifting between the two continents, and produced a horst and graben structure typical of rifted margins[16]. Down-dropped blocks contain up to 2,500 m of Lower Cretaceous age sediments which are fluviatile-lacustrine in origin[15]. Transitional marine to marine sediments do not occur below the uppermost Cretaceous–Lower Tertiary stratigraphic interval, which unconformably overlies the Lower Cretaceous section.

The outer continental margin of East Antarctica, north of the shelf break, contains marginal rift structures similar to those developed along the southern Australian margin[17]. The George V Basin, of maximum depth[18] of 1,591 m, is one of several deep, inner shelf depressions which form a more or less continuous basin parallel to the coast of East Antarctica between 90 and 150° E (ref. 19). This feature is thought to represent a graben structure bounded by faults of Tertiary age[19]. Vanney and Johnson[20], in a more detailed analysis of the orientation of these basins, have also proposed a tectonic origin for these features.

The presence of Lower Cretaceous non-marine strata in the George V Basin implies a sedimentological and tectonic setting similar to that of the South Australian continental shelf during the Cretaceous. However, subsequent sedimentary and palaeoenvironmental conditions of the two regions have differed considerably, particularly with the development of a continental ice sheet on Antarctica, which is generally believed to have originated during the late Oligocene to mid-Miocene[5,21,22]. Unfortunately, early Tertiary sedimentary sequences from Antarctica are as limited as those of the Cretaceous period. With the discovery of early Cretaceous sediments from the East Antarctic continental shelf it seems likely that early Tertiary strata may be found in a similar setting. Future work should concentrate on coring of these marginal basins where a more complete sedimentary sequence may help clarify the palaeoclimatological setting of Antarctica.

This study was funded by NSF grants DPP77-26407 and DPP79-80242, and by grants from the Petroleum Research Foundation, administered by the American Chemical Society (PRF-1101-AC2 and PRF-2472-AC2). We thank officers and crew of the USCGC Glacier who provided the logistics for Operation Deep Freeze 1979, and Dennis Cassidy for help in obtaining samples.

Marine influence in the Triassic 'uplands'

John E. A. Marshall

Department of Geology, The University, Newcastle upon Tyne
NE1 7RU, UK

David I. Whiteside

Department of Geology, The University, Bristol BS8 1TR, UK

Several authors[1–4] have concluded that Mesozoic reptiles found in some fissures of the Bristol area belonged to a distinctive 'upland' fauna. We describe here a new fissure deposit recently found in the Carboniferous limestone near Thornbury which contains characteristic 'upland' reptiles associated with an assemblage of Rhaetian marine phytoplankton and land-derived palynomorphs. The marginal marine location of deposition deduced from the palynomorphs conflicts with the separation of late Triassic reptiles into 'upland' and 'lowland' regimens.

The new fissure is located 16 km north of Bristol in Tytherington quarry (ST 660 890). In 1975, before the level was flooded, several tons of fissure material were recovered and are now held in the University of Bristol.

The fissure material, composed of red and green marls, breccias and conglomerate, contains various terrestrial reptile bones, marine reptile fossils being entirely absent. Archosaur bones, such as those of *Thecodontosaurus*, are disarticulated and often in preferred orientation, but skeletal elements showing little sign of wear are frequently found associated; this suggests that transport has been very limited. Lepidosaur bones (including *Clevosaurus*), a few of which are water worn, occur widely distributed in the sediments. The reptiles include forms often termed as the Triassic 'upland' fauna[1–4] in contrast to the 'lowland' taxa with rhynchosaurs which are absent in the Bristol fissures.

The palynological assemblage was recovered from a grey siltstone. UV fluorescence studies[5] show that the palynomorphs were deposited in organic-rich laminae and have not been introduced in discrete reworked clasts. Furthermore, the assemblage itself is very well preserved. These findings therefore preclude any suggestion that the palynomorphs are derived from a Rhaetian deposit and reworked into the fissure in later times.

The palynomorph-bearing siltstone lies in a small pocket and although it borders an archosaur bone layer it has not itself yielded animal fossils. However, the nature of the enclosing fissure sediments (breccia, conglomerate and detritus-laden marls) and their chaotic bedform suggest a sedimentary episode of short duration. The most likely hypothesis is a cavern roof collapse with restricted pockets of silt forming in the spaces between the fallen rocks where the current flow would have been markedly reduced. In view of this situation and the finding of reptile remains from the same species in the marls enclosing the breccia and siltstone, we conclude that the palynomorphs and reptile bones were deposited penecontemporaneously.

The palynological assemblage (Table 1) has been compared with others of the European Rhaetian[6–8] and unequivocably equates with the *Rhaetipollis gemanicus* zone (phase 3). A comparison with other UK assemblages[9–11] shows that the sporomorph elements and proportions are consistent with a Rhaetian age from the Westbury or possibly lower Cotham Beds. Furthermore, the high percentage of the dinocyst *Rhaetogonyaulax rhaetica* is also consistent with this placing as there is a population acme for this species in the other British Rhaetian outcrops.

A further comparison with local British Rhaetian outcrops shows that the fissure palynomorphs have no distinctive elements which could be ascribed to an ecologically separate

'upland' flora. The presence of acritarchs and dinocysts, well known from the nearby Rhaetian sections, indicate a marine input into the fissure. By analogy with the findings of Wall in some British Jurassic strata[12], the occurrence of the acritarch *Michystridium* sp. (as opposed to *Veryhacium*) suggests a near-shore (brackish?) environment and explains the absence of a stenohaline marine fauna. A morphological typing (Table 2) of the total kerogen shows that nearly half is amorphous organic material. Amorphous organic material is usually considered to have formed diagenetically[13] in marine conditions from algal biopolymers, through a monomer stage to give a condensed geopolymer. The high proportion of amorphous organic material in combination with the consanguineous Rhaetian dinocysts indicate a strong marine component and preclude any suggestion that the marine input was blown into an upland fissure by surface winds.

We postulate that the fissure was partly submerged under the transgressing Rhaetian sea. There is a patch of 'Rhaetic' (probably of the upper Westbury Beds) exposed 1 km south of the quarry and at a present-day altitude of over 20 m above the fossil-bearing cavern. This strengthens the suggestion that the lower fissure levels were flooded by saline waters; these would have brought in the organic-walled phytoplankton and provided the precursors for the formation of the amorphous organic material. At the same time, terrestrial vertebrates living around the entrance of the fissure and land-derived sporomorphs (showing no anomalous 'upland' elements) either fell or were washed into the cavern and were deposited with the marine palynomorphs.

This reconstruction of the environment exposes the anomaly of well preserved late Triassic 'upland' reptiles in a marginal marine deposit. Also, in the past, the difficulty of accurately dating 'upland' reptiles has meant that some 'lowland' taxa used for the comparison may not have been contemporaneous (for example, the last known record of a rhynchosaur is mid-Norian[14] whereas the Tytherington upland reptiles are Rhaetian). In view of these findings we suggest that the loose term 'upland' cannot prudently be applied to distinguish these fissure reptiles from those of other late Triassic sediments.

We thank Bob Savage and Geoffrey Warrington for encouragement and advice, and Mike Curtis for informing us of the find. Useful criticism and comments were also supplied by Keith Allen, Mike Benton, Sue Evans, Bernard Owens, Chris Cornford and Pete Smart. The Universities of Bristol and Newcastle-upon-Tyne and the NERC are thanked for financial aid.

The first fossil cephalopod statoliths to be described from Europe

M.R. Clarke, Linda Maddock & E. Steurbaut

Marine Biological Association, Citadel Hill, Plymouth PL1 2PB, UK
Laboratorium Voor Paleontologie, Institute Gent, Belgium

Statoliths of cephalopods are small, hard calcareous stones which lie within the cartilaginous skulls of octopods, sepioids and teuthoids[1]. Fossil statoliths, clearly belonging to genera which are alive today, have previously been described from 11 Cenozoic deposits spanning from the Eocene to the Pleistocene in North America[2–5]. Such statoliths are of particular interest because they provide a means of studying the evolution of living cephalopod groups which have no calcareous shells, including the cosmopolitan and numerous teuthoids and octopods. Here, the first cephalopod statoliths to be recognized in European deposits are described and identified as *Loligo* sp. They are compared with the North American fossil *Loligo* species and statoliths removed from the two living *Loligo* species of Europe.

Cephalopod statoliths were found in two Burdigalian outcrops of the Southern Aquitanian Basin (early Miocene: age 20–16 Myr). Blue-greyish fine sand was sampled at the hamlets of Paillon, Poyartin (French geological map 1/50.000; XIV–43, Dax: coordinates $x = 342.100$, $y = 158.420$) and Jean Tic, Saubrigues (XIII–43, Saint-Vincent-de-Tyrosse: coordinates $x = 305.550$, $y = 152.050$), and each sample of 750 kg only yielded three statoliths. The deposits occurring at Paillon are considered to be synchronous with the Burdigalian stratotype deposits of northern Aquitaine, whereas those from Jean Tic,

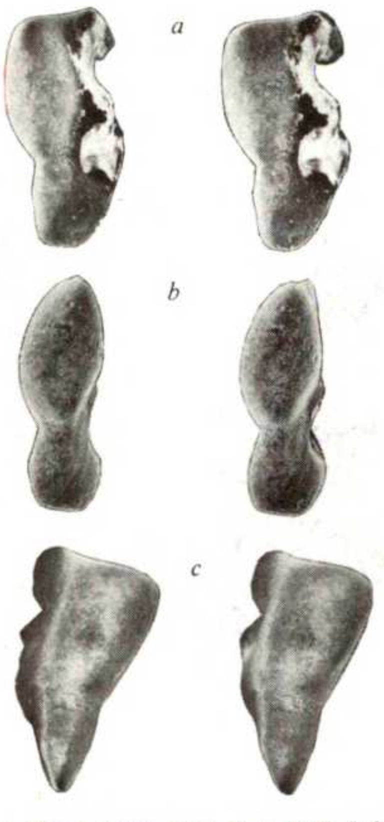

Fig. 1 *a–c*, Three stereo pairs of a fossil *Loligo* statolith (BM(NH) No. C46952) from a Miocene deposit in Europe photographed with a scanning electron microscope. These should be copied and suitably separated for obtaining a three-dimensional effect with a stereo viewer. Length of statolith = 1.75 m.

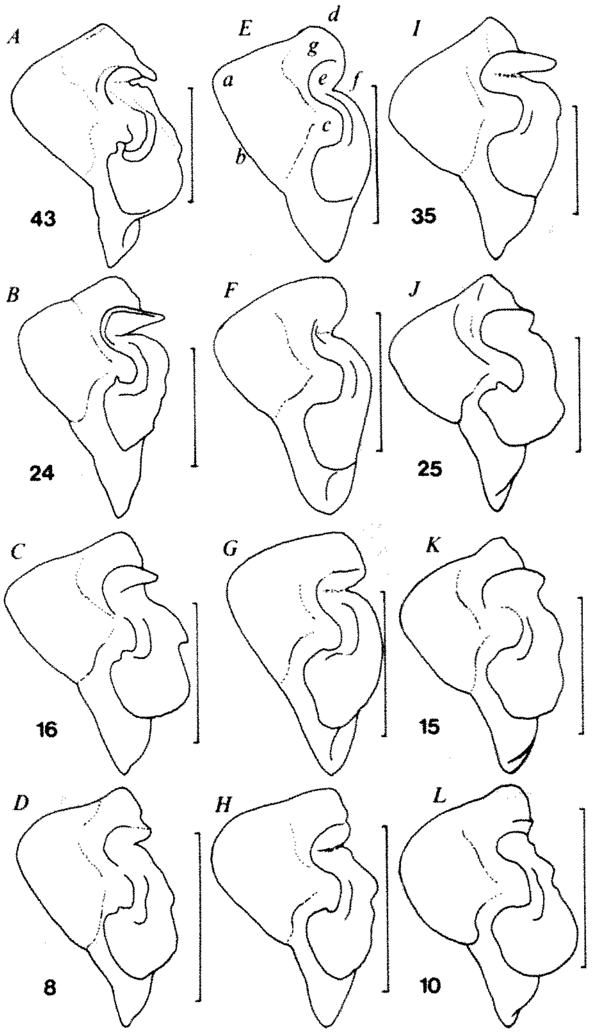

Fig. 2 Anterior views of *Loligo* statoliths. *A–D*, *L. vulgaris*; *E–H*, Miocene fossil statoliths from Europe (BM(NH) Nos. C46953–6). *I–L*, *L. forbesi*. Statoliths are shown as the same length to emphasize variation in form. Scales indicate 1 mm. The dorsal mantle length of the squids from which the statoliths were removed are indicated to the nearest centimetre. Drawings of statoliths *F–H* were reversed because they were the opposite side (left) to the others. Note that *E* and *F* are nearly the same length as *C*, *G* and *K*.

generally known as 'the Marls of Saubrigues', are certainly younger (? Upper or Post Burdigalian) and formed at greater depths[6].

The overall shape of these six statoliths is closely similar to statoliths removed from living *Loligo* species and clearly different from statoliths of cephalopods in other families. In particular, the lateral dome is broadest and rather pointed at its dorsal end (Figs 1, 2*a*), the lateral dome is not divided into superior and inferior lobes (Fig. 2*b*) and is oval from the lateral side and the spur is prominent and almost square (Fig. 2*c*). Other notable features are that the dorsal dome extends dorsally further than the lateral dome (Fig. 2*d*), the dorsal indentation (Fig. 2*e*) is smaller than the ventral indentation being both shorter and narrower, there is a distinct medial fissure (Fig. 2*f*) and the anterior surface of the dorsal dome is flat but not markedly deflected anteriorly (Fig. 2*g*). Although previous work shows that certain of these features distinguish between several *Loligo* species examined elsewhere and statolith shape varies between individuals and with growth (Fig. 2), when these variations are taken into account there are no other obvious features which distinguish between the fossil and the two living species of Europe *Loligo vulgaris* Lamarck 1799 and *Loligo forbesi* Steenstrup 1856. The North American fossil species are more easily distinguished from each other[3].

Comparison of these European fossils with North American fossil species shows that the European are closest in general shape to *Loligo mississippiensis* Clarke & Fitch 1979 from the Lower–Middle Oligocene deposit at Vicksburg, Mississippi[3]. They differ, however, from this species in having a less sharply pointed lateral dome which is more rounded anteriorly and ventro-laterally and has a deeper medial fissure.

To examine the species relationships further, nine dimensions of all the statoliths were used in a multiple discriminant analysis[4]. The measurements were defined previously[1,3,4] and are termed total length (tl), rostral length (rl), lateral dome length (ld), ventro-lateral length (vl), dorso-lateral length (dl), dorsal dome length (dd), dorsal-tip-to-spur length (dts), maximum width (w) and thickness (th). This analysis maximizes the differences between the species on the basis of combining all nine dimensions and extracting axes in decreasing order of importance. Thus, the first and second axes used here account for the greatest proportion of the total variance and give the best separation between the species.

The six European fossil statoliths fall into two size groups of three, corresponding to the two sites from which they were collected, and as the *L. vulgaris* and *L. forbesi* statoliths also both fall into two such size groups the analysis was run with nine groups, six for these three species and three American fossil species. The first two axes extracted accounted for 94% of the total variation between groups and were both significant at $P = 0.001$. All the scores on these two axes were standardized and the means and standard deviations of each of the nine groups are plotted (Fig. 3*A*).

Although there was some variation in the standard deviations between groups, the dispersions of the original variance–covariance matrices were not so different as to invalidate the discriminant analysis. The direction and magnitude of the effect

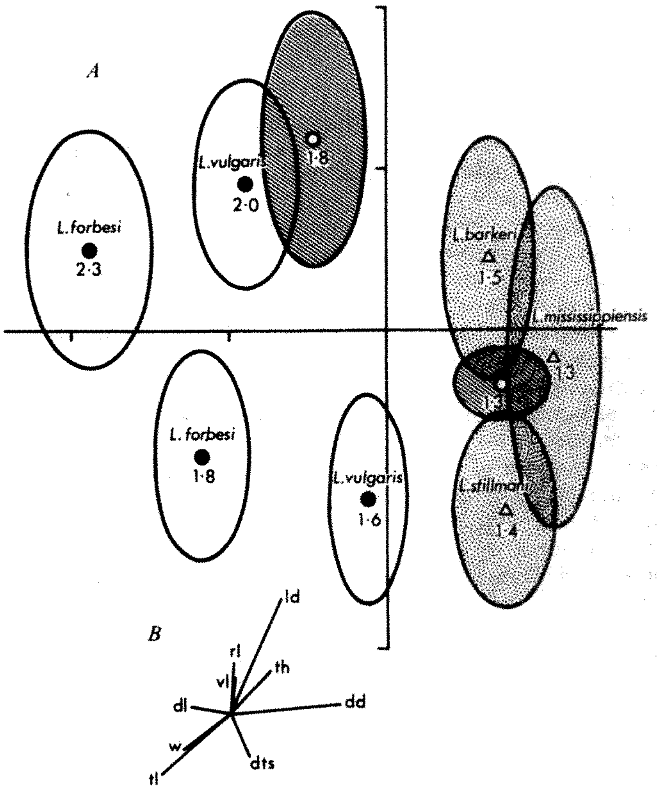

Fig. 3 *A*, Results of the multiple discriminant analysis of statoliths of three North American fossil species (stipled), one European fossil species (hatched) and two European living species of *Loligo*. The mean position of each species (or group) is plotted on the first two discriminant axes, with ellipses representing 1 s.d. for each group on each axis. The mean total length (in mm) of statoliths is given for each group. *B*, The relative weightings of the nine measurements on the axes. The measurements are identified as described in the text.

of each of the nine measurements on the separation of the species on the two axes are shown in Fig. 3*B*.

The spatial relationships between the groups of large and small statoliths of *L. forbesi*, *L. vulgaris* and the European fossil are very similar despite the fact that the fossil statoliths are smallest. This may suggest that the fossil species grew to a smaller adult than the living species. These fossils are approximately the same size as statoliths from *L. forbesi* and *L. vulgaris* individuals, with dorsal mantle lengths of 8.3–15.8 cm (Fig. 2). As the size of statoliths in the Loliginidae is closely correlated with the dorsal mantle length of the animals[5] it is likely that the fossil statoliths came from animals having mantle lengths of approximately 8–16 cm.

When the scores for all individual statoliths were plotted on the first two axes there was no overlap between *L. forbesi* and any of the fossils, whereas the larger *L. vulgaris* overlapped with the larger European fossils. The smaller *L. vulgaris* overlapped with *Loligo barkeri* and *Loligo stillmani* and the smaller European fossils overlapped with all three American fossils.

Thus, although differences between the species are rather too subtle to make identification possible between individual statoliths of *L. forbesi* and *L. vulgaris* or *L. vulgaris* and the large European fossils, discriminant analysis shows that there is a definite trend in form from the American fossils through the European Miocene fossil and *L. vulgaris* to *L. forbesi* (Fig. 3). Although the difference between the two size groups of the European fossil shown in Fig. 3 is probably a function of size, it might indicate a difference in species, because they come from different sites whose fauna show some differences. For example, the fish otoliths assemblage of Paillon, in which the smallest statoliths were found, differs from that of Jean Tic in having no mesopelagic representatives and in having many genera which are restricted today to the Indian Ocean. In addition, the association of Jean Tic contains some typical species recorded only from younger strata (ref. 6 and unpublished data). Such features are due to the difference in depth of deposition, but also reflect slight differences in age.

These data show that *L. vulgaris* or a closely similar species lived in European seas during the early Miocene. These seas were rather shallow (~ 30 m; the deepest parts, the canyon in which the Marls of Saubrigues were deposited, certainly did not exceed 300 m) and the climatic conditions were similar to those on the Atlantic coast of southern Morocco today.

Thus, the form of the statolith has remained virtually unchanged during a period of 20 Myr.

We thank Professors J. Z. Young and D. Donovan for helpful criticism. The fossils are housed in the British Museum (Natural History), London.

Best shape for nature reserves

Margaret Game

Nature Conservancy Council, 19/20 Belgrave Square,
London SW1X 8PY, UK

The ideas of classical island biogeography[1] have been used[2–6] to derive rules for the optimal design strategy for nature reserves. For example, Diamond[3] states that, given limited (financial) resources, it is better to purchase a few large reserves rather than many small ones of equal total area; and that reserves should be as close to one another as possible. The validity of some of these rules has, however, been questioned[7–10]; for example it has recently been shown[9,10] that several small reserves may contain more species than a single one of equivalent area. These rules have nevertheless been accepted uncritically by others, including the IUCN[11]. Here, I examine Diamond's rule[3] that reserves should be as round as possible and conclude that in certain circumstances the optimal shape may be other than circular. There is no *a priori* reason for believing that these circumstances are unrealistic, and I know of no observational evidence to suggest whether they are found in nature or not. I also reason that the rule that reserves should be as close to each other as possible is inconsistent with the statement that they should be circular.

According to the tenets of island biogeography, the number of species inhabiting islands or isolated habitat patches (such as many nature reserves) is governed by the rates of extinction and immigration[1]; when these balance each other on average, the number of species is in equilibrium. If the extinction rate is higher than that of immigration, the island is supersaturated and the number of species will decline or 'relax' towards equilibrium. The rate of relaxation or net loss of species can be reduced by decreasing the rate of extinction or by increasing that of immigration and the purpose of Diamond's rules is to achieve both of these. For example, he states[3] that a large reserve is preferred to a smaller one because, amongst other things, it will have a lower extinction rate; and that reserves should be "as close to each other as possible ... to increase the immigration rates between reserves".

If immigration into nature reserves is indeed an important factor maintaining the total number of species, then it is questionable whether reserves should preferably be circular as this requirement implies the reduction of extinctions without reference to any simultaneous effects on immigration rate. To many dispersing organisms the apparent size of an island, and therefore the probability of colonization, must be more a reflection of the island's linear dimensions perpendicular to the direction of travel, that is the apparent width and height, rather than the area (J. L. Harper, personal communication). Therefore, immigration rate will depend on shape, not just area, whether the organisms are dispersed by voluntary or involuntary means. Thus, whereas departure from circularity may adversely affect extinction rate, this may be ameliorated by an increase in the immigrant population. The optimal shape for a reserve will depend on the balance between these two factors.

To investigate this quantitatively, define the dimensionless parameter R by[12]

$$R = \frac{p}{2(\pi A)^{1/2}}$$

where p is the island perimeter and A its area. R is a simple measure of shape; for any given area A, R may vary from unity for a circular shape to infinity for an infinitely long and narrow one. R is 1.1 for a square and 5.7 for a hedge 100 m long by 1m wide; the greater the departure from circularity, the greater is R.

Assuming that the effects of shape act independently of other influences, such as area and isolation, the average extinction and immigration rates, E and I, may be approximated by[1,4,13]

$$E = SVf(R)$$

$$I = (P - S)Ug(R)$$

where $f(R)$ and $g(R)$ are functions describing the effects of shape on E and I, S is the number of species present on the island at the given time, P is the total number of species in the species pool available for colonization, and V and U express the effects of other factors such as area, isolation, habitat diversity and such. To simplify the analysis, I ask: what value of R maximizes the equilibrium number of species, S_0? An alternative but qualitatively similar question would have been: what

0028–0836/80/410630—03$01.00

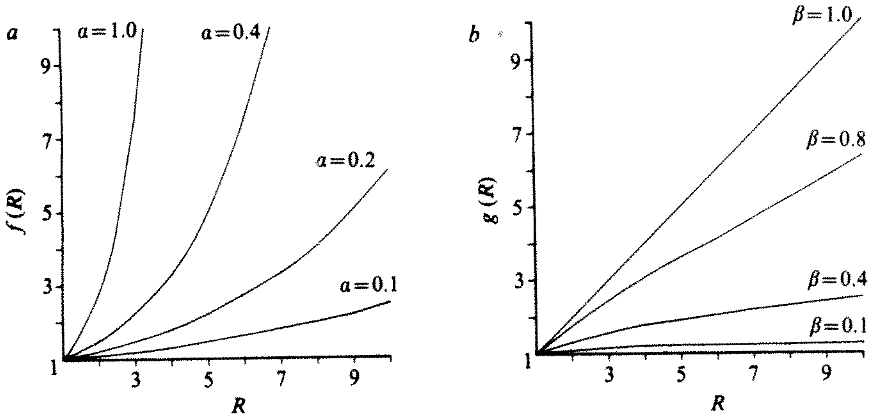

Fig. 1 *a*, Variation of $f(R)=C^{\alpha(R-1)}$ with α. *b*, Variation of $g(R)=R^{\beta}$ with β.

value of R minimizes the net extinction rate, $E-I$? At equilibrium, $I=E$, so that

$$S_0=\frac{PUg(R)}{Vf(R)+Ug(R)}$$

and this is maximum at constant U and V when

$$f(R)\frac{\partial g(R)}{\partial R}=g(R)\frac{\partial f(R)}{\partial R} \qquad (1)$$

I now ask what values $f(R)$ and $g(R)$ may reasonably be expected to take. It might be expected that the influence of shape on E is relatively slight when R is low (nearly circular reserves), but becomes severe at large R so that $f(R)$ would vary with R as shown in Fig. 1*a*. On the other hand, $g(R)$ might rise roughly linearly with R (which is proportional to perimeter length p) or level off towards some asymptotic value, as shown in Fig. 1*b*. Examples of functions with these general shapes, normalized to $f(1)=g(1)=1$, are:

$$f(R)=\exp\left(\alpha(R-1)\right) \text{ with } \alpha\geqslant 0$$

$$g(R)=R^{\beta} \text{ with } 0\leqslant\beta\leqslant 1$$

Substituting these functions in equation (1), the value of R which yields the highest value of S_0 is given by

$$R=\frac{\beta}{\alpha} \qquad (2)$$

(It is easily verified that this represents a maximum rather than minimum in S_0.) As $R\geqslant 1$, equation (2) only has a solution when $\alpha\leqslant\beta$.

The conclusion is: if extinction rate is not too dependent on shape (α is small) but immigration rate has a relatively stronger dependence on shape (β is not small), then the optimal shape for a reserve to maximize the equilibrium number of species is not circular. If these conditions are not met (that is, $\alpha\geqslant\beta$), so that a long boundary length affects the extinction rate more than the immigration rate, then the optimal shape is circular.

The above conclusion does not depend qualitatively on either the exact forms of f and g which were used or the equilibrium state being achieved. In general, if I depends relatively strongly on shape and E relatively weakly at least at low R, then there is no *a priori* reason to believe that a circular reserve will lead to the greatest number of species being conserved. However, this reuslt does depend on immigration contributing significantly to the maintenance of the total number of species.

There are several ways in which reserves may come into existence and this will influence whether immigration or extinction processes predominate. Perhaps the commonest mode of creation is the preservation of a remnant habitat patch while surrounding habitat is removed or degraded. However, reserves have also been created *de novo* by establishing habitats on a site where they had been destroyed or damaged. When existing habitat is being preserved, species extinctions are likely to dominate immigration if the reserve is either heavily supersaturated or has become relatively isolated. Supersaturation may occur through at least two processes. If habitat is destroyed, mobile creatures may concentrate in remaining patches. Alternatively, if the 'area-*per se*' hypothesis is correct[1,14,15] and the number of species increases with area because greater populations of each species cause a decrease in extinction probabilities, then if habitat area is suddenly reduced the site may be supersaturated for a time depending on the rate of relaxation. It is not known whether many reserves in Britain are supersaturated in this sense; Terborgh[2] and Diamond[16] believe that supersaturation occurs on some tropical islands and that it takes thousands of years for the avian fauna to relax to equilibrium, but this time scale is questioned by Abele and Connor[8].

Isolation of suitable habitat affects the ability of species to colonize. Many reserves in Britain are relatively remote from each other, reducing the probability of inter-reserve transfer. However, although species in need of conservation are often sedentary[17–19] this is not the case for migratory animals or for some plants such as orchids and bryophytes (M. O. Hill, personal communication). Therefore there are cases where immigration is an important factor even when long established habitat is involved. Immigration must certainly be of primary significance when new habitat is created. Note that where immigration is not an important factor, there is no need to locate reserves as close to each other as possible because the possibility of inter-reserve transfer of 'desirable' species is slight. Therefore Diamond's rules concerned with reducing mutual isolation of reserves are inconsistent with his statement that reserves should be as circular as possible: the first assumes that immigration is important and the second that it is not.

Finally, reserve shape may also affect other factors not explicitly accounted for in the above analysis. In particular, as J. L. Harper (personal communication) has pointed out, soil diversity and other habitat heterogeneities might be greater in long, linear reserves than in circular ones, and this might increase the number of species.

I thank J. L. Harper and Deborah Rabinowitz for useful discussions.

Habitat selection maintains a deleterious allele in a heterogeneous environment

J. S. Jones & R. F. Probert

Department of Genetics and Biometry, University College London,
4 Stephenson Way, London NW1 2HE, UK

Little is known of how the large amount of genetic variation found in natural populations is maintained. Diversifying natural selection in a heterogeneous environment has great potential for promoting genetic polymorphism[1]. If one allele is favoured in one microhabitat and the alternative allele in another (which may be separated from the first by space or time), the disruptive effects of selection can maintain both alleles in the population. The limiting conditions of niche size, selective intensity and gene flow which could in theory maintain polymorphism in this way have been widely discussed[2,3]. This mechanism is much more effective in promoting genetic diversity if carriers of the alternative alleles are able to select the niche in which their fitness is greatest[4]. Here we explore the properties of a system in which two *Drosophila* eye colour alleles, known to show differences in fitness, are given the opportunity to select different microhabitats in a population cage. It seems that habitat selection in a heterogeneous environment can lead to the maintenance of polymorphism for an allele which is disadvantageous in either habitat when no opportunity for choice is available.

Eye colour mutants in *Drosophila* alter their carriers' response to light[5,6]. Wild-type (red-eyed) flies are in general positively phototactic, but are repelled by very bright light[7]. Flies lacking red screening pigment in the eye are more sensitive to light and tend to choose habitats in which light intensity is lower[8]. Wild-type flies are effectively blind in dim light (which is blocked by their screening pigment) whereas white-eyed flies (which lack this pigment) move towards dim red light as it is within their preferred range of hue and intensity. They avoid the bright white light selected by the wild type. White-eyed *Drosophila melanogaster* are considerably less fit than the wild type in white light, and are rapidly eliminated from polymorphic populations in cages[9].

Drosophila simulans (unlike *D. melanogaster*) mates less well in reduced light[10]. It is therefore possible that, in dim red light, white-eyed *D. simulans* might have a mating advantage over the wild type, as this is within their perceptual range but below that of the wild type. There is thus the opportunity to design a system in which lights of different hue and intensity cause flies of different genotype at the eye colour locus to select, because of their phototactic behaviour, an environment in which they are relatively fit. We describe here an experiment on the role of habitat choice and diversifying selection in a patchy environment on eye colour polymorphism in *D. simulans*.

Experimental populations were founded in cages of volume 8,750 cm^3 each of which was divided into two by a vertical partition having at its upper edge a 20 × 2-mm slit through which flies could pass freely. In the five white light controls, both halves of the cages were illuminated from above by a bright white light produced by three 80-W 'daylight' fluorescent tubes. The light in the five red light controls resulted from the attenuation of this by 10 thicknesses of red filter material to give a dim red light in both sections of the cage. In the five experimental cages, one half was illuminated by the bright white and one half by the dim red light. Each population was founded with 120 homozygous fertilized females from a wild-type strain, and the same number of fertilized female homozygotes from a white-eyed strain. The founding generation of flies was phased in over 3 weeks to reduce later population fluctuations. Cages were kept at 22–25° C and contained 200 ml of cornmeal–agar–molasses medium, one-third of which was replaced each week. Samples were taken by scoring the offspring of four sampling vials introduced to each side of the cage at 3-week intervals.

Figure 1 shows the course of gene frequency change. The frequency of the *w* allele drops rapidly in both white light and red light control cages; by week 30 its mean frequency in the white light controls is 0.01 and in the red light controls 0.06. However, although this allele is deleterious in both environments when no habitat choice is available, in the heterogeneous environment of the experimental cages the polymorphism is maintained for at least 30 weeks; the mean frequency of *w* in the patchy cages after this period is 0.32. Habitat selection (which may lead to an apportionment of resources between flies of different genotype) is maintaining polymorphism for an allele which in a uniform environment is lost from the population.

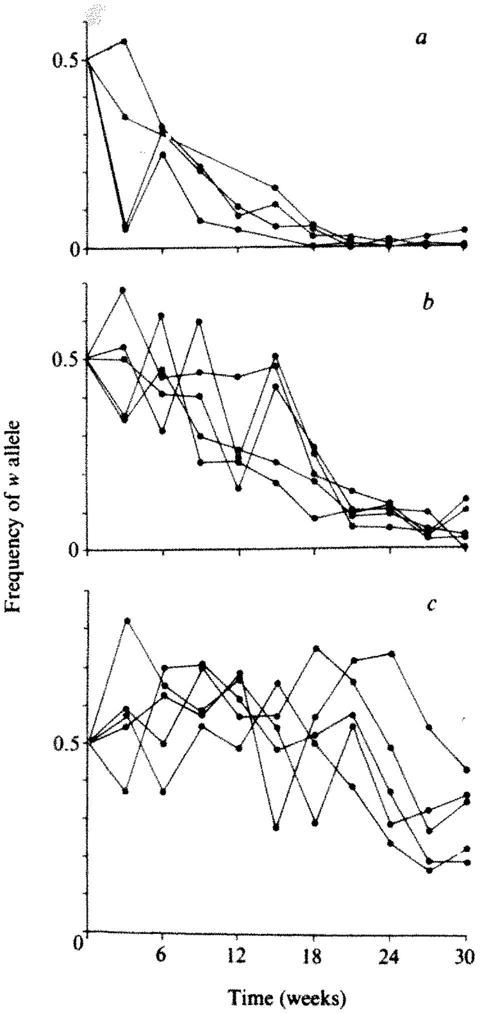

Fig. 1 Changes in the frequency of the *w* allele in *D. simulans* in: *a*, white light controls, *b*, red light controls and *c*, heterogeneous environments. One of the white light controls became extinct early in the experiment. Allele frequencies at this sex-linked locus were estimated using the weighted mean frequency in each sex. Although this does not provide an exact measure of allele frequency (as Hardy–Weinberg conditions do not hold) it is the most efficient estimate available.

0028-0836/80/410632—02$01.00

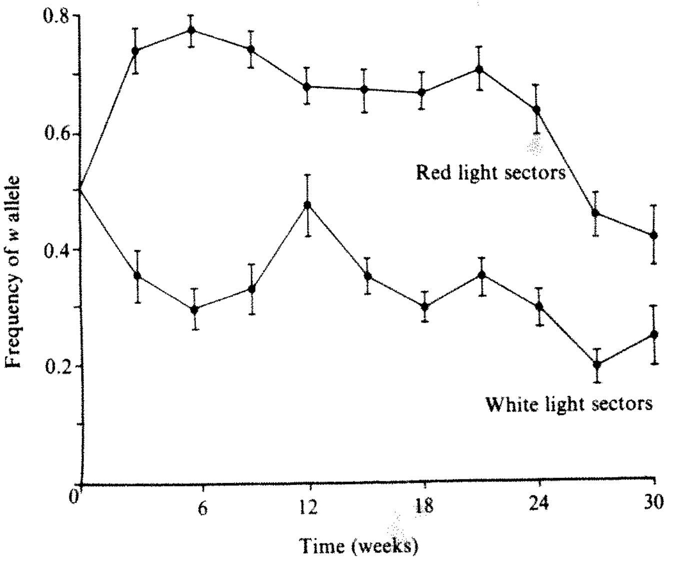

Fig. 2 Divergence in the frequency of the *w* allele between the red light and white light sectors of the experimental cages, summed over all cages.

There is considerable divergence in allele frequency between the two halves of the experimental cages (Fig. 2). To assess gene flow between red and white sectors two movement experiments were carried out. In the first, 12 vials containing *w* larvae were placed in the white light half of an experimental cage, and the same number of vials containing + larvae placed in the red light half. Flies emerged from the vials over the following 7 days and assorted themselves according to their habitat preference. The frequency of each allele among the offspring of the experimental flies was assessed by placing four sampling vials in each sector 1 week later. The frequency of *w* in the flies emerging from the sampling vials was 0.47 in the red light sector and 0.38 in the white light ($x_1^2 = 7.1$; $P < 0.01$). In the second experiment the 12 *w* vials were placed in the red light sector and the 12 + vials in the white light. Their offspring were sampled in the same way as in the first experiment; the frequency of *w* was 0.42 in the red light sector and 0.17 in the white light ($x_1^2 = 31.1$; $P < 0.001$). There is, therefore, the opportunity for substantial habitat selection by each generation between the environmental patches in the experimental cages. This is true whether or not the flies emerge into their preferred microenvironment, and must play a part in maintaining the differences in gene frequency between these patches shown in Fig. 2.

Associations between the extent of genetic polymorphism in natural populations and the ecological diversity of the habitats in which they live have often been reported. Populations of *Drosophila willistoni* living in florally complex environments have more inversion polymorphism than do those from simpler habitats[11] and there may be in some groups of animals a general association between niche breadth and morphological variation[12]. Similarly, *Drosophila* populations exposed to diverse environments in the laboratory retain chromosomal and molecular polymorphism to a greater extent than do those kept in stable conditions[13,14]. Natural and laboratory environments containing a variety of microhabitats offer the opportunity for genotypes to select those which are optimal. Differences in the tendency of individual members of natural populations to select particular microenvironments have indeed been found in *Drosophila*[15,16], and selection of the appropriate niche increases the relative fitness of, for example, melanic moths, cryptically coloured molluscs and lizards, and perhaps also of enzyme polymorphisms in *Asellus* and *Drosophila* exposed to a variety of foods[17–21].

Habitat selection can increase the fitness of an allele which is already advantageous. The experiments described here show that it can also lead to the maintenance of polymorphism for an allele which is otherwise deleterious to its carriers.

Vesicle formation and acetylene reduction activity in *Frankia* sp. CpI1 cultured in defined nutrient media

John D. Tjepkema, William Ormerod & John G. Torrey

Cabot Foundation for Botanical Research, Harvard University, Petersham, Massachusetts 01366

It has been reported that certain species of free-living *Rhizobium* were capable of producing nitrogenase[1–5], thereby demonstrating conclusively that the *nif* genes reside in the bacterial component of the dinitrogen-fixing symbiosis between *Rhizobium* and leguminous host plants. In the comparable dinitrogen-fixing symbiosis between the actinomycete *Frankia* and the actinorhizal woody dicotyledons that serve as nodulated host plants, the endophytic filamentous bacteria have only recently been brought into culture[6–8]. We report here evidence that free-living *Frankia* sp. grown in appropriate nutrient conditions show nitrogenase activity (acetylene reduction) associated with a distinctive morphological structure formed in effective nodules and also developed in culture.

Frankia sp. CpI1 isolated from root nodules of *Comptonia peregrina* and grown in liquid yeast–extract nutrient medium[6] develops as a finely branching filamentous mat that produces enlarged intrahyphal or terminal sporangia of considerable size (up to 60 μm) and complexity containing numerous 1–2-μm diameter spores[9]. During the development of defined synthetic media for the culture of CpI1, it was observed that growth rates and morphological structures of the filamentous bacterium were affected by preparation procedures and chemical components of the medium. A defined medium was developed that elicited sporangium formation and also extensive formation of small spherical to ovoid structures borne terminally on short side branches, which we term vesicles, in agreement with earlier literature. Similar structures have been observed by others[10,11]. Under Nomarski interference phase optics, the vesicles show thickened walls (Figs 1, 2), in contrast to immature developing sporangia. Thus far, they have proved difficult to preserve and section for transmission electron microscopy.

In the yeast-extract medium[8], used for routine subculture, vesicles are not usually observed. Such cultures show no

0028–0836/80/410633—03$01.00

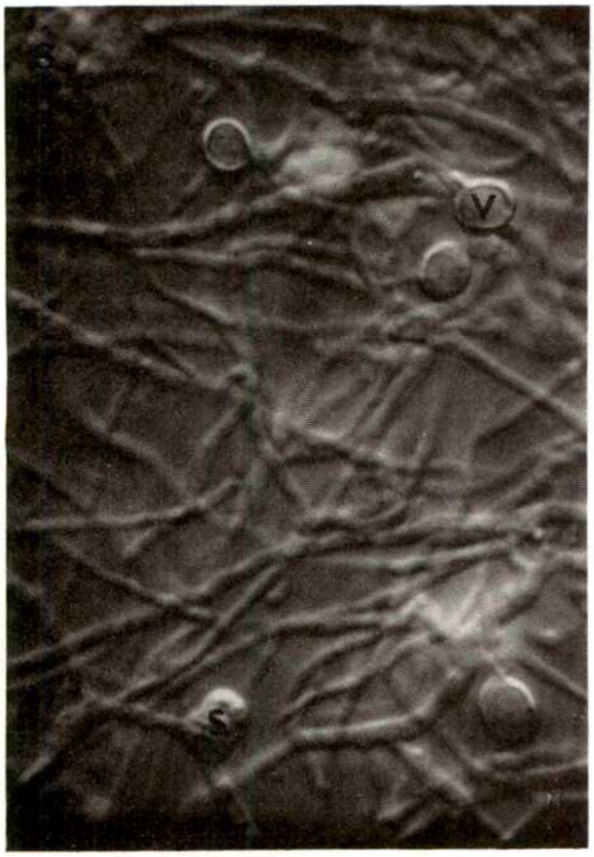

Fig. 1 A 4-week-old culture of *Frankia* sp. CpI1 grown in defined medium photographed with Nomarski phase interference optics. Branched bacterial filaments, enlarged sporangia (S) and a number of thick-walled vesicles (V) are visible. ×2,890.

acetylene reduction activity. The following procedure was used to elicit vesicle formation. The filamentous mat from yeast-extract medium was collected after 4–6 weeks of standing culture in flasks. The mat was homogenized in a Potter–Elvejhem homogenizer and then washed three times with mineral salt solution from the defined medium (see below) and its packed cell volume measured. A sample of known volume was resuspended in mineral salt solution and added to test tubes containing 5 ml of defined medium with the following composition. Mineral salt solution (gm l^{-1}): 1.0 KH_2PO_4, 0.1 $MgSO_4 \cdot 7H_2O$, 0.01 $CaCl_2 \cdot 2H_2O$, 0.01 FeNaEDTA; 1 ml l^{-1} of the following micronutrient stock solution (gm l^{-1}): 2.86 H_3BO_3, 1.81 $MnCl_2 \cdot 2H_2O$, 0.22 $ZnSO_4 \cdot 7H_2O$, 0.08 $CuSO_4 \cdot 5H_2O$, 0.025 $Na_2MoO_4 \cdot 2H_2O$; 1 ml l^{-1} of the following stock solution (mg per 100 ml): 10 thiamine HCl, 50 nicotinic acid, 50 pyridoxine HCl; and 1.2 gm l^{-1} succinic acid, *p*H adjusted to 6.8. Note that the only nitrogen-containing compounds in this medium are EDTA and the vitamins, and that they contain only very small quantities.

Table 1 Time course of nitrogenase activity by *Frankia* sp. CpI1 cultured in defined medium

Time (days)	No. of vesicles per tube ($\times 10^6$)	Acetylene reduction (nmol per tube per day)
0	0	0
5	1.67 ± 0.35	7.3 ± 0.4
7	1.85 ± 0.26	11.9 ± 3.0
14	2.73 ± 0.41	2.9 ± 0.7
	Defined medium plus 100 mg l^{-1} glutamic acid	
7	1.17 ± 0.41	6.6 ± 0.7

Values are ±s.e.m., $n = 5$.

In a typical experiment 0.8 ml packed cell volume of *Frankia* was used to inoculate 100 tubes (an inoculum of 8 μl packed cell volume per tube). Tubes were stoppered with cotton plugs and incubated at 25°C in the dark without agitation. For each sample used in time-course studies, five tubes were sampled for nitrogenase activity, using the acetylene reduction assay[12] with gentle agitation of the tubes. Vesicle counts were made by sonicating the contents of each tube for 30 s at 60 W and then counting in a Petroff-Hausser chamber under phase illumination.

Representative data are given in Table 1 showing the relationship between vesicle formation and acetylene-reducing activity over a culture period of 2 weeks. Cultures at the outset lacked vesicles and showed no acetylene reduction. Vesicle formation was first observed at 5 days and the number of vesicles per tube increased with time. Acetylene reduction occurred only in cultures with vesicles and this activity increased roughly in proportion with the number of vesicles formed between days 5 and 7. Nitrogenase activity decreased at 14 days, even though vesicle numbers continued to increase. The cause of this decrease is not known but may have been due to accumulation of inhibitory substances. The maximum activity recorded in any of these experiments was 44 nmol per tube per day. One experiment was conducted with *Frankia* sp. Ar13 from *Alnus rubra*[7] and this also resulted in vesicle formation and nitrogenase activity.

The nitrogenase activity observed is consistent with that of intact nodules, which is ~10 μmol $C_2H_4\ h^{-1}\ cm^{-3}$ of nodule volume. We estimate that vesicles make up about 1% of nodule volume; assuming that the vesicles are the site of nitrogenase, their activity would be 1,000 μmol $C_2H_4\ h^{-1}\ cm^{-3}$ of vesicle volume. Using a vesicle diameter of 2.5 μm, the highest activity we have observed (Table 2) is equivalent to 180 μmol $h^{-1}\ cm^{-3}$, or 18% of the value estimated for vesicles in nodules. For comparison, we calculate that bacteroids in legume nodules have a nitrogenase activity of ~100 μmol $C_2H_4\ h^{-1}\ cm^{-3}$ of bacteroid volume.

It is very unlikely that the nitrogenase activity of our cultures was due to contaminating organisms as activity was observed only in cultures with vesicles and was correlated with the number of vesicles. Further evidence is the lack of growth when CpI1 is inoculated into Difco nutrient broth, absence of turbidity in all cultures, and lack of growth and nitrogenase activity in anaerobic conditions.

Inoculum density was an important variable not easily controlled because of the difficulty in accurately measuring

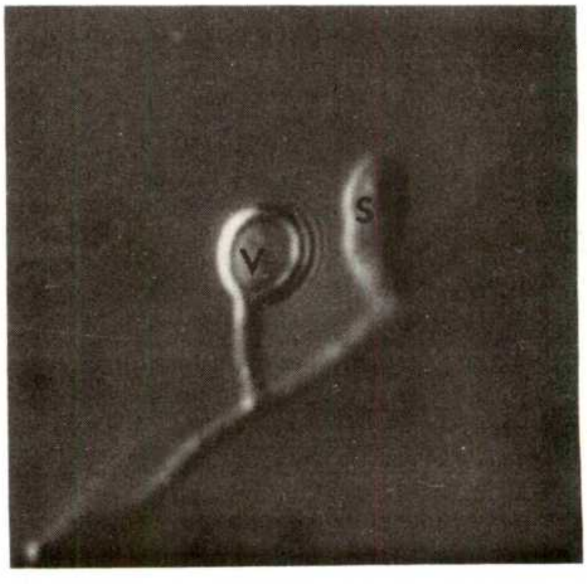

Fig. 2 A young culture of CpI1 showing a bacterial filament with an immature developing sporangium (S) side by side with a mature thick-walled vesicle (V). Nomarski optics. ×4,375.

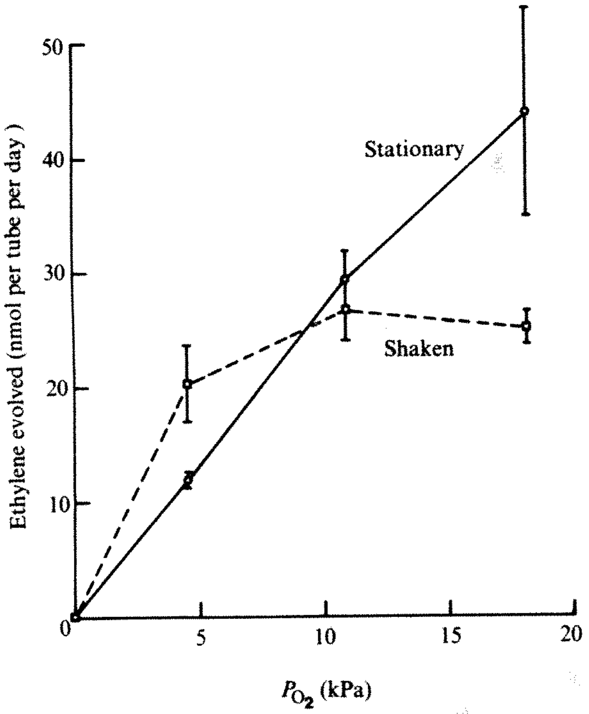

Fig. 3 Acetylene reduction by cultures of *Frankia* as a function of P_{O_2}. One set of tubes was shaken throughout the experiment and the other was stationary. From 0 to 19 days after inoculation, the tubes were incubated in air. They were then gassed with mixtures of air, N_2, and 10% C_2H_2. Vertical bars represent ±s.e.m.; $n = 5$.

actinomycete mass and growth. Positive correlations were found between inoculum density, vesicle number, and acetylene reduction activity (Table 2). Experimental differences in similar tests were probably most often attributable to variation in initial inoculum density.

In several series of experiments we tested the effect of additions of inorganic or organic components to the defined medium on acetylene reduction activity. Cellobiose added at 1% (w/v) completely inhibited vesicle formation and acetylene reduction over a period of 3 weeks. Glutamic acid added at 100 mg l^{-1} reduced the number of vesicles and nitrogenase activity by about half (Table 1). Ammonium chloride (54 mg l^{-1}) completely suppressed vesicle formation and acetylene reducing activity. From the experiments performed to date, medium additions which inhibit acetylene reduction activity do so by suppressing vesicle formation. We have no information to suggest that the ammonium chloride and glutamate inhibited nitrogenase activity *per se*.

Finally, in view of the known instability of the nitrogenase enzyme to molecular oxygen[13], we were interested in studying the effects of P_{O_2} on acetylene reduction activity in cultures of CpI1 in defined medium. As shown in Fig. 3, acetylene reduction by shaken cultures was little affected by the P_{O_2} values examined, while stationary cultures were oxygen limited. Apparently, the enzyme within the vesicle is protected from oxygen in some way, either by special metabolism within the vesicle or by the relative impermeability of the thickened wall. This suggests analogy with heterocyst formation and function in the blue-green algae.

Table 2 Effect of inoculum density on nitrogenase activity by *Frankia* sp. CpI1 cultured in defined medium

Time (days)	Inoculum density (%)	No. of vesicles per tube ($\times 10^6$)	Acetylene reduction (nmol per tube per day)
0	100	0	0
7	100	—	1.4±0.3
14	100	0.95±0.09	25.0±3.1
14	50	0.56±0.04	20.4±3.9
14	25	0.23±0.04	9.1±2.7
14	10	0.05±0.01	1.0±0.7

Values are ±s.e.m., $n = 5$.

These experiments establish several new and interesting facts. They give the first published evidence that free living *Frankia* sp. are capable of nitrogenase activity in appropriate nutrient conditions. The positive correlation between vesicle formation and acetylene reduction activity *in vitro* gives strong support to the already expressed view[8,13–17] that vesicles are the site of nitrogenase activity in actinorhizal plants. Our experiments further show that vesicle formation is elicited or made possible by the physico-chemical conditions which surround the microorganism *in vitro*, a fact which raises interesting questions about the lack of vesicle formation in certain incompatible cross inoculations[16,18]. These observations open up a new approach to the problems of structure and function in these important symbiotic nitrogen fixing relationships.

Complete reversal of antero–posterior polarity in a centrifuged insect embryo

Klaus-Gerhard Rau & Klaus Kalthoff

Department of Zoology, University of Texas at Austin, Austin, Texas 78712

Spatial pattern formation during embryogenesis is ascribed to differential gene expression, which in turn is thought to result in part from interactions of nuclei with cytoplasmic determinants[1]. In the chironomid midge *Smittia*, and probably in other dipterans as well, blastoderm cells seem to make an early decision as to whether they contribute to cephalic and thoracic or to abdominal (and possibly thoracic) structures[2]. Inactivation or translocation of cytoplasmic components involved in this antero–posterior decision could conceivably lead to duplications of head and thorax, or abdomen, or to complete but inverted embryos forming the head posteriorly and the abdomen anteriorly in the egg. Whereas the former two malformations have been described[3,4], completely inverted embryos are reported for the first time, to our knowledge, in this letter. Reversal of partial germ bands has previously been observed following combined ligation and cytoplasmic translocation in eggs of the leaf hopper, *Euscelis plebejus*[5].

0028-0836/80/410635—03$01.00

Smittia eggs were centrifuged during early intravitelline cleavage (stage P_2, two pole cells) for 20 min at 6,700*g* and 20 °C. During centrifugation, eggs were lined up, with their posterior poles pointing in the direction of the centrifugal force, in a tightly fitting groove between microscope cover slips[4]. Eggs recovered from the centrifuge were screened for proper stratification as shown in Fig. 1*i*; obliquely stratified eggs were removed. Out of 6,206 centrifuged eggs, 3,140 survived and formed analysable germ bands. Among these, we found 1,713 normal embryos (Fig. 1*d*, *f*), 1,341 double cephalons (Fig. 1*a*), 55 double abdomens (Fig. 1*b*) and 31 inverted embryos (Fig. 1*c*, *e*). As controls, 581 embryos were centrifuged with their anterior poles pointing in the direction of the centrifugal force. All of the 333 survivors developed into normal embryos. In similar experiments using higher centrifugal forces, centrifugation with the anterior pole pointing in the direction of the centrifugal force resulted in low yields of double cephalons and double abdomens[4].

Inverted embryos were identified using the following criteria: (1) the contour of the chorion (egg shell) is more pointed at the posterior and more blunted at the anterior pole (Fig. 1*a*–*f* and *i*); (2) the micropyle at the anterior pole is visible as a small but distinct dark area in transmitted light under the compound microscope (Fig. 1). With Nomarski optics, the micropyle region shows a bright blue coloration, depending on the position of the second Wollaston prism, and the angle between the polarisator plane and the plane tangential to the anterior pole of the embryo. Variation of this angle leads to appearance and disappearance of the blue colour in the micropyle every 90°; and (3) the stratification of yolk components in centrifuged embryos is maintained until after germ anlage formation; the gray and opaque proteid spheres accumulated centrifugally are easily distinguished from the lipid droplets in the centripetal region which have a brownish hue. In embryos of normal orientation, the head lobes formed in the lipid-containing region, while the 'Schwanzwulst' (posterior end of germ anlage) originated in the proteid-containing region (Fig. 1*f*). Conversely, the inverted embryos developed with their head lobes in the proteid and the Schwanzwulst in the lipid region (Fig. 1*e*). Application of criteria 1–3 led in no case to contradictory conclusions.

It is important to realize that the polarity inversions did not result from turning of the entire embryos inside their egg shells. This possibility is excluded by criterion (3) which indicates the orientation of the embryo relative to the yolk-rich endoplasm. The development of inverted embryos was also observed, in eleven cases, from the very beginning of germ anlage formation. The ensuing formation of amnion and serosa, embryonic rotations, germ band extension and contraction, dorsal closure, and spiralization of inverted embryos appeared normal or nearly so. More than half of the inverted embryos hatched and showed normal larval movements.

A hypothesis to explain the formation of four different segment patterns (normal embryos, double cephalons, double abdomens, and inverted embryos) after centrifugation is shown diagrammatically in Fig. 2. The hypothesis builds on a model developed earlier[6], according to which the potential for abdomen formation (p, p′) is present not only in the posterior but also

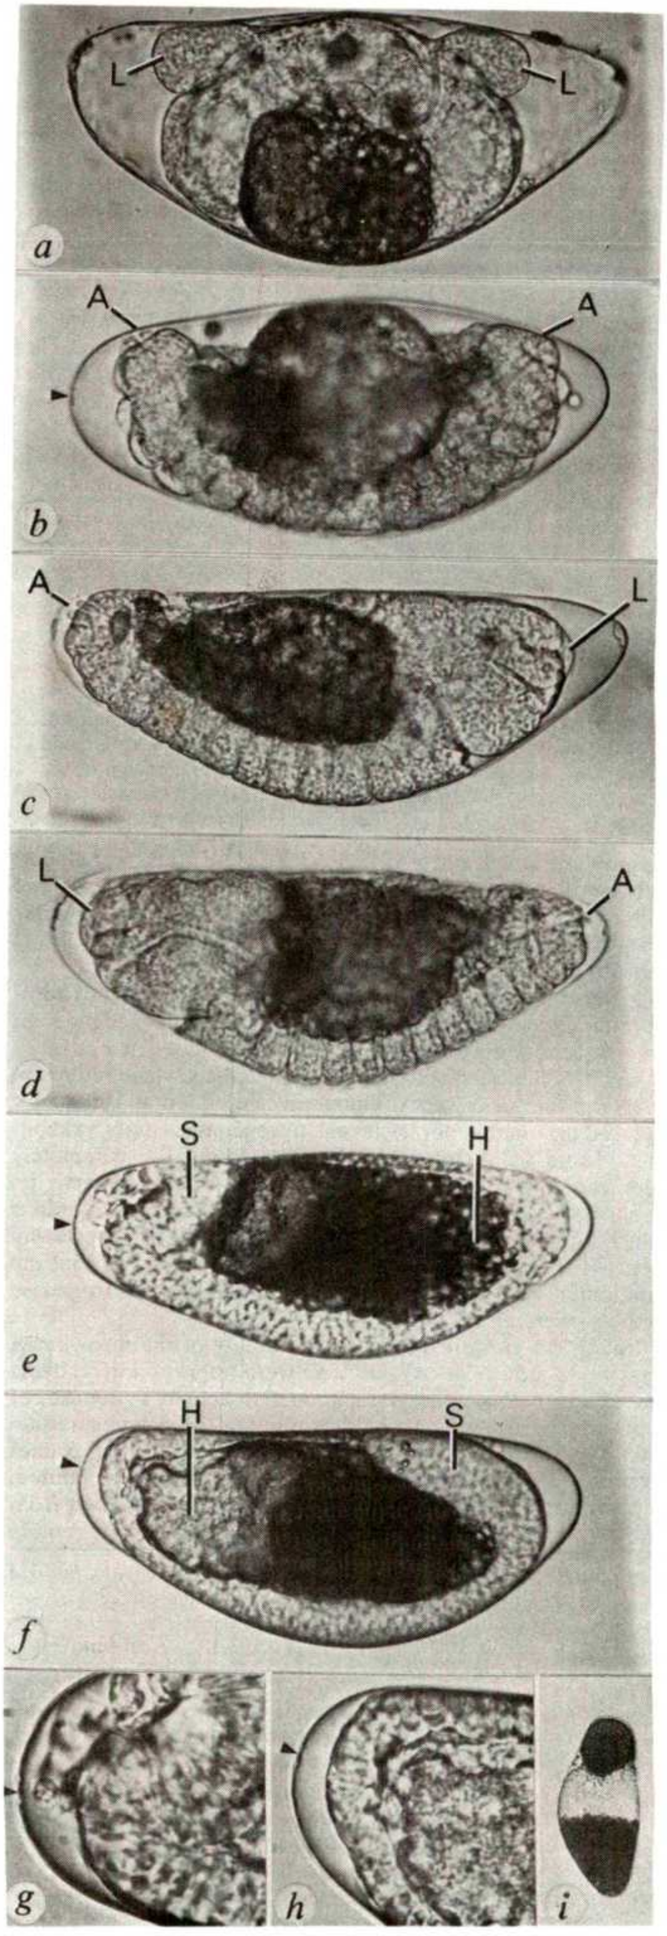

Fig. 1 Normal and abnormal segment patterns of *Smittia* embryos developing from centrifuged eggs. *a*–*h*, Ventral side down, anterior pole of egg shell to the left. *a*–*d*, Embryos after shortening of germ band, 53–78 h after deposition: *a*, double cephalon; *b*, double abdomen; *c*, inverted embryo; *d*, normal embryo. *e*–*h*, Embryos during formation of germ anlage, 18–19 h after deposition: *e*,*g*, inverted embryo; *f*,*h*, normal embryo; *i*, centrifuged egg, posterior pole (down) was facing in direction of centrifugal force. Note centrifugal accumulation of proteid spheres (at bottom in *i*, to right in *e* and *f*) and centripetal accumulation of lipid droplets. L, Labrum (anteriormost head structure); A, anal papillae marking abdominal end; S, Schwanzwulst (posterior bulge of germ anlage); H, head lobes, in lateral position, displacing yolk material in between; ►, micropyle at anterior end of egg shell.

in the anterior egg half. This is shown by the ability of isolated anterior fragments to form abdomens[7], and is also reflected in the synchronous and symmetrical development of double abdomens. The formation of head and thorax is ascribed to the superimposed activity of 'anterior determinants' which have been characterized as cytoplasmic ribonucleoprotein particles[6]. This is mainly based on the formation of double abdomens after application of RNase or UV light to the anterior pole region, on the action spectrum for UV-ray induction of double abdomens, and on the subcellular localization of the effective targets of UV light. Although the exact function of the anterior determinants remains to be elucidated, it is assumed that their activity in crucial regions of an embryonic half has to surpass a threshold level for head and thorax to be formed there. Sub-threshold levels of activity are thought to result in abdomen formation.

Centrifugation of *Smittia* eggs obviously causes stratification of yolk components (Fig. 1*i*) and probably of nuclei, and hence displacement of other egg components. In addition, disruption of some cytoskeletal structures and other less obvious consequences may occur. Redistribution of egg components after centrifugation involves disappearance of the intermediate layer of yolk-free cytoplasm within 4 h, and a somewhat abnormal blastoderm formation which seems to proceed from the egg equator to the poles[4]. These processes may lead, in the embryo, to various spatial distributions of anterior determinants whose activity may also depend on their intracellular environment and/or the time of their interaction with nuclei. As an overall result, one of the following four situations could arise with respect to anterior determinant activity. Above-threshold activity in both anterior and posterior halves (Fig. 2*c*), below-threshold activity in both anterior and posterior halves (Fig. 2*d*), above-threshold activity in the posterior half only (Fig. 2*e*), or above-threshold activity in the anterior half only (Fig. 2*f*). These situations, according to our model, should lead to formation of double cephalons, double abdomens, inverted embryos, or normal embryos, respectively. In fact, all of these segment patterns have been observed after centrifugation.

Fig. 2 Hypothesis explaining the formation of different segment patterns by different distributions of anterior determinant (a) activity after stratification and redistribution of egg material. p, p′, Posterior factors.

Moreover, this hypothetical explanation of our centrifugation experiments allows us to make four predictions as to the modifying effects of UV light (thought to inactivate anterior determinants) before or after centrifugation. (1) UV-ray irradiation of the anterior pole region before centrifugation should cause a major increase in the yield of double abdomens, and the disappearance of normal embryos, double cephalons, and inverted embryos; (2) UV-ray irradiation of the posterior pole before centrifugation should have little or no effect; (3) UV-ray irradiation of the anterior pole region after redistribution should reduce the yields of normal embryos and double cephalons, and enhance the yields of double abdomens and inverted embryos; and (4) UV-ray irradiation of the posterior pole region after redistribution should enhance the yields of normal embryos and double abdomens at the expense of double cephalons and inverted embryos. These predictions will be tested.

Incidentally, we expected and first discovered inverted embryos after centrifugation and subsequent UV-ray irradiation of the anterior pole region. In these conditions, they occurred more frequently than after centrifugation alone. Possibly they were also produced in earlier centrifugation experiments[4] but overlooked because they were not anticipated. *Note added in proof*: We have learned that inverted embryos have been generated earlier by centrifugation of *Chironomus samoensis* embryos[8].

Cytochalasin D does not produce net depolymerization of actin filaments in HEp-2 cells

Allen Morris* & Janet Tannenbaum†‡

* Department of Biology, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139
† Department of Pathology, College of Physicians and Surgeons, Columbia University, New York, New York 10032

The altered morphology, disappearance or 'disruption' of actin filaments (microfilaments) in cells treated with cytochalasin[1] has sometimes been attributed to depolymerization of filamentous actin (F-actin) to its globular subunit (G-actin), but attempts to confirm that mechanism have been inconclusive. Treatment of purified actin filaments with cytochalasin B (CB) decreased their viscosity[2,3], consistent with depolymerization, which was not, however, revealed by electron microscopy[4], although the filaments appeared abnormal[5]. CB also increased the ATP-ase activity of F-actin, suggesting that it had been destabilized[3], while actin filaments in the acrosomal process were not depolymerized[6]. CB or cytochalasin D (CD) can dissolve actin gels (reviewed in ref. 7, see also refs 8 and 9) without depolymerizing their filaments. The 'disrupted' actin structures in CD-treated cells bound heavy meromysin[10], indicating that at least some of the cellular actin was filamentous. Using a rapid assay for G- and F-actin in cell extracts, based on the inhibition of DNase I[11], we have found that neither short-nor long-term exposure of HEp-2 cells to CD produce net depolymerization of actin filaments.

The human tumour cell line HEp-2 (ATCC CCL23) was grown in monolayers in minimal essential medium (Earle's salts) supplemented with 10% newborn calf serum, penicillin (100 U ml^{-1}), streptomycin (100g µl^{-1}) and Fungizone (0.25 µg ml^{-1}, Gibco). Cells were planted at a density of 5×10^5 per 60 mm plastic Petri dish (Falcon), incubated in a humidified atmosphere of 5% carbon dioxide–95% air at 37 °C, and used within 2–3 days (sub-confluent). CD (Sigma) was stored as a 1 mg ml^{-1} stock solution in DMSO and diluted into Earle's balanced salt solution (EBSS, Gibco) to prepare a working stock solution immediately before use. Treatment with CD was initiated by refeeding cells with fresh medium containing CD (or an equivalent amount of DMSO for controls). After incubation as indicated in Table 1, the monolayers were drained, rinsed quickly with warm EBSS and scraped into 0.3–0.4 ml of 5 mM potassium phosphate, *p*H 7.6, 150 mM NaCl, 2 mM $MgCl_2$, 0.2 mM dithiothreitol, 0.2 mM ATP, 0.5% Triton X-100 and 1 mM PMSF (added immediately before use). Samples of 10–20 µl of this cell lysate were used for the DNase I assay as described by Blikstad *et al.*[11]. Samples of lysate mixed with the guanidine hydrochloride depolymerizing solution[11] were sheared in a syringe with a 26-gauge needle to decrease viscosity. All other procedures were as described by Blikstad *et al.*[11]. Chemicals were reagent grade; highly polymerized calf thymus DNA (Sigma) and bovine pancreas DNase I (Sigma DN-Cl, lyophilized powder) were used. Protein concentration was estimated by the method of Bradford[12], using the Bio-Rad Protein Assay reagent and bovine gamma globulin or serum albumin standards.

HEp-2 cells treated with CD exhibited characteristic morphological effects, the protrusion of zeiotic knobs from the cell surface[13,14] at all three concentrations of CD tested. As Table 1 shows, short-(3.75 h) or long-term (24–27 h) treatment with CD did not result in a net depolymerization of actin. Although there was some variability in the results, the long-term effect of CD appeared to be a net decrease in the proportion of G-actin to total actin in the cell. Calculation of the total units of actin per µg of protein (Tables 1, 2) suggested that long-term treatment with CD resulted in an increased accumulation of actin in HEp-2 cells; this effect has been observed repeatedly in further experiments (unpublished data of J.T. and G. C. Godman). Addition of 1 µg ml^{-1} of CD (DMSO for controls) to the EBSS and the Triton-containing buffer used during collection and lysis of CD-treated cells (to prevent any possible reversal of the effects of CD during these steps) did not alter these results (Table 2).

Table 1 Effect of treatment with CD on proportion of G-actin and total actin in HEp-2 monolayers

Expt no.	Treatment	% G-actin	$\frac{\text{Units actin}}{\mu\text{g cell protein}}$
1	DMSO, 0.1% (3.75 h)	67.8 ± 16.4	ND
	CD, 0.5 µg ml^{-1} (3.75 h)	62.5 ± 5.8	ND
	CD, 1.0 µg ml^{-1} (3.75 h)	69.3 ± 13.5	ND
2	DMSO, 0.05% (24.0 h)	57.5 ± 5.4	ND
	CD, 0.5 µg ml^{-1} (24.0 h)	56.4 ± 7.4	ND
3	DMSO, 0.1% (26.75 h)	61.4 ± 4.4	ND
	CD, 0.5 µg ml^{-1} (26.75 h)	42.3 ± 9.0	ND
	CD, 1.0 µg ml^{-1} (26.75 h)	36.2 ± 4.7	ND
4	DMSO, 0.1% (27.0 h)	63.5 ± 5.0	2.2 ± 0.2
	CD, 0.2 µg ml^{-1} (27.0 h)	47.3 ± 6.7	2.6 ± 0.1
	CD, 0.5 µg ml^{-1} (27.0 h)	52.4 ± 6.3	2.7 ± 0.3
	CD, 1.0 µg ml^{-1} (27.0 h)	49.4 ± 5.3	2.8 ± 0.2

Replicate monolayers of HEp-2 cells were incubated with CD or DMSO solvent in medium as indicated (in experiments 1, 3, 4, all concentrations of CD were prepared in 0.1% DMSO). Cells were then collected and lysed as described in the text. Samples of lysate were assayed for their DNase I inhibitor activity before (a measure of G-actin) and after (a measure of total actin) addition of the guanidine hydrochloride depolymerizing buffer. For each determination, the amount of sample used was adjusted to produce inhibition of the DNase I within the linear range of the assay (30–70% inhibition). The percentage of G-actin was calculated by comparing the G-actin inhibitory activity with the total actin inhibitory activity for equal amounts of cell material. Data shown are each averages of three or four determinations per sample, ± s.d. Each experiment was performed with a separate set of replicate monolayers. In experiment 4, protein concentrations in the lysates were, in the order shown: 2.35, 2.25, 2.15 and 2.10 mg ml^{-1}. Values for units of actin per µg protein were calculated from the total actin in each sample (after guanidine hydrochloride depolymerization) for 10-µl volumes; 1 U inhibits 1% of the 1 µg of DNase in the standard assay. ND, not determined.

Table 2 Effect of continued exposure to CD during collection and lysis of CD-treated HEp-2 cells

Expt no.	Treatment	% G-actin	$\frac{\text{Units actin}}{\mu\text{g cell protein}}$
1	DMSO, *in vivo* and *in vitro*	80.0 ± 8.8	3.3 ± 0.2
	CD, *in vivo* (DMSO *in vitro*)	68.1 ± 10.0	4.1 ± 0.3
	CD, *in vivo* and *in vitro*	66.8 ± 4.2	3.9 ± 0.1
2	DMSO, *in vivo* and *in vitro*	86.0 ± 12.0	3.8 ± 0.3
	CD, *in vivo* (DMSO *in vitro*)	69.9 ± 6.3	4.6 ± 0.2
	CD, *in vivo* and *in vitro*	69.4 ± 10.8	4.5 ± 0.3

Replicate monolayers of HEp-2 cells were incubated with 0.1% DMSO or CD (1.0 µg ml^{-1}) in 0.1% DMSO for 17.0 h (experiment 1) or 19.5 h (experiment 2) (*in vivo* treatment). Cells were then rinsed and collected as indicated in the text, except that rinsing and lysing solutions contained 0.1% DMSO (cells exposed to DMSO '*in vitro*') or 1.0 µg ml^{-1} CD in 0.1% DMSO (cells exposed to CD '*in vitro*'). Thus, for cells treated with CD *in vivo* and *in vitro*, exposure to CD was continuous to prevent possible recovery from effects of the drug. All other details are given in the legend for Table 1. Separate stocks of HEp-2 cells were used in the experiments for Tables 1 and 2; possibly differences between these two stocks account for the higher % G-actin in Table 2 compared with Table 1. The values for units of actin per µg protein are not directly comparable between Tables 1 and 2, because different lots of DNase 1 and DNA substrate were used for each.

The approximate concentration of G-actin in the lysates can be determined from Table 1 and our estimate that 6.8% of the protein in DMSO-treated HEp-2 cells is actin (unpublished observations based on ^{35}S-methionine labelling of HEp-2 cells and isolation of actin by polyacrylamide gel electrophoresis). For the protein concentrations in experiment 4, we calculated that the lysates contained G-actin at a concentration of 102 µg ml^{-1} (DMSO control) and at 87, 94 and 90 µg ml^{-1} (respectively, for CD at 0.2, 0.5 and 1 µg ml^{-1}; all values were corrected for the increase in total actin per µg protein compared with DMSO controls). All these values are greater than the critical concentration reported for various non-muscle actins in similar conditions[15], possibly because the cellular G-actin is associated with inhibitors of polymerization such as profilin[16].

These results indicate that CD does not cause a massive net depolymerization of actin filaments *in vivo*. It should be noted, however, that the DNase I assay used does not distinguish the length of the actin filaments and therefore cannot test a proposed mechanism involving the scission of F-actin to shorter lengths of filament[17]. In addition, the data do not exclude the possibility that CD converts actin microfilaments to some other configuration rather than depolymerizing them.

Cytochalasins B, E and D have been reported to inhibit the *in vitro* induction of F-actin polymerization by a high molecular weight complex which binds dihydro-CB at high affinity[18]. Similarly, CD inhibited polymerization of actin nucleated by F-actin[19,20]. On the basis of these observations, it was suggested that cytochalasins might act by inhibiting polymerization of actin microfilaments in the cell. Because the actin in non-muscle cells probably undergoes cycles of polymerization and depolymerization (reviewed in ref. 21), this proposal implies that cytochalasin should eventually produce a net increase in the proportion of G-actin in the cell by inhibiting its repolymerization during the normal cycle. Our failure to detect such an increase, even after 27 h of treatment with CD at concentrations sufficient to alter cell morphology, tends to contradict this hypothesis. However, because the DNase I assay only determines the net balance of F and G-actin at the time the cells are collected, our experiments do not test the possibility that CD inhibited the nuclei-induced, rapid polymerization of actin in the cell but also allowed (and perhaps accelerated[22,23]) a compensating polymerization of this actin on to the more slowly growing end of actin filaments.

Our observation that CD does not cause a net depolymerization of actin filaments *in vivo* argues against any mechanism for the action of cytochalasin on cells which is based on the replacement of microfilaments by depolymerized actin. In particular, it suggests that normal levels of actin microfilaments would be available for participation in an energy-dependent contractile response of the cells to treatment with CD, as previously proposed[10,13,14,24,25].

In summary, treatment of live HEp-2 cells with CD did not cause a net depolymerization of filamentous actin. Rather, there seemed to be a small increment in the proportion of filamentous actin in cells treated for 27 h and an increase in the total content of actin. The possibility that an accumulation of F-actin in CD-treated cells corresponds to the actin-containing masses (reviewed in ref. 25) seen in such cells is being investigated.

Lack of heterogeneity in anti-hapten antibodies of a phylogenetically primitive shark

O. Mäkelä

Department of Bacteriology and Immunology, University of Helsinki, SF-00290 Helsinki 29, Finland

G. W. Litman

Sloan-Kettering Institute for Cancer Research, Walker Laboratory, Rye, New York 10580

Individual mammals have the capacity to express at least one million distinct antigen binding specificities, implying a high degree of structural heterogeneity in the variable heavy and light chain (V_H and V_L) portions of the antibody molecules. Studies of higher vertebrate species suggest that this heterogeneity is created both through a sizeable repertoire of germ-line V_H and V_L genes[1] and through random rearrangements of V and joining genes[2–4]. Additional somatic mechanisms probably also contribute to the ultimate heterogeneity; one-third of murine plasmacytomas producing λ_1 immunoglobulin carry a somatically mutated Igl-V gene[5,6]. The relative contributions of these various mechanisms to the overall immunoglobulin variability are difficult to evaluate. The production of different antibodies to a defined determinant in different individuals of an inbred mouse strain [for example, (3-iodo-4-hydroxy-5-nitrophenyl) acetyl (NIP) in CBA mice[7]] suggests the involvement of somatic mutations or rearrangement but does not rule out the possibility that each individual CBA mouse expresses only a small random fraction from a large germ-line repertoire of V genes determining different anti-NIP binding sites. The opposite finding, that different individuals produce nearly identical antibodies to a defined determinant, would suggest the presence and expression of a limited number of germ-line genes without somatic alterations. Data presented here suggest that primitive sharks (*Heterodontus fransisci*)[8] produce such antibodies to the hapten furyloxazolone.

Heterodontus (0.2–0.5 kg) of estimated age 2–3 yr were maintained as described previously[9]. Intramuscular immunization with *Brucella abortus* to which 2-furyloxazolone (furyl Ox) was coupled[10] was carried out on day 0 and day 30. Inbred male rats of the SDK strain (0.34–0.43 kg) aged 3–4 months were immunized with the same dose and timing. Antibody to furyl Ox was measured by neutralization of bacteriophage T4 coupled with furyl Ox-aminocaproyl (furyl Ox-cap-T4)[10]. The shark antibody was found to reside in the high molecular weight serum fraction as judged by sensitivity to 0.1 M 2-mercaptoethanol and the 19S sedimentation constant of the phage neutralizing activity. Antibodies of rat sera were found in both high and low molecular weight fractions. However, in the experiments reported we have used the 19S fraction prepared by sucrose density gradient centrifugation, or for the day 9 sera, antibody remaining after elimination of IgG by incubation of 1.0 ml of 20% serum with 0.7 ml of packed protein A–Sepharose for 1 h at 20 °C (ref. 11).

The shark antisera discriminated between the structurally different haptens furyl Ox and azobenzene arsonate (Ars) in a manner comparable to rat antisera (Table 1). The anti-furyl Ox titres after immunization with furyl Ox were 170 times higher than the anti-Ars titres. The only anti-Ars serum that we tested exhibited a 56-fold difference in the reverse direction.

The affinity and fine specificity of the antibodies were characterized by the inhibition of the phage neutralization using seven structurally related haptens. The concentration of hapten required to reduce the antibody titre by 50% was termed the IC_{50}; a low IC_{50} value indicated a high affinity and vice versa[12].

Table 1 Anti-furyl Ox or anti-Ars titres of *Heterodontus* or rat antisera

	Anti-furyl Ox titres at various days post-immunization				Anti-Ars titres
Day	—	9	20	55	55
Heterodontus	1,300	—	18,000	143,000	270
Rat (whole sera)	—	4,600	12,000	386,000	160

The data are geometric mean titres of four *Heterodontus* and six rat sera. The antibodies were measured by neutralization of bacteriophage T4 coupled with furyl Ox–aminocaproyl[10] or BOC-ABA-tyrosine[16]. An anti-Ars serum obtained on day 180 of an immunization course with *B. abortus* coupled with azobenzene arsonate[9] was tested with the same phage conjugates; its anti-furyl Ox titre was 830 and anti-Ars titre 15,000.

0028–0836/80/410639—02$01.00

This analysis revealed three differences between shark and rat 19S antibodies (Fig. 1).

The shark antibodies had lower affinities for the immunizing hapten furyl Ox-cap (log mean IC_{50} 35 μM) than did rat antibodies (IC_{50} 0.82 μM). It might be argued that the IC_{50} values cannot be used to compare affinities because the degree of polymerization may differ in the rat and the shark IgM. Even if this were true, shark antibodies are likely to be less polymeric than rat antibodies. (Rat antibodies are pentameric, some fishes have tetrameric antibodies[13].) The true species difference of affinities would then be greater than the IC_{50} values indicate. The low affinity may be characteristic of all piscian antibodies[13].

Another difference between the two species is in the discriminating power of the antibodies. Shark antibodies had rather similar affinities for the immunizing hapten and all six analogues. The average relative affinities for the analogues only varied from 37% (styryl Ox-cap) to 150% (fluorophenyl Ox-cap), whereas rat antibodies discriminated strongly between furyl Ox-cap and some of the analogues. For example, the average affinity for nitrophenyl Ox-cap and styryl Ox-cap was less than 1/10th of the average affinity for furyl Ox-cap.

The third characteristic of shark antibodies which distinguishes them from rat antibodies was a constant pattern of relative affinities for the structural analogues of furyl Ox-cap. This species-specific pattern was exhibited by all eight sera representing four individual fish and two time points post-immunization. For example, the affinity for fluorophenyl Ox-cap was always ~150% and the affinity for styryl Ox-cap was always ~37% relative to the affinity for furyl Ox-cap. The greater vertical variations of rat values than shark values shown in Fig. 1 indicate that the rats showed no such species-specific pattern. Even more striking differences could be seen when comparing individual rats: thus, antibodies of one rat had a three times higher affinity for iodophenyl Ox-cap than for furyl Ox-cap whereas antibodies of another rat had a 40-fold difference in the reverse direction. A modest increase of affinities for furyl Ox-cap was observed in the rats from day 9 to day 55 but the differences were not statistically significant.

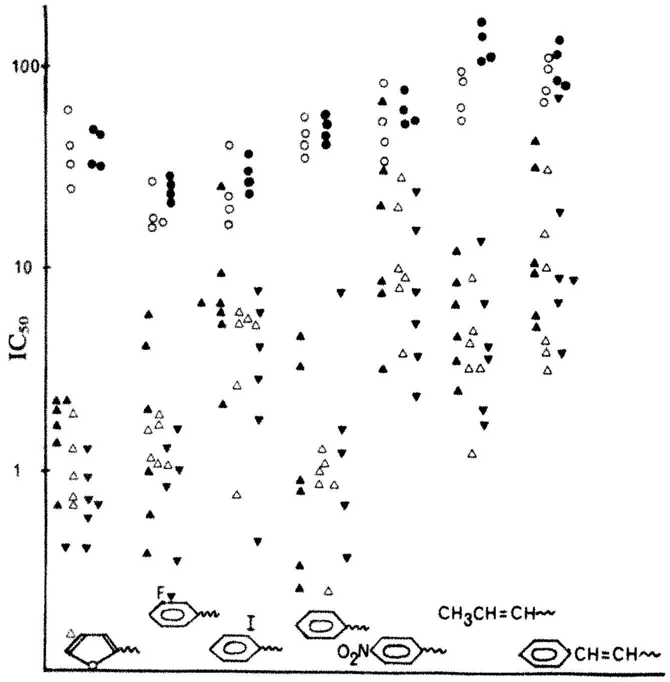

Fig. 1 Fine-specificity characteristics of *Heterodontus* and rat antibodies (19S). Relative affinities for seven different oxazolones were determined. Each symbol represents an IC_{50} value of an antiserum or its 19S fraction for the compound illustrated below the column. All compounds shared the oxazolone-ε-aminocaproyl (Ox-cap) structure. The structures illustrated were attached to the C-2 of Ox-cap. From the left the compounds are: furyl Ox-cap (closely resembles furyl Ox-lysine, the immunizing determinant), fluorophenyl Ox-cap, iodophenyl Ox-cap, phenyl Ox-cap, nitrophenyl Ox-cap, propyl Ox-cap and styryl Ox-cap. Circular symbols represent *Heterodontus* sera from day 20 (○) or day 55 (●). Triangles represent rat sera from day 9 (▲), day 20 (△) or day 55 (▼).

Thus, we found that furyloxazolone induced a similar low-affinity antibody population of limited discriminating capacity in four individual sharks and that this population did not change detectably over a 25-day period of immunization. By contrast, rat IgM antibodies elicited in response to immunization with the same bacterium–hapten conjugate had a high affinity for the immunizing hapten but a low affinity for some of its chemical analogues; differences between individual animals were large. These data are consistent with the presence in *Heterodontus* of a stable, limited repertoire of antibody molecules of probable germ-line origin, and expand preliminary structural observations which support this hypothesis[14,15]. *Heterodontus* may represent a valuable developmental model for examining the genetic processes which have been involved in the diversification of the variable-region gene pool during vertebrate evolution.

Phenypressin (Phe^2-Arg^8-vasopressin), a new neurohypophysial peptide found in marsupials

M. T. Chauvet, D. Hurpet, J. Chauvet & R. Acher

Laboratory of Biological Chemistry, University of Paris VI,
96 Boulevard Raspail, Paris 75006, France

Recent investigations on marsupial neurohypophysial hormones have revealed that species belonging to the Australian family Macropodidae and the American family Didelphidae have, apart from an oxytocin-like hormone, two vasopressin-like peptides which can be separated either by ion-exchange chromatography or chromatoelectrophoresis[1–3]. The major pressor hormone of two Australian species, the red kangaroo (*Macropus rufus*) and the tammar (*Macropus eugenii*), has been identified as lysine vasopressin by its amino acid sequence and its pharmacological properties[1,2]. We report here that the minor pressor hormone, which chromatographs on Amberlite CG-50 like arginine vasopressin[1,2], differs from it in sequence only at position 2 where phenylalanine replaces the tyrosine of arginine vasopressin[4].

The procedure described previously for isolation of lysine vasopressin[1,2] was used for the purification of the minor pressor hormone. Acetone-desiccated posterior pituitary lobes (oxytocic activity 0.7 U mg^{-1} and pressor activity 2.9 U mg^{-1} for red kangaroo, oxytocic activity 0.8 U mg^{-1} and pressor activity 2.3 U mg^{-1} for tammar) were extracted by 0.1 M HCl (1 ml for

0028-0836/80/410640—03$01.00

8 mg) for 4 h at 4 °C. Two experiments were carried out for each species with nine (42 mg) and 14 (67.7 mg) glands of red kangaroo and 24 (40.1 mg) and 33 (51 mg) glands of tammar. Supernatant solutions, separated by centrifugation, were subjected to molecular sieving on a column (1 × 120 cm) of Biogel P_4 equilibrated with 0.1 M acetic acid. Proteins were excluded and an oxytocic peak (yield in activity 78–83%) was separated from a pressor peak (yield in activity 77–87%). Fractions of each peak were pooled and solutions concentrated to a small volume by lyophilization. Materials were subjected to paper chromatoelectrophoresis in conditions described previously[5]. Regarding the pressor fraction, two pressor peptides having similar electrophoretic migrations (21 cm) but different chromatographic migrations (6–8 cm for lysine vasopressin, 10–12 cm for the new hormone) could be isolated. Spots, detected with dilute ninhydrin, were eluted with 0.1 M acetic acid. The yields in pressor activity were 27–36% for lysine vasopressin and 7–11% for the new hormone. Performic acid-oxidized or mercaptoethanol-added samples were subjected to hydrolysis (6 M HCl, 48 h, 105 °C *in vacuo*) and analysed with a Spinco 120B automatic analyser fitted with a high-sensitivity cell[6]. Results for the new hormone are given in Table 1. About 70 nmol of lysine vasopressin and 30–40 nmol of phenypressin were recovered from about 40 mg of acetone posterior pituitary powder.

For sequential studies, products purified from 14 glands of red kangaroo on one hand, and from 33 glands of tammar on the other, were used. In this case, spots were not eluted after chromatoelectrophoresis but Edman recurrent degradation was directly applied by using the paper-strip adaptation described by Chauvet and Acher[7]. Identification of phenylthiohydantoin (PTH) amino acids was carried out by thin-layer chromatography according to Edman and Henschen[8]. Spots were located by fluorescence and by reaction with ninhydrin which often gives characteristic colours[8]. About 100 nmol of pig lysine vasopressin and 50 nmol of ox arginine vasopressin were subjected, for comparison, to chromatoelectrophoresis and Edman degradation in the same conditions.

In the new hormone, Phe, Phe, Gln, Asn and Pro were identified in positions 2, 3, 4, 5 and 7 (Cys in positions 1 and 6 could not be seen because of the disulphide bridge). Comparison with arginine vasopressin or lysine vasopressin clearly showed PTH-Tyr in position 2 (lemon-yellow coloration) for these hormones instead of PTH-Phe (violet coloration after ninhydrin) for the new hormone. In contrast, PTH-Phe was found in position 3 for the three peptides. To characterize the residues in position 8 and 9 in the new hormone, after the eighth cleavage material was eluted from the paper strip with 0.1 M acetic acid and subjected to paper electrophoresis (0.1 M pyridine acetate buffer at *p*H 3.7, 50 V cm^{-1}, 35 min). PTH-Arg could be identified by a modified Sakaguchi reaction[9] (8.6-cm migration) and glycinamide with ninhydrin (20-cm migration). The two half-cystines, found as cysteic acid residues in performic acid-oxidized sample, were assigned to positions 1 and 6. A complete sequence is proposed for the new hormone in Table 2. We suggest the name *phenypressin* because of the substitution by phenylalanine of the second residue of arginine vasopressin, the classical pressor hormone of mammals[4]. On the other hand the biological properties resemble those of vasopressins.

Table 1 Amino acid composition of red kangaroo and tammar phenypressins

Amino acid	Red kangaroo (13 nmol)	Tammar (15 nmol)	Phenypressin (theoretical values)
Arg	0.88	0.93	1
Asp	1.00	1.00	1
Glu	1.06	1.08	1
Pro	1.03	0.71	1
Gly	1.15	1.22	1
Tyr	—	0.10	—
Phe	1.77	2.10	2
Cys*	1.18	1.33	2

Values are in molar ratios, using aspartic acid as reference.

* Half-cystines are determined as cysteic acid on a separate performic acid-oxidized sample. A partial destruction of cysteic acid is observed when hydrolysis is carried out with paper-eluted peptide.

Table 2 Amino acid sequence of phenypressin

Phenypressin	$\overset{1}{\text{Cys}}$-$\overset{2}{\text{Phe}}$-$\overset{3}{\text{Phe}}$-$\overset{4}{\text{Gln}}$-$\overset{5}{\text{Asn}}$-$\overset{6}{\text{Cys}}$-$\overset{7}{\text{Pro}}$-$\overset{8}{\text{Arg}}$-$\overset{9}{\text{Gly}}$ (NH$_2$)
Arginine vasopressin	$\overset{1}{\text{Cys}}$-$\overset{2}{\text{Tyr}}$-$\overset{3}{\text{Phe}}$-$\overset{4}{\text{Gln}}$-$\overset{5}{\text{Asn}}$-$\overset{6}{\text{Cys}}$-$\overset{7}{\text{Pro}}$-$\overset{8}{\text{Arg}}$-$\overset{9}{\text{Gly}}$ (NH$_2$)
Lysine vasopressin	$\overset{1}{\text{Cys}}$-$\overset{2}{\text{Tyr}}$-$\overset{3}{\text{Phe}}$-$\overset{4}{\text{Gln}}$-$\overset{5}{\text{Asn}}$-$\overset{6}{\text{Cys}}$-$\overset{7}{\text{Pro}}$-$\overset{8}{\text{Lys}}$-$\overset{9}{\text{Gly}}$ (NH$_2$)

Phe^2-Arg^8-vasopressin was synthesized, 18 years ago, by Huguenin and Boissonnas[10]. They compared the pharmacological properties of this analogue with those of arginine vasopressin. The substitution reduces the rat antidiuretic activity per μmol from 435 to 375 U and the rat blood pressure activity from 435 to 130 U. The intrinsic oxytocic activity is dramatically reduced from 17 to 0.2 U. From a limited number of measures, the rat blood pressure activity of natural phenypressin was found to range from 130 to 200 U, value in accordance with that reported for the synthetic peptide. Because of the small amount of material available and its very weak oxytocic activity, a reliable value could not be determined for this activity.

Examination by ion-exchange microchromatography[1] of six individual glands of red kangaroo collected either in Western Australia or in New South Wales, and of three individual glands of tammar, systematically revealed two pressor hormones. Duality was also found in individual glands of three other macropodid species (grey kangaroo, euro, quokka) and of two species belonging to the American family of Didelphidae (South American opossums)[3]. Apparently vasopressin duplication is current among marsupials. However, whether the pressor hormones of Didelphidae are identical with those of Macropodidae still needs clarification. Lysine vasopressin and phenypressin, characterized in two macropodid species, differ by two amino acid residues in positions 2 and 8. They are likely products of two distinct structural genes rather than two allelic forms of a single gene. Vasopressin dimorphism has previously been reported for some pig-like species (peccary, warthog, hippopotamus) without individual characterization[11,12]. It was assumed that the placental pressor hormones, arginine vasopressin and lysine vasopressin, were present, and because both hormones were not observed in all the glands examined, dimorphism was explained by heterozygosity[11].

Egg-laying prototherians are supposed to be the closest present-day mammals to the ancestral mammalian reptiles. The neurohypophysial hormones of an Australian prototherian, echidna, have been isolated and conventional mammalian peptides, oxytocin and arginine vasopressin, have been characterized[13]. All the non-mammalian tetrapods examined to date, including four reptile species, have mesotocin and arginine vasotocin[4] so that the change of arginine vasotocin into arginine vasopressin seems to have occurred early in mammalian evolution. In *Metatheria*, a duplication of the vasopressin gene occurred later and subsequent mutations might have produced lysine vasopressin on one hand and phenypressin on the other. Because neurohypophysial hormones are probably fragments of larger precursors in which they are bound to neurophysins[14] and because two types of neurophysins have been found in placental mammals[15], it will be of interest to establish whether the additional marsupial hormone is accompanied by an additional neurophysin.

We thank Professor C. H. Tyndale-Biscoe and Drs G. Byrne and F. N. Carrick for supplying pituitary glands. We also thank Mrs Danielle Thévenet and Miss Christine Jourdain for technical assistance. This investigation was supported in part by grants from CNRS (ERA no. 563 and ATP 3674), DGRST (no. 77-7-0290) and the Fondation pour la Recherche Médicale.

HCG stimulation of testicular LHRH-like activity

Richard M. Sharpe & Hamish M. Fraser

MRC Reproductive Biology Unit, Centre for Reproductive Biology,
37 Chalmers Street, Edinburgh EH3 9EW, UK

It is well established that the administration of high doses of luteinizing hormone (LH) or human chorionic gonadotropin (HCG) to animals can impair gonadal function in both the male and female^{1}. These effects can be duplicated by the administration of LH releasing hormone (LHRH) or its agonists to intact animals$^{2-5}$, including man^{6}. Somewhat surprisingly, recent results have demonstrated that similar impairment of gonadal function by LHRH and its agonists can be achieved in the absence of the pituitary (for review see ref. 7), and the demonstration of specific, high-affinity binding sites for LHRH and its agonists on ovarian luteal cells^{8} and on testicular Leydig cells$^{9-11}$, could mean that LHRH-like factors are involved in the local regulation of the gonads. A further intriguing finding is the striking similarity between the direct, inhibitory effects of LHRH and LH/HCG on the gonads^{7}; for example, both treatments reduce LH receptor numbers and the steroidogenic responsiveness of rat Leydig cells^{2,4,12,13}. We now offer a possible explanation for this similarity by demonstrating that HCG treatment stimulates the testicular production of a biologically active LHRH-like factor, suggesting that the inhibitory actions of HCG on the Leydig cell may be mediated by the local production of this factor.

We have utilized the receptor-binding ability of rat Leydig cells for LHRH and its agonists$^{9-11}$ to establish a robust and sensitive assay for LHRH-like activity present in testicular interstitial fluid (IF) (Fig. 1). Using this assay system, negligible activity was detectable in IF from saline-injected (control) rats whereas clearly detectable amounts were present 16 h after injection of 100 IU HCG. Interstitial fluid from such animals gave parallel displacement curves to unlabelled LHRH agonist (Fig. 1), and stimulated the release of pituitary LH from hemi-pituitaries *in vitro* (Table 1), establishing that the material was biologically active. Other factors present in high amounts in the IF, such as HCG^{14} and testosterone^{15}, did not contribute to this activity, as the addition of these hormones in large amounts (HCG up to 10^{-6} M, testosterone up to 10 μg ml^{-1}) to the receptor assay was without significant effect. Again, the inclusion of IF from control and HCG-injected animals in the rat LH radioimmunoassay was without detectable effect, thus demonstrating that the LH measured in hemi-pituitary incubation medium was derived from the pituitary tissue and not from the added IF.

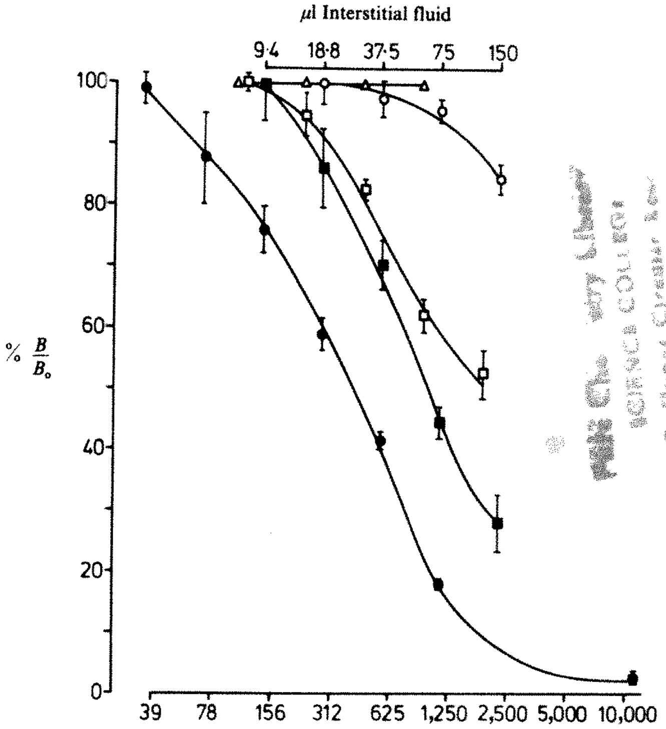

Fig. 1 Displacement of the binding of ^{125}I-LHRH agonist ((D-Ser-*t*-bu^{6}, *des*-Gly-NH$_2$^{10}) LHRH ethylamide) to dispersed Leydig cells by unlabelled LHRH agonist and testicular interstitial fluid from control and HCG-injected rats. Leydig cells were prepared by collagenase dispersion of decapsulated testes from adult (age ⩾90 days) Liverpool/Hooded rats, using techniques described previously^{11,19}. The dispersed cells were resuspended in Krebs–Ringer bicarbonate (KRB) solution (*p*H 7.5) containing 0.2% bovine serum albumin (BSA; fraction V, Sigma) and 200 μg ml^{-1} Bacitracin (Sigma). The volume of resuspension was equivalent to 1 ml per original testis and, for assay, aliquots (0.2 ml) of this cell suspension were dispensed into 63 × 11-mm polystyrene tubes. As determined by the staining of dispersed cells for 3β-hydroxysteroid dehydrogenase^{19}, each 0.2-ml aliquot contained approximately 5×10^{6} positively staining (Leydig) cells. The test materials or unlabelled LHRH agonist were added in a volume of 0.15 ml and ^{125}I-LHRH agonist (~150,000 c.p.m.) in a volume of 0.05 ml. Nonspecific binding was determined by parallel incubation in the presence of 10^{-6} M unlabelled LHRH agonist (see ref. 11 for details). All samples/standards were run in duplicate or triplicate and incubation was for 45 min at 21 °C. Incubation was ended by placing tubes on ice and immediately diluting the incubate with 1 ml ice-cold medium. Tubes were then centrifuged for 15 min at 1,000*g* and radioactivity in the pellet measured in a γ counter. LHRH agonist was labelled with ^{125}I using lactoperoxidase^{20} as described previously^{11} and, as determined by self-displacement in the receptor assay, had a specific activity of 1,200 mCi per mg. In eight successive assays the mean (±s.d.) binding of ^{125}I-LHRH agonist was 7.4 ± 1.5% of the total counts added, of which 32–40% was not displaceable by parallel incubation with 10^{-6} M unlabelled LHRH agonist, and was taken to represent the nonspecific binding; specific binding was 5.6 ± 1.3% of the total counts added. The sensitivity of the assay, defined as the concentration of unlabelled LHRH agonist required to suppress binding to 90% B/B_0, was 48 ± 16 pg ml^{-1}($n = 8$), and the intra-assay coefficient of variation was ± 5% for standards and ± 8.4% for interstitial fluid samples. Sprague–Dawley rats aged 70–80 days were injected subcutaneously with either 0.9% saline or 100 IU HCG (Chorulon) and killed with ether 16 h later. Testicular IF was collected as described previously^{14,15}, by allowing the fluid to percolate from the incised caudal end of the testis over a 16-h period at 4 °C; the fluid was then centrifuged for 5 min at 1,000*g* at 4 °C and the IF from 8–12 rats per treatment group was pooled before assay. The displacement curves for two such pools of IF from independent experiments are detailed in the figure. ●, Unlabelled LHRH agonist (standard); △, ○, interstitial fluid from saline-injected (control) rats; ■, □, interstitial fluid from HCG-injected rats. Results are plotted as the mean and range of duplicate determinations and, as determined by 2-factor analysis of variance (with replication), there was no evidence ($P > 0.05$) for non-parallelism of the displacement curves for standard and IF dilutions.

0028–0836/80/410642—02$01.00

We have used the receptor assay to quantify the LHRH activity in IF at various times after HCG injection (Table 2). In only 2 out of 12 samples from control rats (expts 1 and 2, Table 2) was there detectable LHRH activity, whereas high levels were found in all six samples from rats 16 h after injection of 100 IU HCG; at other times after this treatment, the frequency and level of detectable LHRH activity did not differ from controls. This effect of HCG on LHRH activity in IF at 16 h after injection was dose dependent (expt 2, Table 2), and a low dose of HCG (6 IU) was without detectable effect. As found previously[14,15], injection of HCG also increased the amounts of IF in the testis at 8–24 h after injection (Table 2), as a result of increased capillary wall permeability[16], and therefore calculation of the total amounts of LHRH activity in IF at 16 h after injection would exaggerate the difference from control levels.

Although we have shown that a factor present in IF from HCG-injected rats has LHRH-like activity *in vitro* at both the Leydig cell and pituitary levels, it seems most likely that any physiological effects of this factor are restricted to the testis. In support of this idea, we have preliminary evidence which suggests that the receptor-binding potency *in vitro* of this LHRH-like factor is considerably lower at the pituitary than at the Leydig cell level (H.M.F. and R.M.S., unpublished data). This may mean that there are differences in the type of degradative enzymes within the pituitary and the Leydig cell or that there are differences between the structures of hypothalamic LHRH and the LHRH-active factor produced by the testis. In this respect, the latter may correspond to the LHRH-active factor recently isolated from ovarian follicular fluid[17,18], which possesses LHRH-like biological activity but is immunologically distinct from native LHRH.

Table 1 Stimulation of pituitary LH release *in vitro* by LHRH and testicular IF from control and HCG-injected rats

Test material added to incubation medium	% LH released by test hemi-pituitary
10 ng LHRH	635 ± 192*
1 ng LHRH	101 ± 34
0.1 ml control IF	118 ± 50
0.01 ml control IF	76 ± 25
0.1 ml HCG + 16 h IF	357 ± 68*
0.01 ml HCG + 16 h IF	91 ± 15

Hemi-pituitaries from Sprague–Dawley rats aged 55 days were incubated at 37 °C *in vitro* for 4 h as described previously[21]. One-half of each pituitary was incubated in buffer alone (Krebs Ringer + 1 mg ml^{-1} glucose + 0.2% bovine serum albumin (BSA)) while the contralateral hemi-pituitary was incubated in the presence of one of the test materials listed. The incubation volume was 0.5 ml. LH in the incubation medium was determined by radioimmunoassay[22]. LH released in the presence of the test material is expressed as a % of that released by the (control) contralateral hemi-pituitary. For the two test materials which stimulated LH release, the basal and test-stimulated LH release (mean ± s.d.) were as follows—10 ng LHRH: basal, 2.45 ± 0.25 μg NIAMDD rat LH-RP-1 per hemi-pituitary; stimulated, 15.35 ± 4.68 μg; 0.1 ml HCG + 16 h IF: basal, 2.78 ± 1.05 μg; stimulated, 9.38 ± 1.59 μg. Results are the mean ± s.d. for three incubations.

* $P < 0.01$ (paired t-test comparison of control and test-stimulated LH release).

Table 2 The relationship between the dose of HCG injected and the time after injection on the levels of LHRH-active material in testicular interstitial fluid

					LHRH activity in IF (ng equiv. of LHRH agonist per ml)	
Expt	Treatment	Hours after injection	No. of animals	Interstitial fluid (μl per paired testes)	Detectable/ undetectable	Mean ± s.d.*
1	Saline	16	6	145 ± 19	1/5	1.24 ± 0.6
	100 IU HCG	2	4	123 ± 30	0/4	<1
		8	4	193 ± 21†	2/2	1.24 ± 0.2
		16	6	229 ± 44‡	6/0	5.48 ± 2.3‡
		24	4	213 ± 40†	0/4	<1
		40	4	130 ± 25	1/3	2.05 ± 1.8
2	Saline	16	6	107 ± 16	1/5	1.28 ± 0.7
	150 IU HCG	16	4	160 ± 7§	4/0	8.49 ± 4.0‡
	30 IU HCG	16	4	160 ± 14‡	4/0	5.29 ± 1.8‡
	6 IU HCG	16	4	138 ± 26	1/3	1.36 ± 0.6

Treatment of animals and collection of IF were as described in Fig. 1 legend, except that IF from individual animals was kept separate and not pooled. All the above samples were assayed together in 0.05-ml amounts in a single receptor assay, and the concentration equivalent of LHRH agonist in each sample was computed after log–logit transformation of the data. All samples were assayed in duplicate except for three control fluids for which only a single assessment was possible. The limit of detection of the assay (the level corresponding to 90% B/B_0) was equivalent to 1 ng LHRH agonist per ml for a 0.05-ml sample.

* All undetectable samples (<1 ng ml^{-1}) were assigned a value of 1 ng ml^{-1} to calculate the mean ± s.d. and assess statistical significance.

† $P < 0.02$; ‡ $P < 0.01$; § $P < 0.001$, in comparison with respective control group (Student's t-test).

In rats injected with high doses of HCG, impairment of the steroidogenic responsiveness of the Leydig cells and the loss of LH (HCG) receptors occur dramatically beyond 16 h after injection[14]. This time coincides precisely with the appearance of detectable levels of the LHRH-active factor in the interstitial fluid that bathes the Leydig cells. As LHRH agonists can themselves directly reduce LH receptor numbers and the steroidogenic responsiveness of the Leydig cells[12,13], it seems plausible that the inhibitory effects of HCG on the Leydig cell are mediated at least in part by the local production of this LHRH-active factor. Its origin is unknown but, as granulosa cells seem to be the site of production of an LHRH-active factor in the ovary[18], possibly the corresponding cell type in the testis, the Sertoli cell, is the site of production of the LHRH-active factor which we have detected. Certainly, the possibility that gonadotropins may affect gonadal function through locally produced LHRH-like substances opens exciting new dimensions for reproductive biology and its control.

We thank Drs J. Sandow and S. Dombey for supplies of LHRH and LHRH agonist, and the National Pituitary Agency, NIAMDD, US for materials for rat LH radioimmunoassay.

Gating charge immobilization and sodium current inactivation in internally perfused crayfish axons

R. P. Swenson Jr

Department of Physiology/G4, University of Pennsylvania,
Philadelphia, Pennsylvania 19104

The sodium permeability in nerve is regulated by two gating processes, activation and inactivation[1]. Their relationship to one another has been described as 'independent'[1] or 'coupled'[2,3]. An independent model, the Hodgkin and Huxley formulation, makes two testable predictions regarding gating current. First, as inactivation is voltage sensitive, it requires its own voltage sensor and might be expected to generate its own gating current. Second, gating current associated with activation should be unaffected by inactivation. Although charge movement associated with sodium activation is well characterized[4], no inactivation charge movement has been described. Instead, depolarizations long enough to produce sodium current inactivation were found to diminish the charge movement associated with channel closing[5]. Inactivation temporarily immobilized a substantial fraction of the gating charge. These observations suit a coupled model in which inactivation gains its voltage dependence by coupling to activation[3], and inactivation may in turn influence activation. However, the relative time course of the development immobilization (τ_{immob}) was found to be the same[3], the same in some voltage ranges[6] and slower than that for inactivation (τ_{inact}). In crayfish axons inactivation is roughly five times faster than in squid, providing an interesting opportunity to compare inactivation and immobilization. Further, inactivation is so rapid that inactivation gating current should be easily visible. No inactivation charge movement was found and τ_{immob} equals τ_{inact}.

Experiments were performed on internally perfused crayfish giant axons using an axial wire for voltage clamping the nerve. The solutions were prepared so that external sodium was the only permeant ion and gating currents were measured in the presence of tetrodotoxin (TTX). The relative time courses of inactivation in crayfish and squid nerve are compared in Fig. 1. The lower traces show that the sodium current (I_{Na}) decays with a time constant (τ_{h}) of 2.5 ms in squid and more quickly in crayfish, 0.45 ms at the same temperature and voltage. The upper traces in the figure show gating current recorded at the same voltage in the presence of TTX. The rapid time course of inactivation in crayfish should make it easy to resolve an additional component in the gating current due to inactivation, yet no such current is detectable at any potential.

Immobilization can be measured by integrating the gating current tails as the channels close at pulse termination (Q_{OFF}) and comparing them with the activation charge movement (Q_{ON}). The OFF gating currents diminish in both amplitude and area as the duration of the pulse was increased as shown in Fig. 2. After a depolarization of 10 ms (not shown), the OFF/ON ratio was 0.2; that is, 80% of the gating charge was temporarily immobilized and returned to its resting position too slowly to detect.

Table 1 Comparison of the time constants at 8 °C of sodium current inactivation (τ_{h} and τ_{tails}) and gating current immobilization (τ_{immob})

Potential	$\tau_{\text{h}}(n)$	$\tau_{\text{tails}}(n)$	$\tau_{\text{immob}}(n)$
−20 mV	0.55 ± 0.01 (4)	—	—
0 mV	0.46 ± 0.01 (4)	0.44 (1)	0.45 ± 0.04 (2)
+20 mV	0.39 ± 0.02 (3)	—	0.39 (1)
+40 mV	0.36 ± 0.01 (3)	0.31 (1)	0.38 (1)

n, Number of readings.

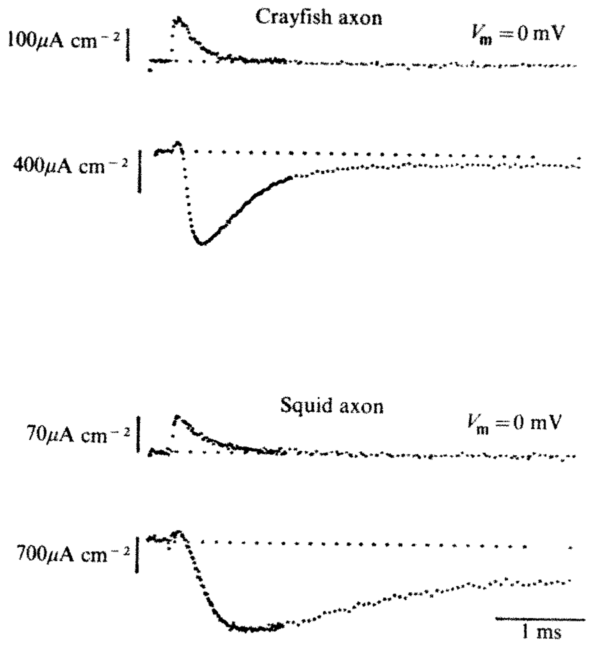

Fig. 1 Sodium and gating currents from crayfish and squid giant axon. Depolarizations to 0 mV from holding potentials of −80 mV (crayfish) and −70 mV (squid) elicit sodium currents of dramatically different time courses (lower traces). The ON gating currents (upper traces), are similar from the two nerves, and in neither is there a component with the time course of inactivation. Leakage and capacitive currents were subtracted using P/4 technique[5] from both I_{Na} and I_{g} records, and I_{g} represents the addition of 10 records. Crayfish currents were recorded with 70 mM NaCl, 140 mM Trizma (*p*H 7.0), and 20 mM $CaCl_2$ externally and 60 mM CsF, 60 mM Cs_3Citrate, and 120 mM mannitol internally. 10^{-7} M TTX was added externally to record I_{g} (axon Fe010Z). Squid currents were recorded in 112 mM NaCl, 378 mM Trizma (*p*H 7.0), 50 mM $CaCl_2$ externally and 150 tetramethylammonium (TMA) glutamate, 50 mM TMAF, and 650 mM sucrose internally (axon AU169Z). Temperature, 8 °C.

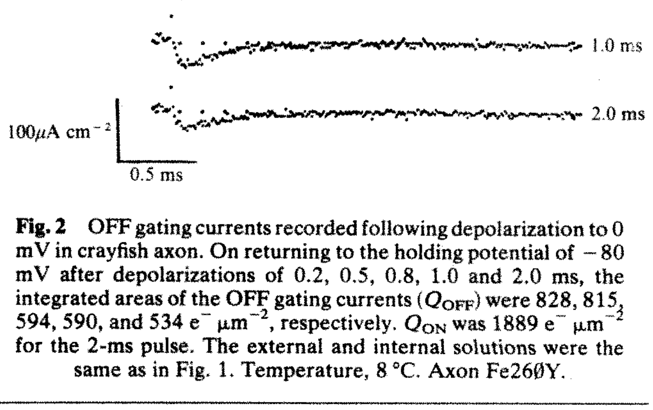

Fig. 2 OFF gating currents recorded following depolarization to 0 mV in crayfish axon. On returning to the holding potential of −80 mV after depolarizations of 0.2, 0.5, 0.8, 1.0 and 2.0 ms, the integrated areas of the OFF gating currents (Q_{OFF}) were 828, 815, 594, 590, and 534 e⁻ μm^{-2}, respectively. Q_{ON} was 1889 e⁻ μm^{-2} for the 2-ms pulse. The external and internal solutions were the same as in Fig. 1. Temperature, 8 °C. Axon Fe260Y.

0028-0836/80/410644—02$01.00

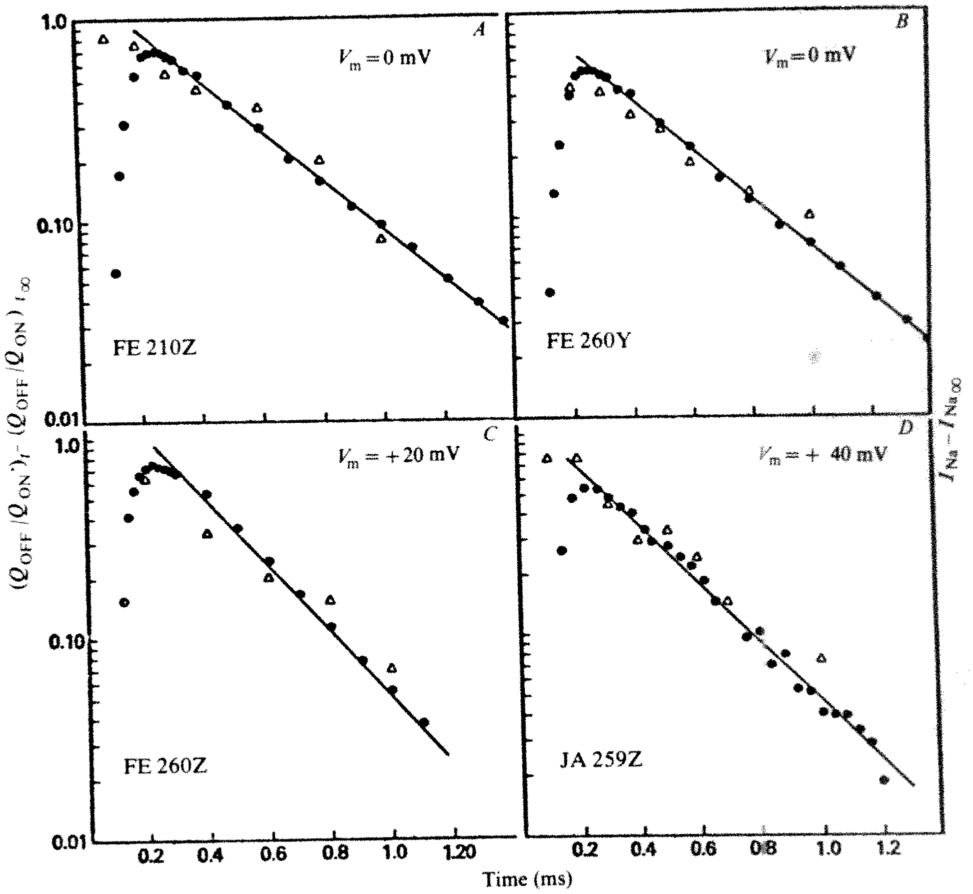

Fig. 3 Comparison of the rates of inactivation of the sodium current (●) and immobilization of the gating current (△) at 0, +20, and +40 mV in crayfish axon. ($I_{Na} - I_{Na\infty}$) is plotted where $I_{Na\infty}$ is the steady state sodium current. Axon Fe010Z. The sodium current in *a* and *b* is identical but slightly compressed on the vertical axis in *b*. Solutions as in Figs 1 and 2 without TTX. Peak amplitudes of the sodium currents were 0.84, 0.43, and 0.16 mA/cm^2 for 0, +20, and +40 mV, respectively. Superimposed on the sodium currents is the degree of immobilization (△) from four different axons measured from the area of the OFF gating currents after varying duration pulses. The OFF areas are plotted as the ratio of the integrated OFF gating current to ON gating current, $(Q_{OFF}/Q_{ON})_t$, minus a baseline correction, $(Q_{OFF}/Q_{ON})_{t\infty}$. t_∞ was 3.0 or 10.0 ms. *a*, Axon Fe210Z; *b*, Fe260Y; *c*, Fe260Z; and *d*, JA259Z. Solutions were the same as in Figs 1 and 2 with TTX. Temperature, 8 °C in all cases.

The temporal correlation between inactivation and immobilization is exemplified in Fig. 3, where sodium currents from one experiment are plotted on a semilogarithmic scale together with the OFF/ON ratio from other experiments. To allow for incomplete ON charge movement following brief pulses (0.5 ms), the OFF charge movement is normalized against the ON charge movement at various times ($[Q_{OFF}/Q_{ON}]_t$) and the baseline ($[Q_{OFF}/Q_{ON}]_{t\infty}$) was subtracted. Four experiments are shown, two at 0 mv, and one each at +20 and +40 mV. In all four, inactivation and immobilization agree closely in time course.

Table 1 summarizes the measurements of the time constant of immobilization (τ_{immob}), the time constant of inactivation of the sodium current measured from falling phase of the sodium current (τ_h), and the time constant of inactivation of the sodium current measured from sodium tail currents (τ_{tails}) at several potentials. The falling phase of the sodium current was well fitted by a single exponential. The two methods of measuring the rate in inactivation agree with one another, and were practically identical to τ_{immob}.

Although crayfish gating currents differ slightly in form from those measured in squid axons, the relatively fast rate of inactivation has allowed further evaluation of the relationship between the processes of inactivation and immobilization. The measurements reported here conform closely to the predictions of a coupled model: no inactivation gating current is visible in spite of the rapid time course of inactivation, and the time courses of inactivation and immobilization are identical. From these observations and others[3,6] it seems that inactivation of the sodium current and immobilization of the gating charge are in fact manifestations of the same underlying event. Following reorganization of the charged particles in the nerve which permits sodium conductance, a state develops which is characterized by both diminished conductance and a decreased ability of the charged particles to reprime. The development of this state can be followed either as inactivation of sodium current or immobilization of sodium gating current.

Are only α_2-adrenergic receptors present in bovine retina?

Helmut Bittiger, Jakob Heid & Niklaus Wigger

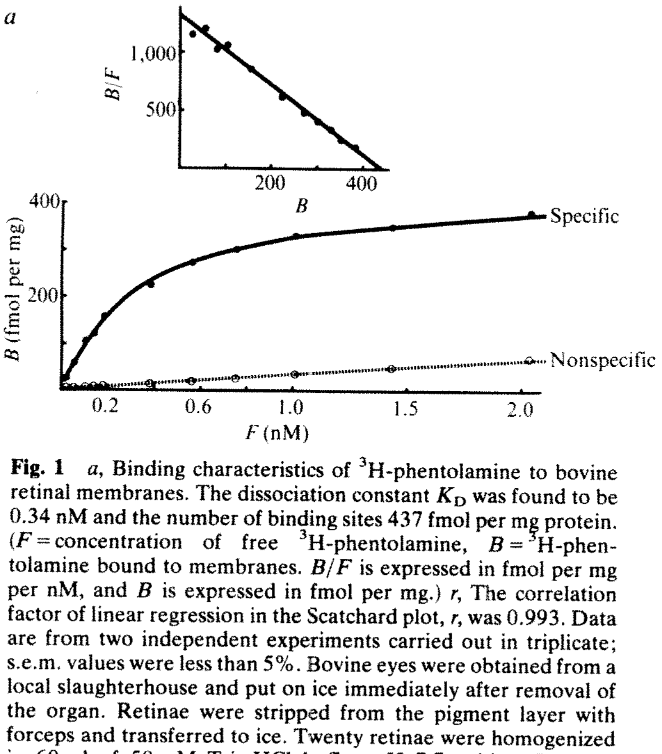
Research Department of the Pharmaceuticals Division of Ciba-Geigy Ltd, CH-4002 Basle, Switzerland

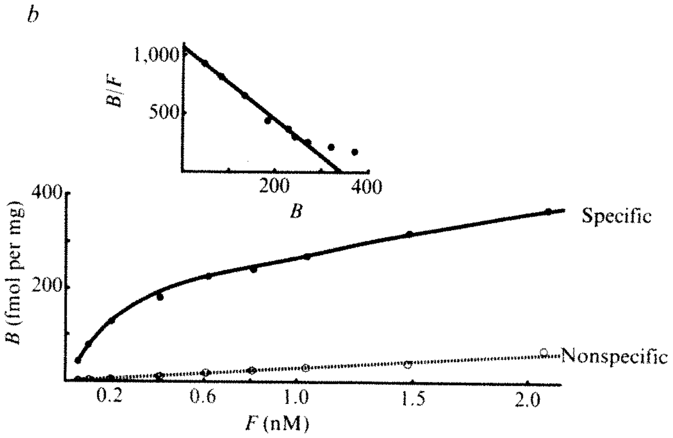
The retina represents a part of the central nervous system (CNS) with a well studied, geometrically defined structure and a specialized function—the processing of light signals[1]. Neurotransmitters such as glutamate,. aspartate, glycine[2–4], γ-aminobutyric acid (GABA), dopamine and acetylcholine[5–9] are considered to be involved in the neuronal activity of the retina. Receptors for acetylcholine[10,11], GABA[12], dopamine[13] and benzodiazepines[14,15] have also been demonstrated. Thus, the retina can be considered as a model for the study of neuronal processing in general, in which the input, light signals, can be selected and regulated in a defined way. We report here that α-adrenergic receptors in the bovine retina have been characterized using radioreceptor assays. ^{3}H-phentolamine (an α_1- and α_2-antagonist), ^{3}H-clonidine (a preferential α_2-agonist) and ^{3}H-WB 4101 [(2,6-dimethoxyphenoxyethyl)aminomethyl-1,4-benzodioxane, an α_1-antagonist[16]] were used as radioligands,

and WB 4101 and prazosin[17] (α_1-antagonists), tolazine (an α_2-antagonist)[18], yohimbine and its stereoisomers rauwolscine (preference for α_2-receptors) and corynanthine (preference for α_1-receptors)[19,20], were used as inhibitors of radioligand binding. Only α_2-adrenergic receptors[21,22] were found.

Figure 1*a* gives the saturation curve and corresponding Scatchard plot for ^{3}H-phentolamine binding. The dissociation constant (K_D) was found to be 3.4×10^{-10} M and the number of binding sites 437 fmol per mg protein. Nonspecific binding was defined in the presence of 10^{-6} M phentolamine and was only 5–10% of total binding. Association and dissociation were remarkably rapid in view of the low K_D values. At 20 °C and a concentration of 0.5 nM ^{3}H-phentolamine, half-saturation of binding was achieved within 2.5 min, and the half life of dissociation was 2.5 min (data not shown). ^{3}H-clonidine showed nearly identical binding characteristics (Fig. 1*b*), with a dissociation constant of 3.2×10^{-10} M and 341 fmol binding sites per mg protein. Association and dissociation had half lives of 1.5–2 min for a fast component, but there were, in addition, slower components with about 5–10-min half lives, which contributed about 20% of the total binding sites (data not shown). The binding characteristics of ^{3}H-WB 4101 are presented in Fig. 1*c*. Phentolamine, 10^{-6} M, was used to define nonspecific binding. The dissociation constant of 3.42 nM was higher but the number of binding sites of 378 fmol per mg protein comparable to those obtained with ^{3}H-phentolamine and ^{3}H-clonidine. The ratio of specific to nonspecific binding was much less favourable than with ^{3}H-clonidine and ^{3}H-phentolamine. Selected compounds were tested for their effects on ^{3}H-phentolamine, ^{3}H-clonidine and ^{3}H-WB 4101 binding in the retina and on ^{3}H-WB 4101 binding in the rat brain (see Table 1). The latter values are from own experiments or the literature[23]. Data from rat brain are usually similar to those from bovine brain[23,24]. Surprisingly, all compounds studied in the retina inhibited with about equal potency in all three radioreceptor assays. The somewhat lower IC$_{50}$ values in the ^{3}H-WB 4101 assay are probably due to the fact that the ^{3}H-ligand concentrat on of 1 nM was below the K_D of 3.42 nM, whereas those of ^{3}H-phentolamine and ^{3}H-clonidine were slightly above. Only agonists like noradrenaline, dopamine and clonidine were more potent in the ^{3}H-clonidine assay.

The order of inhibitory potencies of yohimbine and its stereoisomers in the retina was found to be rauwolscine > yohimbine > corynanthine, typical of α_2-receptors[20]. In the brain ^{3}H-WB 4101 assay, however (Table 1, last column), the reverse order, typical of α_1-receptors, was found[20]. Consistent with these findings, tolazoline, interacting preferentially with α_2-receptors, inhibited 140 times more potently in the retina





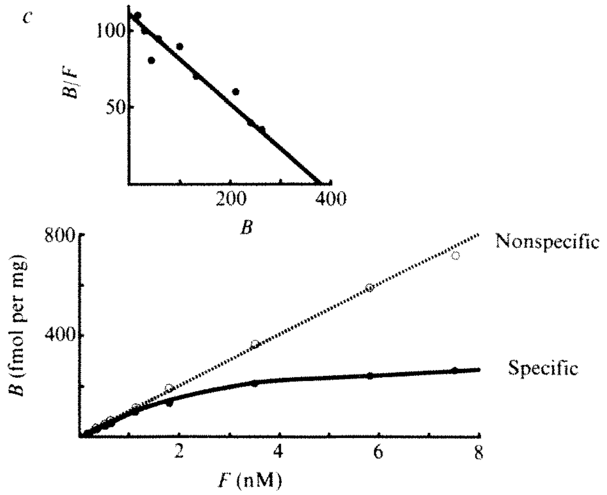


Fig. 1 *a*, Binding characteristics of ^{3}H-phentolamine to bovine retinal membranes. The dissociation constant K_D was found to be 0.34 nM and the number of binding sites 437 fmol per mg protein. (F = concentration of free ^{3}H-phentolamine, B = ^{3}H-phentolamine bound to membranes. B/F is expressed in fmol per mg per nM, and B is expressed in fmol per mg.) r, The correlation factor of linear regression in the Scatchard plot, r, was 0.993. Data are from two independent experiments carried out in triplicate; s.e.m. values were less than 5%. Bovine eyes were obtained from a local slaughterhouse and put on ice immediately after removal of the organ. Retinae were stripped from the pigment layer with forceps and transferred to ice. Twenty retinae were homogenized in 60 ml of 50 mM Tris-HCl buffer, *p*H 7.7, with a Polytron homogenizer (2 × 15 s, position 5) at 4 °C. The homogenate was centrifuged at 1,000*g* for 15 min and the resulting supernatant at 40,000*g* for 15 min. The pellet was resuspended in 50 mM Tris-HCl buffer, *p*H 7.7, and recentrifuged at 40,000*g* for 15 min. This step was repeated. The final pellet was suspended in about 100 ml buffer to give a final concentration of 1.5–2 mg protein per ml. The assay was carried out at 20 °C in 3 ml 50 mM Tris-HCl buffer, *p*H 7.7, containing 150–200 μg membrane protein and different concentrations of ^{3}H-phentolamine (20 Ci mmol^{-1}, prepared in the Ciba-Geigy radioisotope laboratories by halogen–tritium exchange in the aromatic ring, purity >98% as shown by pressure liquid chromatography and isotope dilution analysis). Incubation was for 15 min and was terminated by rapid filtration through Whatman glass fibre filters GF/B and three washes with 4 ml ice-cold buffer. Nonspecific binding was defined in the presence of 10^{-6} M phentolamine. Filter-bound material was digested in Soluene (Packard) and radioactivity was counted by addition of scintillator (Aquasol, NEN) in an Intertechnique liquid scintillation counter at an efficiency of 42%. *b*, Binding characteristics of ^{3}H-clonidine (NEN, 22.2 Ci mmol^{-1}) to bovine retinal membranes. The dissociation constant K_D was found to be 0.32 nM, the number of binding sites 341 fmol per mg protein and r 0.992. The experiments were performed as described in *a*. Nonspecific binding was defined in the presence of 10^{-6} M clonidine. *c*, Binding of ^{3}H-WB 4101 (NEN, 24.2 Ci mmol^{-1}) to bovine retinal membranes. Nonspecific binding was defined in the presence of 10^{-6} M phentolamine. The dissociation constant was found to be 3.42 nM, the number of binding sites 378 fmol per mg protein, comparable to those of ^{3}H-phentolamine and ^{3}H-clonidine, and r 0.948. To reduce nonspecific binding, retinae were osmotically shocked during the first homogenization in 1 mM Tris-HCl buffer and filtration was through GF/C glass fibre filters. Otherwise the procedure was as described in *a*.

Table 1 Radioligand inhibition of drug binding to retinal and brain membranes

	Retina			Brain	
Compound	^{3}H-phentolamine IC$_{50}$ (M)	^{3}H-clonidine IC$_{50}$ (M)	^{3}H-WB 4101 IC$_{50}$ (M)	^{3}H-WB 4101 K_i or IC$_{50}$ (M)	
Phentolamine	1.0×10^{-9}	1.0×10^{-9}	8.0×10^{-10}	1.0×10^{-8}	
Clonidine	6.4×10^{-9}	1.4×10^{-9}	3.6×10^{-9}	4.3×10^{-7}	(ref. 23)
WB 4101	2.0×10^{-8}	2.0×10^{-8}	1.6×10^{-8}	6.0×10^{-10}	(ref. 23)
Prazosin	5.8×10^{-6}	7.2×10^{-6}	2.0×10^{-6}	8.0×10^{-10}	
Tolazoline	5.0×10^{-8}	3.6×10^{-8}	6.4×10^{-8}	8.0×10^{-6}	
Yohimbine	5.0×10^{-8}	5.6×10^{-8}	3.6×10^{-8}	4.8×10^{-7}	
Rauwolscine	1.0×10^{-8}	1.6×10^{-8}	5.6×10^{-9}	1.0×10^{-5}	
Corynanthine	1.1×10^{-6}	1.1×10^{-6}	6.4×10^{-7}	3.0×10^{-7}	
Noradrenaline	2.6×10^{-7}	5.0×10^{-8}	2.2×10^{-7}	1.0×10^{-6}	(ref. 23)
Dopamine	2.0×10^{-6}	6.0×10^{-7}	1.6×10^{-6}	4.4×10^{-5}	(ref. 23)
Propranolol	$>10^{-5}$	$>10^{-5}$		6.9×10^{-6}	(ref. 23)

Assays were carried out as described in Fig. 1 legend. Drugs were added to the incubation medium at the same time as the radioligands. Concentrations of ^{3}H-phentolamine and ^{3}H-clonidine were 0.5 nM (slightly above K_D) and that of ^{3}H-WB 4101 nM (below K_D). IC$_{50}$ values were determined graphically from 8–10 different concentrations of drugs, each point performed in triplicate. Brain membranes were prepared as described in the literature[23] and the radioreceptor assays were carried out as described for retinal membranes.

than in the brain, whereas WB 4101 and prazosin, α_1-antagonists, were respectively, 30 and up to 2,000 times, more potent in the brain. Thus, the retinal α-receptors labelled by ^{3}H-phentolamine, ^{3}H-clonidine and ^{3}H-WB 4101 seem to be of the α_2-type and the brain receptors labelled by ^{3}H-WB 4101 of the α_1-type.

The retinal α-receptors seem to differ from α-receptors in all tissues or cells so far studied with these three radioligands. The K_D for ^{3}H-clonidine binding (0.32 nM) is much lower than that found in brain (5.6 nM)[23], although recently by using a special technique, a minority of high affinity ^{3}H-clonidine binding sites (0.5 nM) has been detected in brain[26]. ^{3}H-WB 4101, on the other hand, binds with much lower affinity to retinal (3.42 nM) than to brain membranes (0.35 nM)[23] and seems to label α_2-receptors in the retina and α_1-receptors in the brain. As seen in Table 1, prazosin seems to be more specific for α_1-receptors than is WB 4101. ^{3}H-phentolamine has a 35 times higher affinity for retinal α-receptors ($K_D = 0.34$ nM) than has been reported for α-receptors on human platelets ($K_D = 12$ nM)[25]. We have found that ^{3}H-phentolamine is not a suitable ligand for studying α-receptors in brain membranes, as very little specific binding can be detected. This may be due to the approximately 30 times higher dissociation constant in brain, as estimated from the inhibition constants in the ^{3}H-clonidine and ^{3}H-WB 4101 assays, which were of the order of 10^{-8} M (Table 1).

Retinal α-receptors seem to be peculiar in another respect. The relative inhibitory potencies of the agonists clonidine, dopamine and noradrenaline differ at most by a factor of five in the three radioreceptor assays. In the brain, however, these agonists are 60–180 times more potent in the ^{3}H-clonidine assay than in the ^{3}H-WB 4101 assay[23].

Receptors of the α_2-type have also been described on postsynaptic organs[27,28], so it cannot be concluded that the retinal α_2-receptors are functionally presynaptic. In marked contrast to the large number of α-receptors present in the retina, the concentration of noradrenaline is very low[8]. On the other hand, dopamine is found in retinae of different species[8]; binding to the retinal α_2-receptors and a functional interaction between the two cannot be excluded. Our studies do not reveal whether retinal α-receptors are functional or simply phylogenetic remnants.

In conclusion, the retina seems to be specific not only in geometry and function, but also in terms of neurotransmitter receptors. The specialization of α_2-receptors in the retina may have important consequences not only for the mechanism of signal processing in this part of the CNS, but also in a minority of receptors[26] for neuronal processing in other parts of the CNS.

Retrograde axonal transport of target tissue-derived macromolecules

I. A. Hendry & C. E. Hill

Department of Pharmacology, John Curtin School of Medical Research, Australian National University, PO Box 334, Canberra, Australia

Neurones depend on contact with their target tissues for survival and subsequent development[1–4]. The protein, nerve growth factor (NGF), can be selectively taken up by sympathetic nerve terminals and reaches the neuronal perikaryon by a process of retrograde intra-axonal transport[5], suggesting that its role *in vivo* is to act as a target tissue-derived trophic factor[6]. The development of the neurones of the chick ciliary ganglion requires the presence of structures derived from the optic cup[4]. Several studies *in vitro* have shown that media conditioned by non-neuronal cells contain factors that result in the survival of neurones from ciliary ganglia[7–11]. In particular, chick embryo iris, ciliary body and choroid contained large amounts of these factors indicating the presence of a target tissue-derived trophic factor for the cholinergic ciliary ganglion[12]. This study demonstrates that neurones of the ciliary ganglion accumulate, by retrograde intra-axonal transport, proteins synthesized and released by optic tissues in culture.

0028-0836/80/410647—03$01.00

The iris, ciliary body and choroid were dissected aseptically from 19-day-old chicken embryos, and material from one eye placed in 2 ml of Eagle's medium containing Hanks salts, 50 mM HEPES and 100 U ml^{-1} penicillin, and incubated at 37 °C in humid air. The ability of the conditioned medium to support parasympathetic neurones from 8-day-old chick embryos was assessed after 24 h in culture as previously described[13], and one trophic unit was defined by the volume of conditioned medium required to obtain a 50% neuronal survival[11,13].

The amount of neurotrophic activity in the medium increased with time and reached a level of 80 U ml^{-1} after 5 days. Parallel cultures containing ^3H-labelled amino acid mixture (Amersham, TRK 440) at 0.5 mCi ml^{-1} in place of the corresponding unlabelled amino acids showed a large accumulation of labelled protein in the medium; at 5 days 9% of the total radioactivity was precipitated by 5% trichloroacetic acid. The radioactive medium was dialysed against 154 mM NaCl to lower the labelled amino acid content and then 25-μl aliquots were injected into the right eye of either 1-day-old or 2-week-old chicks. After 16 h, right and left ciliary ganglia were removed, homogenized separately in 100 μl distilled water, and 20-μl samples counted in a scintillation counter. There was a significant accumulation of radiolabel in the ganglion on the injected side compared to the non-injected side indicating the retrograde axonal transport of material from the conditioned medium (Table 1). This accumulation of radioactivity was unlikely to be due to diffusion from the injection site, as an injection of 25 times the amount of ^3H-labelled amino acids in 154 mM NaCl did not result in a significant accumulation of radioactivity on the injected side (Table 1). This also demonstrates that the effect seen with the conditioned medium was not due to transport of residual labelled amino acids in the medium.

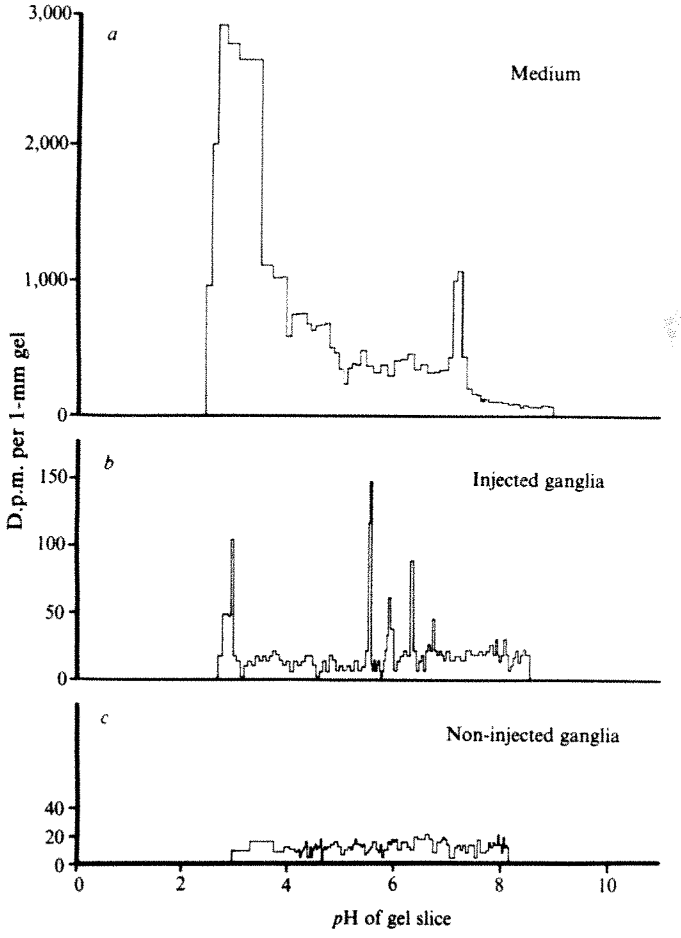

Fig. 1 Distribution of radioactivity after isoelectric focusing of: *a*, medium containing ^3H-labelled amino acids and conditioned by a 5-day exposure to optic tissues from 19-day-old chick embryos. *b*, Pooled homogenates of right ciliary ganglia from six 2-week-old chicks injected in the right eye with this conditioned medium. *c*, Homogenates of left ciliary ganglia from the same animals. In each case gels were cut into 1-mm sections which were eluted with 1 ml distilled water for radioactivity and *p*H measurements. The radioactivity (d.p.m.) is plotted against the *p*H of each gel slice.

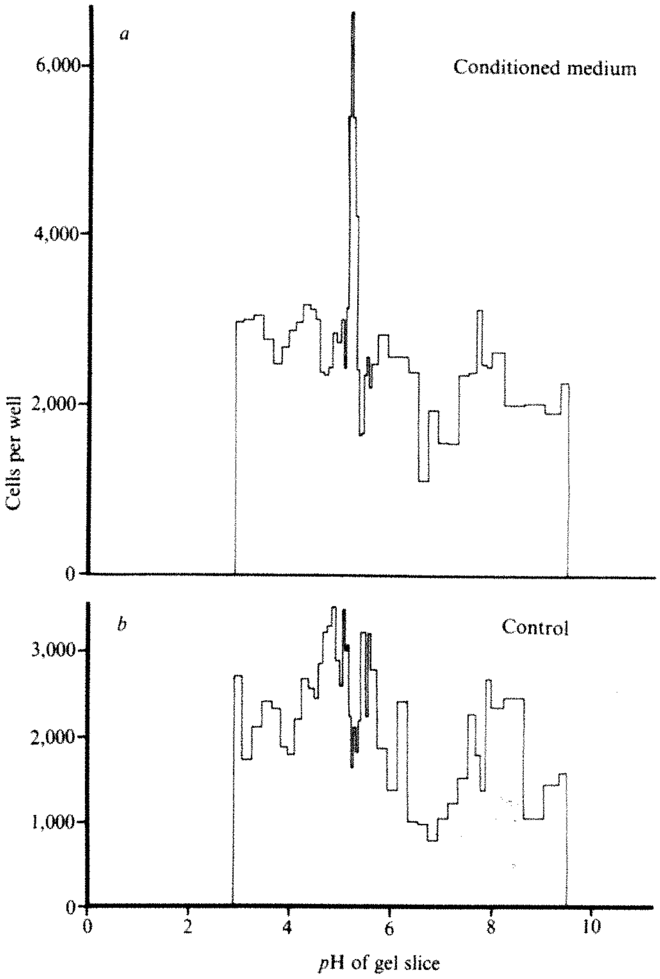

Fig. 2 Survival of parasympathetic neurones from 8-day-old chick embryos after 24 h in the presence of dialysed eluates of 1-mm slices from polyacrylamide isoelectric focusing gels. *a*, Medium conditioned by optic tissues. *b*, Control gel. The number of surviving neurones per 2-cm^2 well is plotted against the *p*H of each gel slice. In the absence of conditioned medium or gel eluates 900–1,500 cells per 2-cm^2 well survived.

To determine the selectivity of the retrograde transport, the macromolecules in the conditioned medium and in the pooled ciliary ganglion homogenates from the injected and non-injected sides were separated by polyacrylamide gel isoelectric focusing using *p*H 3.5–10 ampholines (LKB). There were many labelled macromolecules in the conditioned medium (Fig. 1*a*) but only five major labelled species were seen in homogenates of ciliary ganglia from the injected sides of 2-week-old chicks (Fig. 1*b*). Thus the retrograde axonal transport was selective for comparatively few of the macromolecules released by the cultured target tissues. There were no major radioactive peaks detected in the homogenates of the ciliary ganglia from the non-injected sides (Fig. 1*c*).

The ability of the conditioned medium to support parasympathetic neurones was assessed after polyacrylamide gel isoelectric focusing to see if any of the transported species might have neurotrophic activity. Conditioned medium was dialysed for 6 h against distilled water and the gels run for 3 h at 0 °C. Serial 1-mm slices were each eluted with 1 ml distilled water and the *p*H determined. The ampholines were then removed by

Table 1 Accumulation of radioactivity in chick ciliary ganglion after intraocular injection of radioactive conditioned medium or ^{3}H-labelled amino acids

	Age of injected chicks	Radioactivity (d.p.m. per ganglion)	
		Injected	Non-injected
Conditioned medium	1 day	2820 ± 630 (4)	15 ± 11 (4)
	2 week	6690 ± 645 (7)	90 ± 33 (7)
^{3}H-labelled amino acids	1 day	50 ± 10 (6)	33 ± 10 (6)
	2 week	9 ± 6 (6)	13 ± 5 (6)

The right eye was injected with 25 μl of either ^{3}H-labelled amino acids, 10 μCi or conditioned medium, 0.4 μCi. Sixteen hours later the right and left ciliary ganglia were removed and the radioactivity estimated. No. of ganglia in parentheses.

dialysis against 10 mM HEPES, *p*H 7.4, before the sample was mixed with medium for the determination of neurotrophic activity. Control gels were run similarly with distilled water in place of the conditioned medium. The component of the conditioned medium responsible for neuronal survival focused in the region of *p*H 5 (Fig. 2). One of the retrogradely transported radioactive proteins also focused in this region, suggesting that they may be the same.

In all neurones there must be a system for the retrograde transfer of information from the target cell to the innervating neurone. This information transfer can be accomplished by target tissues synthesizing and releasing proteins which are taken up by nerve terminals and *retro*gradely transported to neuronal cell bodies resulting in appropriate stimulation of metabolic pathways. It is likely that at least one of the retrogradely transported species described here is a retrophin (the *retro*gradely transported target tissue-derived neuro*trophic* factor) for neurones of the ciliary ganglia.

We thank Swee Lan Tan, Beverley Foote and Charles Claudianos for technical assistance and Dr I. S. McLennan, Mrs R. E. Bonyhady and Professor D. R. Curtis for helpful discussions. C.E.H. is a recipient of a Research Fellowship and a Grant-in-Aid from the National Heart Foundation of Australia. The name retrophin was first suggested by Professor G. A. R. Johnston.

Transmitter release from frog motor nerve terminals depends on motor unit size

A. A. Herrera & A. D. Grinnell

Department of Physiology, Jerry Lewis Neuromuscular Research
Center, Ahmanson Laboratory of Neurobiology, School of Medicine,
University of California, Los Angeles, California 90024

It has been postulated that the success with which a motor nerve terminal competes for synaptic connections[1,2] or the ability of an axon to maintain sprouts[3] may depend on the support each terminal receives from its soma, presumably in the form of some substance(s) synthesized there. The support received by each terminal may in turn depend on the total number of terminals maintained by that soma, namely, motor unit size. We show here that when motor unit size is experimentally decreased, transmitter release from the terminals is markedly enhanced. This is consistent with the view that the extent of support from the soma may also influence the effectiveness of synaptic transmission.

Eight to 12 weeks before acute experiments, the left sartorius nerve of adult *Rana pipiens* (body length 4.5–6.5 cm, anaesthetized in 0.2% tricaine methanesulphonate) was crushed near its entrance to the muscle. A lengthwise cut was made through the sartorius to remove muscle fibres in its lateral half. Thus when the motor axons regenerated, they encountered and re-innervated approximately half the normal number of fibres. Although there was repair of damaged muscle fibres at the cut edge, there was no evidence of substantial muscle regeneration. Control sartorius muscles, where the nerve was crushed but the muscle left intact, and normal muscles from unoperated frogs were tested for comparison. Samples were compared with the Mann–Whitney *U*-test unless otherwise noted. All data are presented here as mean ± s.e.m.

The number of increments in twitch tension produced by slowly increasing or decreasing the strength of a stimulus to the nerve was not significantly different ($P < 0.05$, Kruskal–Wallis *H*-test) in experimental (9.7 ± 0.5, $n = 14$), control (9.1 ± 0.9, $n = 7$) and normal (8.2 ± 0.35, $n = 13$) muscles suggesting that muscles in both operated groups become re-innervated by the same number of motor axons. Maximal twitch tension in experimental muscles (10.7 ± 1.4 g, $n = 15$) averaged approximately two-thirds that of controls (16.3 ± 2.0 g, $n = 7$), reflecting the removal of a substantial number of muscle fibres. In both whole and halved re-innervated muscles, the distribution of motor unit sizes, relative to the maximum tension that could be evoked, was essentially the same as normal. Mean motor unit size, expressed as a percentage of maximal nerve evoked tension, was not significantly different in experimental (10.1%), control (11.0%) or normal (12.2%) muscles. These observations suggest that most or all motor axons participated in re-innervation and that the size of the peripheral field of each motoneurone in the experimental case was indeed reduced.

Synaptic strength was tested in two ways, using previously described techniques[4]. In each case the degree of stretch of the muscle, known to affect synaptic strength[5], was carefully controlled. The first method, which estimates safety factors for junctional transmission, consisted of measuring the tension of twitches evoked by a single nerve stimulus while varying Ca^{2+} concentration in the Ringer's solution. When the Ca^{2+} concentration is lowered, twitch tension falls as transmission at the strongest junction on different fibres becomes sub-threshold[4]. At any particular low Ca^{2+} concentration, the extent to which tension has fallen is a measure of safety factors at junctions in that muscle. Using this approach, we compared safety factors in experimental, control and normal muscles by measuring the tension remaining after Ca^{2+} concentration was lowered from a normal value of 1.8 mM to 1.0 and 0.6 mM (Fig. 1). In Ringer containing 1 mM Ca^{2+}, tension in experimental muscles with reduced motor unit size fell only to 79% of the tension in normal Ringer. This was significantly more than the tension remaining in control or normal muscles (55% and 42% respectively, $P < 0.01$). Results from control and normal muscles were not significantly different ($P > 0.05$). In 0.6 mM Ca^{2+}, experimental muscle tension only fell to 22%, whereas control tension averaged 4% and normal tension 5%. Again, the differences between the experimental case and the other two cases were significant ($P < 0.02$).

The second method of testing synaptic strength was designed to determine if the increase in safety factor was due to a

0028–0836/80/410649—03$01.00

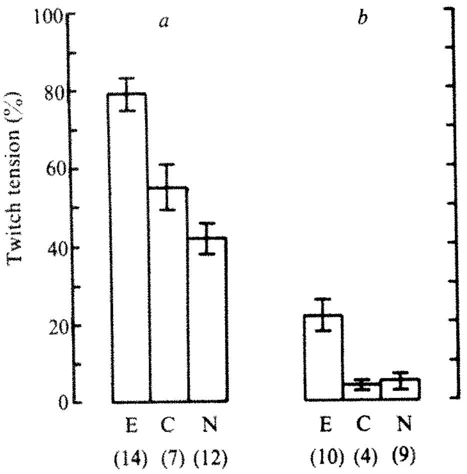

Fig. 1 The effect of lowered Ca^{2+} concentration (*a*, 1.0 and *b*, 0.6 mM) on twitch tension evoked by nerve stimulation. Tension is expressed as a percentage of the tension generated in normal Ringer containing 1.8 mM Ca^{2+}. At each concentration the mean, 2×s.e.m., and the number of muscles tested are shown for experimental (E, re-innervated half sartorius), control (C, re-innervated whole sartorius) and normal (N, unoperated sartorius) muscles. Experimental and control muscles were denervated by nerve crush 60–84 days earlier.

difference in the amount of transmitter release from nerve terminals in the experimental muscles. We measured end plate potential (e.p.p.) quantal content in Ringer containing 0.3 mM Ca^{2+} and 1 mM Mg^{2+}. For the operated muscles, junctions on regenerated muscle fibres in the area of the cut were not included in the quantal content analysis, nor were multiply innervated junctions, which were occasionally found but not at a frequency noticeably higher than in re-innervated whole muscle controls. As shown in Table 1, quantal content in muscles with reduced motor unit size was more than twice as great as that of control junctions (6.3 compared with 2.8) and three times greater than quantal content at normal junctions (2.1). The difference between experimental and control junctions was statistically significant ($P < 0.02$), but that between control and normal junctions was not. Miniature e.p.p. frequencies in the half muscles were also greater to approximately the same degree.

Because it has been shown that quantal content depends in part on nerve terminal size[6], the junctions from which recordings were made were marked by injection of a dye into the muscle fibre. These fibres were then identified in the light microscope and stained with the nitro blue tetrazolium (NBT) nerve terminal stain[7] and cholinesterase (ChE) stain[8]. Nerve terminal length was taken to be the sum of the individual lengths of NBT-stained processes located within the synaptic gutters outlined by ChE stain. As ChE activity persists for many weeks even in denervated gutters, we were able to observe that for both the re-innervated whole muscles and the undamaged fibres of the halved muscle, re-innervation occurred only at old endplate sites. No NBT-stained terminals were found without ChE and ChE deposits always looked normal in shape and size, unlike ectopic synapses seen in foreign nerve re-innervated sartorius muscles (A.D.G., unpublished data) or *de novo* synapses on cutaneous pectoris muscle fragments[9]. We conclude, therefore, that few if any ectopic synapses were formed. Using identified terminals that had been studied electrophysiologically, quantal contents were normalized to nerve terminal length. As shown in Table 1, terminals in muscles with reduced motor unit size released 1.89 quanta per 100-μm nerve terminal length. This was significantly higher than release per unit length in control (0.46) and normal (0.45) terminals (experimental versus control: $P < 0.002$; control versus normal: $P > 0.05$).

Table 1 Quantal content at sartorius junctions in Ringer containing 0.3 mM Ca^{2+} and 1 mM Mg^{2+}

	Quantal content	Quanta released per 100 μm
Re-innervated half sartorius	6.30 ± 0.84 (34)	1.89 ± 0.43 (21)
Re-innervated whole sartorius	2.79 ± 0.59 (19)	0.46 ± 0.09 (16)
Normal sartorius	2.07 ± 0.36 (25)	0.45 ± 0.09 (24)

Data shown are mean ± s.e.m. (*n*). For re-innervated muscles, the sartorius nerve was crushed 59–84 days previously.

Nerve terminals in experimental and control muscles were examined in the electron microscope to search for morphological correlates of this enhanced release. After processing the tissue as described previously[4], micrographs of randomly chosen transverse sections (×43,500) were examined for differences in: (1) the number of vesicles in a standard 0.528-μm² area just above the presynaptic membrane, (2) the number of mitochondria, (3) cross-sectional area, and (4) the width and character of the synaptic cleft. As shown in Table 2, neither vesicle density (possibly proportional to the number of readily releasable transmitter packets), nor the number of mitochondria (whose Ca^{2+}-sequestering activity may affect release[10]) differed significantly for experimental and control terminals. The cross-sectional area of control terminals did exceed that of experimental terminals by a marginally significant amount. We lack evidence for determining how such a difference could affect release. More relevant perhaps is our preliminary finding that control junctions show a higher incidence of interposition of Schwann cell processes between the pre- and post-synaptic membranes. Further observations on this point are in progress.

Table 2 Aspects of nerve terminal structure at experimental (re-innervated half sartorius) and control (re-innervated whole sartorius) junctions

	Experimental	Control	*P*
Vesicle density (no. vesicles per 0.528 μm²)	7.5 ± 0.5 (55)	7.0 ± 0.4 (34)	>0.05
No. mitochondria	3.0 ± 0.4 (65)	2.6 ± 0.4 (38)	>0.05
Cross-sectional area (μm²)	0.80 ± 0.06 (71)	1.10 ± 0.12 (38)	<0.05
% Junctions with interposed Schwann cell processes	18% (17/95)	36% (15/42)	
% Junctions with unobstructed synaptic apposition	82% (78/95)	64% (27/42)	

Data shown are mean ± s.e.m., with number of sections in parentheses.

It seems, therefore, that the process of transmitter release at frog neuromuscular junctions can show plasticity, with the size of the peripheral field of a motoneurone an important determining factor. If such variability in motor unit size occurs normally, it could help explain the relatively poor correlation that has been found between quantal content and nerve terminal size[4,6]. The dependence of release on motor unit size may, on the other hand, occur only as an experimental result in response to altered motor unit size. Further, it is not known if the increase in transmitter output per unit length is a permanent change.

Our data are consistent with the hypothesis that the level of transmitter output from a terminal may be related to the amount of material that that terminal receives from its soma. Production and/or transport of this material is fixed during development so that the supply is appropriate for the peripheral field of each motoneurone. If the field size is changed, the motoneurone may not compensate and one would expect to see a change in transmitter release. In the present experiments, for example, the original amount of this material would be distributed to a smaller number of terminals, resulting in enhanced transmitter release.

Further experiments are in progress to determine if an increase in the number of terminals per axon results in a decrease in transmitter release.

Benzodiazepine recognition sites on GABA receptors

Moshe Gavish & Solomon H. Snyder*

Departments of Neuroscience, Pharmacology and Experimental Therapeutics, and Psychiatry and Behavioral Sciences, Johns Hopkins University School of Medicine, Baltimore, Maryland 21205

A role of γ-amino butyric acid (GABA) in benzodiazepine actions[1–3] is supported by the GABA stimulation of membrane-bound[4–8] and soluble[9,10] benzodiazepine receptors and preliminary evidence that GABA protects benzodiazepine receptors from heat inactivation[11]. We show here that the GABA receptors labelled by ^{3}H-muscimol possess a benzodiazepine recognition site, as benzodiazepines, in proportion to their pharmacological activity, protect ^{3}H-muscimol binding from inactivation by heat and the protein modifying reagent iodoacetamide. We also show that benzodiazepines and GABA act at apparently distinct sites to protect benzodiazepine receptors from heat and iodoacetamide.

Brain membranes were incubated with receptor 'protector' compounds, then were either heated or treated with iodoacetamide, and washed 15 times to remove the 'protectors'. In control membranes, seven washes restored ^{3}H-muscimol binding to control values after addition of GABA, while 15 washes were required to restore ^{3}H-flunitrazepam binding to control values after incubation with diazepam. The 15 routine washes used did not lower control binding of ^{3}H-flunitrazepam or ^{3}H-muscimol, presumably because any labile binding sites had already been degraded during the initial six washes used to remove endogenous GABA (Fig. 1).

GABA protects both ^{3}H-flunitrazepam and ^{3}H-muscimol binding from inactivation by heat or iodoacetamide (Fig. 1), but seems to be more effective in protecting ^{3}H-muscimol binding. Addition of 10 μM and 0.1 mM GABA apparently enhances ^{3}H-muscimol binding after heating. This may be due to the removal of factors[12] tightly bound to receptors by heating, which resembles the increased binding with freezing and thawing or with detergents[13]. Preliminary experiments with briefer periods of heating produced the same enhanced ^{3}H-muscimol binding in GABA-protected membranes.

The protection of flunitrazepam and muscimol binding by GABA reflects GABAergic synaptic actions, for diaminobutyric acid, structurally similar to GABA but devoid of GABAergic activity, fails to protect either ^{3}H-flunitrazepam or ^{3}H-muscimol binding from heat or iodoacetamide. In contrast, imidazoleacetic acid (IAA), which is slightly weaker than GABA in its synaptic effects, is somewhat less potent than GABA in protecting ^{3}H-flunitrazepam and ^{3}H-muscimol binding from heat inactivation.

4,5,6,7-Tetrahydroisoxazolo(5,4-*c*)pyridine-3-ol (THIP) competes strongly for ^{3}H-muscimol binding but does not stimulate benzodazepine receptor binding[14]; it acts as an antagonist at the GABA recognition site on benzodiazepine receptors to block GABA stimulation of ^{3}H-diazepam binding[15,16]. The finding that both THIP and the GABA antagonist bicuculline protect ^{3}H-flunitrazepam and ^{3}H-muscimol binding sites from heat inactivation indicate that occupancy by either agonist or antagonist can protect the receptor.

Benzodiazepines also protect both ^{3}H-flunitrazepam and ^{3}H-muscimol sites from heat and iodoacetamide. This effect reflects an affinity for benzodiazepine receptors, because Ro 5-6227, a benzodiazepine with a similar receptor affinity to diazepam, protects as well as does diazepam, whereas RO5-4964 and halazepam, benzodiazepines with low, weak benzodiazepine receptor affinity, do not protect ^{3}H-flunitrazepam and ^{3}H-muscimol binding.

In saturation analyses using 6–8 concentrations of ^{3}H-ligand, heat inactivation reduces numbers of binding sites (B_{max} in control and heated conditions, respectively, in fmol per mg protein are 440 and 142 for ^{3}H-muscimol and 600 and 190 for ^{3}H-flunitrazepam) for GABA and benzodiazepine receptors but has no effect on the dissociation constants (K_D: ^{3}H-muscimol 10.1 nM, ^{3}H-flunitrazepam 4.4 nM). Protection by GABA and diazepam involves changes in B_{max} values with no change in K_D. The increased values following heating observed for GABA-protected ^{3}H-muscimol binding also reflect increased B_{max} with unaltered K_D.

To explore the specificity of these protective effects we evaluated whether diazepam can protect dopamine or muscarinic cholinergic receptors from heat inactivation. Heating membranes at 55 °C for 30 min reduces ^{3}H-quinuclidinyl benzilate (^{3}H-QNB) binding to calf whole brain membranes (muscarinic receptors) and ^{3}H-spiroperidol binding to rat corpus striatal membranes (dopamine receptors) by 90%. Pretreatment with 10 μM diazepam in the same conditions that protected GABA and benzodiazepine receptors fails to protect dopamine and muscarinic receptor binding from heat inactivation. As an additional indication of specificity, chlorpromazine, haloperidol and phenothiazine pretreatment do not protect ^{3}H-muscimol or ^{3}H-flunitrazepam binding from heating.

To determine whether heat inactivation has similar effects on distinct GABA and benzodiazepine recognition sites on benzodiazepine receptors and whether protection by GABAergic and benzodiazepine compounds is exerted at both sites, we evaluated the influence of GABA (100 μM) on

Table 1 Interactions of GABA analogues and benzodiazepines in protecting ^{3}H-flunitrazepam and ^{3}H-muscimol binding sites from heat inactivation

Drug concentration (μM)	Per cent of unheated control ^{3}H-Flunitrazepam	^{3}H-Muscimol
—	15 ± 2	17 ± 1
GABA (10)	76 ± 8	128 ± 12
Diazepam (10)	48 ± 5	35 ± 3
Clonazepam (100)	45 ± 4	32 ± 3
IAA (100)	47 ± 6	80 ± 7
Bicuculline (100)	49 ± 5	47 ± 5
THIP (4,5,6,7-tetrahydroisoxazolo (5,4-*c*)pyridine-3-ol) (100)	38 ± 4	98 ± 8
GABA (10) + diazepam (10)	108 ± 9	194 ± 15
GABA (10) + clonazepam (10)	105 ± 7	188 ± 14
GABA (10) + IAA (100)	75 ± 6	130 ± 10
GABA (10) + bicuculline (100)	74 ± 5	135 ± 9
GABA (10) + THIP (100)	60 ± 4	109 ± 8
Diazepam (10) + IAA (100)	93 ± 8	140 ± 13
Diazepam (10) + bicuculline (100)	95 ± 8	79 ± 6
Diazepam (10) + THIP (100)	98 ± 8	140 ± 11

Methods were essentially as described in Fig. 1. Combinations of protecting substances were added simultaneously. Data are means ± s.e.m. for 8–10 determinations.

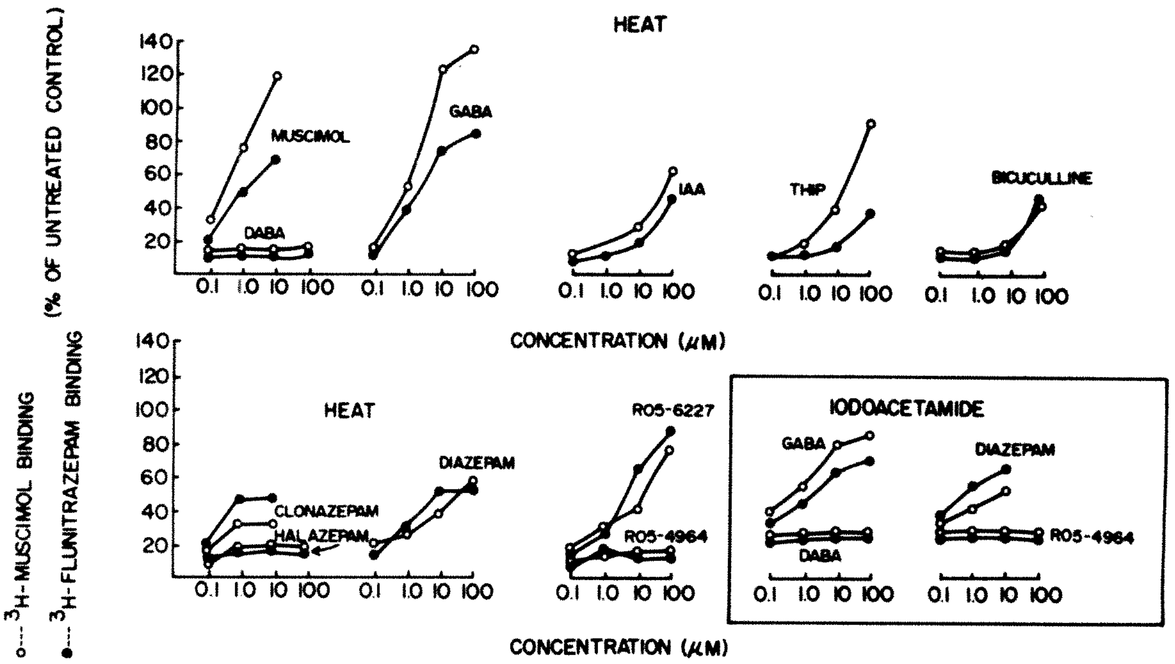

Fig. 1 Fresh calf brains were obtained from a slaughterhouse on ice within 30 min of death. Brains minus cerebella were homogenized with a Waring blender in 10 vol cie-cold 0.32 M sucrose and centrifuged 49,000*g* for 15 min at 4 °C. Pellets were resuspended in 2 vol 0.32 M sucrose and frozen for 18 h. After thawing, the tissue was washed five times by resuspension and recentrifugation with 40 vol 0.05 M Tris-HCl buffer (*p*H 7.4 at 4 °C) and refrozen for 18 h. After thawing, the tissue was washed once again by resuspension and recentrifugation with 40 vol 0.05 M Tris-HCl buffer. The pellet was then resuspended (70 µg protein ml^{-1}) in Tris-HCl buffer. The tissue was incubated for 30 min at 0 °C with different concentrations of drugs followed by either heat inactivation (30 min at 55 °C) or iodoacetamide treatment (0.1 M iodoacetamide 30 min at 37 °C). Samples were washed 14 times with Tris-HCl buffer and once again with 0.05 M Tris-citrate buffer (*p*H 7.1 at 4 °C). Incubation media contained 1.7 ml tissue (120 µg protein in Tris-citrate buffer), 0.1 ml ^{3}H-flunitrazepam (final concentration 0.4 nM), or ^{3}H-muscimol (final concentration 5.5 nM) and 0.2 ml of unlabelled drug (nonspecific binding) or H_2O (for total binding). To determine nonspecific binding incubations included 10 µM clonazepam (for flunitrazepam binding) or 100 µM GABA (for muscimol binding). After incubation (60 min at 0 °C) samples were filtered over GF/B filters and washed twice with cold Tris-HCl buffer. Filters were placed in vials containing 10 ml Formula 947 (NEN), shaken for 60 min and radioactivity was measured by liquid scintillation spectrometry. Data are means of 8–10 determinations. Protection from heating of both ^{3}H-flunitrazepam and ^{3}H-muscimol sites was significant ($P < 0.01$) for concentrations equal to or greater than 0.1 µM muscimol, 1 µM GABA, 10 µM IAA 10–100 µM THIP, 100 µM bicuculline, 1 µM clonazepam, 1 µM diazepam, 1 µM Ro 5-6227. Protection from iodoacetamide for ^{3}H-muscimol and ^{3}H-flunitrazepam was significant ($P < 0.01$) for concentrations equal to or exceeding 0.1 µM GABA and 0.1 µM diazepam. DABA, D,L-2,4-diaminobutyric acid.

^{3}H-flunitrazepam binding. In control unheated membranes as well as in heated membranes this concentration of GABA enhances ^{3}H-flunitrazepam binding about 60%. Moreover, half-maximal enhancement of ^{3}H-flunitrazepam binding occurs at 0.9 µM in both control and heated membranes. Additionally, in membranes treated with all the various protecting agents used in the present study, GABA (100 µM) uniformly enhances ^{3}H-flunitrazepam binding by 60%. Thus, GABAergic and benzodiazepine compounds protect the GABA recognition site of benzodiazepine receptors as well as their benzodiazepine recognition site.

Although GABA receptors clearly possess benzodiazepine recognition sites, we have failed to find stimulation or inhibition of ^{3}H-muscimol binding with 10 nM–10 µM clonazepam, an extremely potent benzodiazepine, and diazepam using Tris-citrate as well as Tris-HCl buffers.

To determine whether benzodiazepines and GABA protect the two receptors at the same or at different sites, we ascertained whether the effects of these substances were additive in protection experiments (Table 1). Maximal protection by GABA and IAA of ^{3}H-flunitrazepam and ^{3}H-muscimol binding is not additive, indicating that these substances act at the same sites. Might bicuculline or THIP antagonize GABA-elicited protection? Maximal protection of both ^{3}H-flunitrazepam and ^{3}H-muscimol sites by GABA and bicuculline is the same as with GABA alone, indicating no such antagonism. Protection by THIP and GABA for ^{3}H-flunitrazepam and ^{3}H-muscimol sites is slightly less than the maximal protection by GABA alone. In contrast to results with combinations of GABAergic substances, maximal effects of GABA and diazepam are even greater than the sum of the individual effects of these two compounds. Similarly, maximal effects of THIP and diazepam or IAA and diazepam are greater than the sum of the two substances acting separately. Thus, GABAergic agents and benzodiazepines exert their protective effects at distinct recognition sites both on the receptors labelled by ^{3}H-flunitrazepam and on those labelled by ^{3}H-muscimol. The synergistic interactions of GABA and diazepam in protecting these receptors suggest that the two sites are allosterically linked.

Our major finding here is that GABA receptors labelled by ^{3}H-muscimol possess recognition sites for benzodiazepines. Moreover, these sites have the same as or very similar drug specificity to benzodiazepine receptors. The findings that GABA receptors have benzodiazepine recognition sites and that benzodiazepine receptors have GABA recognition sites together with few differences in the chromatographic behaviour of the two purified receptors (M.G. and S. H. S., in preparation) indicates considerable structural similarity of the two receptor proteins.

Uninfected avian cells contain structurally unrelated progenitors of viral sarcoma genes

Mitsuaki Yoshida*, Sadaaki Kawai† & Kumao Toyoshima†

* Department of Viral Oncology, Cancer Institute, Toshima-ku, Tokyo, Japan
† Department of Oncology, Institute of Medical Science, University of Toko, Minato-ku, Tokyo, Japan

A single gene, *src* of Rous sarcoma virus (RSV) coding for a protein of $pp60^{src}$, is responsible for the transformation of fibroblasts[1-3]. DNA sequences homologous to *src* (the endogenous *sarc*) are present in uninfected cells of chickens[4] and other vertebrates[5]. Endogenous nucleotide sequences have also been found in the putative transforming genes of MC29 (ref. 6) and avian erythroblastosis virus[7]. These viruses, however, induce different spectra of tumours in animals. From analysis of a new avian sarcoma virus, Y73, we present here evidence suggesting that multiforms of viral sarcoma genes originated from cellular genetic sequences, and that these viral genes are structurally unrelated, but have similar pathogenicities.

Y73, a strain of avian sarcoma virus newly isolated from a spontaneous tumour of White Leghorn[8], is a defective virus inducing fibrosarcoma in chickens but not any type of acute leukaemia, and contains 26S RNA as its genome[9]. To characterize the transforming gene (*yas*) of Y73, we prepared cDNA specific to 26S genome RNA (cDNA_{yas}) by transcribing 26S RNA into cDNA and selecting single-stranded cDNA after hybridization with a large excess of 35S genome RNA of Y73-associated virus (YAV). The specificity of the $^{32}\text{P-cDNA}_{yas}$ obtained was confirmed by the fact that the preparation showed no detectable hybridization with RNA of YAV or with 28S ribosomal RNA, which might contaminate the 26S RNA fraction owing to its similar size. This specific $^{32}\text{P-cDNA}_{yas}$ would represent about 2.5 kilobases of the middle portion of 26S RNA genome, because fingerprinting analysis of 26S RNA showed that 1–1.5 kilobases of both ends are common to 35S RNA of YAV leaving about 2.5 kilobases in the middle as specific sequence (manuscript in preparation).

The $^{32}\text{P-cDNA}_{yas}$ was hybridized with RNAs of various sarcoma and acute leukosis viruses in stringent conditions (Table 1). Most of the $^{32}\text{P-cDNA}_{yas}$ hybridized with 50–70S or 26S RNA of Y73, but not with the other virus RNAs tested (that is RNAs of avian myeloblastosis virus, avian erythroblastosis virus, MC29, the Prague strain of RSV, Fujinami sarcoma virus (FSV)[10] and PRCII sarcoma virus[11]). Hybridization of $^{32}\text{P-cDNA}_{total}$ indicated the presence of an appreciable amount of viral RNA and less than 1% of the viral RNA could easily be detected in the conditions used. These results clearly indicate that the Y73-specific sequences have no homology with the transforming sequences of known avian retroviruses. In particular, it should be emphasized that cDNA_{yas} is not structurally related to *src* of RSV or the transforming gene of FSV or PRCII. We also showed that cDNA_{src} of RSV did not cross-hybridize with the RNAs of Y73, FSV and PRCII (Table 1). Lee *et al.*[12] and Hanafusa *et al.*[13] recently reported that there is no sequence homology between *src* of RSV and FSV. These findings show that Y73 is a new type of avian sarcoma virus and that avian sarcoma viruses contain structurally distinct multiforms of sarcoma genes. The putative transforming genes of MC29 (ref. 6) and AEV[14], which can transform chicken fibroblasts *in vitro*, were reported to be distinct from *src* of RSV, but these viruses have different target specificity in animals. Our findings demonstrate that at least three structurally unrelated genes can induce similar fibrosarcomas in chickens.

As the *src* sequences of RSV were shown to be derived from host cell sequences[4,15], it was interesting to test whether the sarcoma sequences in Y73, which are unrelated to *src* of RSV, also originated from the avian genome. Thus, we analysed restriction fragments hybridizable with cDNA_{yas} by the blotting procedure of Southern[16]. DNA of uninfected chicken cells was digested with various restriction endonucleases and the fragments separated by electrophoresis in 0.8% agarose and fixed on a nitrocellulose filter. When the filter was hybridized with total $^{32}\text{P-cDNA}_{RSV}$, many bands of the endogenous viruses, as well as those of the endogenous *sarc*, were detected in digestions with *Eco*RI, *Hin*dIII, *Bgl*II and *Kpn*I (Fig. 1, *a* lanes). With $^{32}\text{P-cDNA}_{src}$ prepared from RSV, only a few bands representing endogenous *sarc* were detected in each digest (Fig. 1, *b* lanes). For example, in the digest with *Hin*dIII, two bands of approximately 12 and 28 kilobases were detected with $^{32}\text{P-cDNA}_{src}$ (lane *b*) and these bands corresponded to two of five bands detected with $^{32}\text{P-cDNA}_{RSV}$ (lane *a*). The fact that the three other bands could not be detected with cDNA_{src} showed that there was no significant contamination of the probe with other portions of the viral gene and thus that the fragments of 12 and 28 kilobases are those of the endogenous *sarc* sequences. Similar results were obtained with other enzyme digests, thus confirming the reliability of the method used.

When $^{32}\text{P-cDNA}_{yas}$ was used to hybridize the filter, only a few bands were detected in each digest (Fig. 1, *c* lanes) and the bands did not correspond to those of endogenous *sarc* in *b* lanes or those of endogenous viral gene in *a* lanes. These results unequivocally demonstrate that chicken DNA contains nucleotide sequences related to transforming gene of Y73 and that these endogenous DNA sequences (c-*yas*) are different from the endogenous *sarc* related to *src* of RSV and do not correspond to any endogenous viral sequences. Furthermore, the intensities of

Table 1 Absence of sequence homology of Y73-specific sequences with other avian sarcoma-leukosis viruses

RNA		^{32}P-cDNA (% hybridized)		
		cDNA_{yas}	cDNA_{src}	cDNA_{total}
Sarcoma viruses				
Y73	50–70S	91	4	98

	Cellular	11	–	21

Hybridization was carried out at 42 °C in buffer containing 0.6M NaCl, 50 mM Tris-HCl (*p*H 7.5), 1 mM EDTA and 50% formamide to a C_rt value of 15 mol s l^{-1} with purified virion RNAs or 600 mol s l^{-1} with total cytoplasmic RNA. The C_rt values (600 mol s l^{-1}) for cellular RNA were 50–70-fold in excess of C_rt for hybridization between cDNA_{total} and individual RNA preparation. $^{32}\text{P-cDNA}_{yas}$ and $^{32}\text{P-cDNA}_{total}$ were prepared as follows: the 26S RNA fraction of Y73 was transcribed into $^{32}\text{P-cDNA}_{total}$ with AMV reverse transcriptase in the presence of -[α ^{32}P]dCTP and random primer of calf thymus DNA digested with DNase I as described by Taylor *et al.*[17]. The $^{32}\text{P-cDNA}_{total}$ was hybridized with a large excess of 35S RNA of Y73-associated virus (YAV) to a C_rt of 100–150 mol s l^{-1} and single-stranded DNA, $^{32}\text{P-cDNA}_{yas}$, was separated on a hydroxyapatite column. $^{32}\text{P-cDNA}_{src}$ of RSV was prepared as described by Stehelin *et al.*[18] from the Prague strain of RSV and RNA of the transformation-defective mutant of the strain (td-RSV).

* Total cytoplasmic RNA was extracted from cells infected and fully transformed with the viruses and the contents of defective viral RNA were estimated to be more than 20% of the helper 35S RNA by the Northern transfer technique[19]; thus, if they have any homology, significant hybridization should be observed in the conditions used.

† Q8 is a nonproducer quail cell line[20].

0028-0836/80/410653—02$01.00

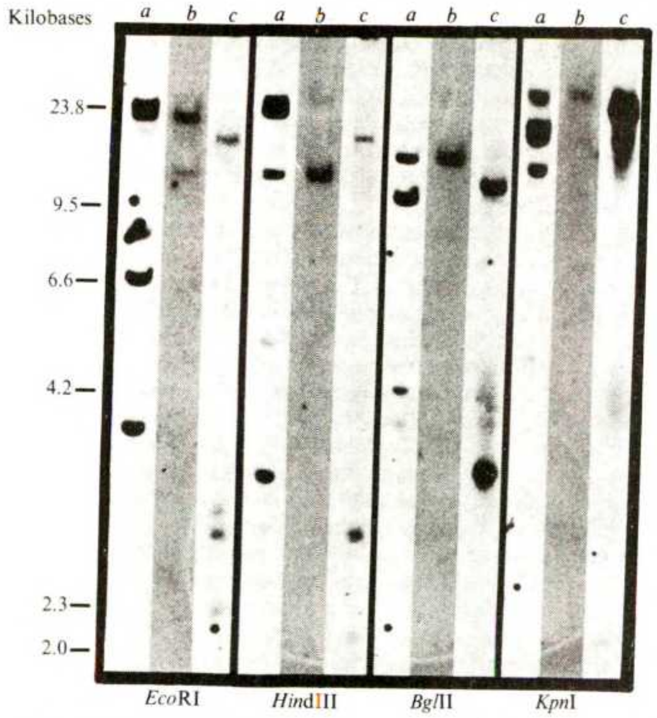

Fig. 1 Detection of nucleotide sequences homologous to the putative transforming gene of Y73 in uninfected chicken DNA and their comparison with endogenous *sarc* sequences related to *src* of RSV. DNA was extracted from uninfected chicken embryo fibroblasts and digested with *Eco*RI, *Hin*dIII, *Bgl*II and *Kpn*I respectively. Each digest was introduced into three slots in 0.8% agarose. The DNA fragments were separated by electrophoresis and blotted on to a nitrocellulose filter as described by Southern[12]. The three strips of the filter of each digestion were separately hybridized with total ^{32}P-cDNA$_{\text{RSV}}$ (*a*) ^{32}P-cDNA$_{yas}$ that had been prehybridized with RNA of td-RSV (*b*), and ^{32}P-cDNA$_{yas}$ that had been prehybridized with RNA of YAV (*c*), and autoradiograms were re-aligned. The marker for molecular size was λ DNA digested with *Hin*dIII.

the bands detected using ^{32}P-cDNA$_{yas}$ suggested that one or a few copies of c-*yas* sequences are present in chicken DNA. These findings strongly suggest that Y73 acquired the transforming gene from the c-*yas* sequences and that it belongs to a distinct class of avian sarcoma viruses. In preliminary results, the c-*yas* sequences are transcribed into RNA containing poly (A), suggesting that this RNA is translated into protein(s).

Our findings on the probable cellular origin of the putative transforming gene (*yas*) of Y73 indicate that the avian genome contains at least two copies of structurally unrelated progenitors of sarcoma genes of avian sarcoma viruses. These findings suggest that spontaneous or chemically induced sarcomagenesis might involve some modification and/or abnormally activated expression of one of these progenitor sequences, including as yet unidentified sequences. This hypothesis could be tested using a set of cDNAs specific to various classes of sarcoma genes.

We thank Dr H. Sugano for discussion and for critical reading of the manuscript, Drs H. Hanafusa and P. K. Vogt for gifts of FSV and PRCII virus, and Miss Y. Hirayama for technical assistance. This work was partly supported by a Grant-in-Aid for Cancer Research from the Ministry of Education, Science and Culture of Japan.

The molecular basis of the neoplasmic transformation of plant cells by the crown gall bacterium *Agrobacterium tumefaciens* is the transfer to and stable maintenance of T DNA—a well defined segment of the bacterial Ti plasmid—in plant cells[1–4]. Transformed cells express new biosynthetic capacities, such as the synthesis of opines[5], of which octopine[6] and nopaline[7] are well known examples. Ti plasmids harbour genes enabling the bacteria to degrade opines and use them as carbon and nitrogen sources[8]. pTi-linked genes also determine the specificity of synthesis of opines in the plant tumour cells[8]. On this basis the Ti plasmid can be considered an unusual type of catabolic plasmid, which induces the synthesis of its substrate in transformed plant cells. This relationship, called genetic colonization[2], has opened prospects for the use of Ti plasmids as vectors for genetic manipulation of plants. To evaluate this possibility we inserted a well defined DNA segment, the bacterial transposon Tn*7* (ref. 9), into the Ti-plasmid DNA sequence that determines nopaline synthesis in *A. tumefaciens* strain T37 Noc$^{\text{c}}$1 (ref. 10). As we report here, the inserted Tn*7* DNA segment became part of the T DNA because the 9.6×10^6 molecular weight (MW) Tn*7* DNA sequence was transferred to, and maintained in, the DNA of tumour tissue cultures induced by this mutant strain.

Tn*7*, which encodes streptomycin, spectinomycin and trimethoprim resistance, was introduced into the chromosome of strain T37 Noc$^{\text{c}}$1. An RP4 :: Tn*7* plasmid[9], pGV1 (our isolate) was transferred from the auxotrophic *Escherichia coli* strain GV1000 (ref. 11) to strain T37 Noc$^{\text{c}}$1 by plate conjugation[12]. A transconjugant subsequently cured of its pGV1 plasmid was obtained by selection with the pilus-specific bacteriophage GU5 (J. P. H., in preparation). A culture of a transconjugant colony, exponentially growing in LB medium, was infected with a multiplicity of 5 plaque-forming units of GU5 per bacterium and plated after overnight incubation at 32 °C. About 15% of surviving cells were shown to have lost the carbenicillin, kanamycin and tetracycline resistance markers of RP4 but retained the spectinomycin (100 μg ml^{-1}) and trimethoprim (1,000 μg ml^{-1}) resistance markers of the Tn*7* transposon.

One such T37 Noc$^{\text{c}}$1 chr :: Tn*7* strain, GV15, was used for the isolation of Tn*7* insertions in the transfer-derepressed Ti plasmid of strain T37 Noc$^{\text{c}}$1 by selecting for the Ti-plasmid mediated conjugative transfer of the transposon resistance markers.

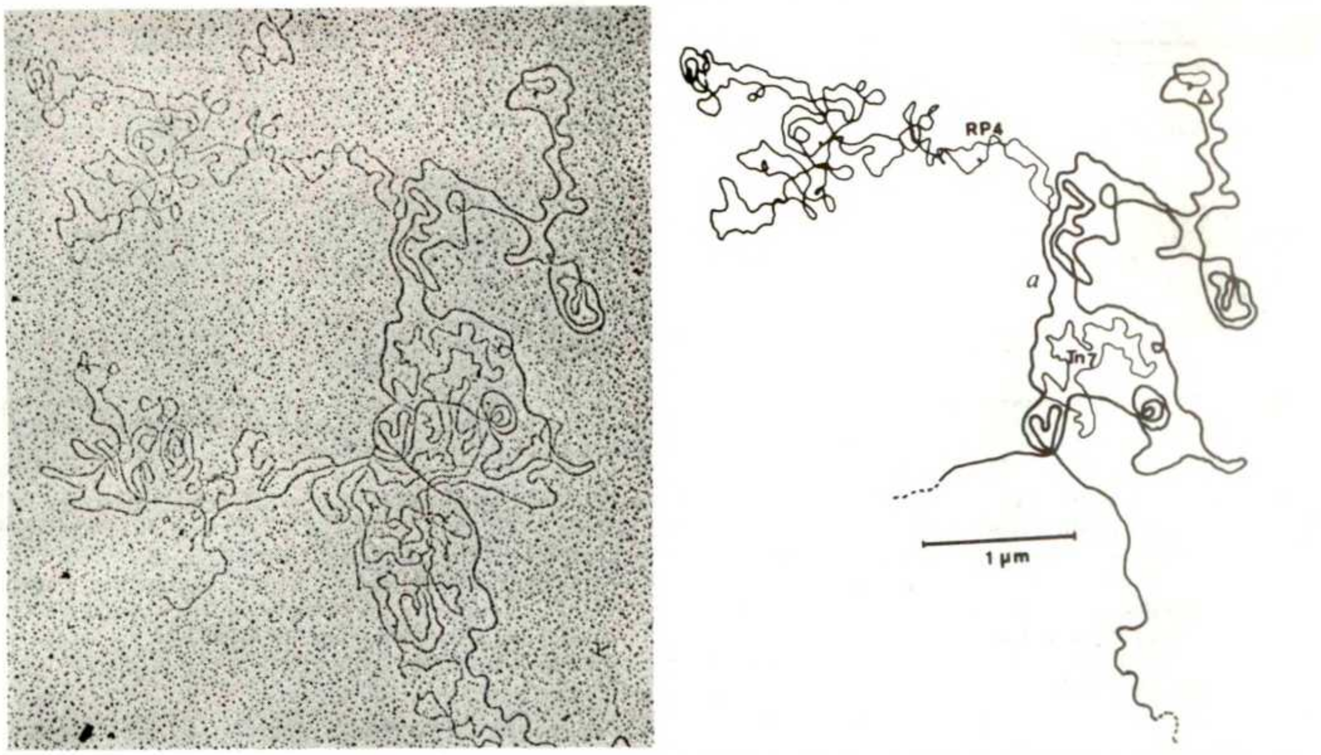

Fig. 1 Physical mapping of the Tn*7* insertion in a nopaline-synthesis deficient (Nos^-) mutant of pTiT37. pGV3106 DNA was prepared from strain GV3171 as described previously[12]. The Tn*7* insertion in pGV3106 was localized by electron microscopic analysis of heteroduplex molecules[20] formed by renaturation of single-stranded DNA molecules of pGV3106 and of pGV4000 (ref. 18), a co-integrate plasmid consisting of pTiC58 and the P plasmid RP4. The distance (*a*) between the Tn*7* transposon in pGV3106 and the RP4 insertion (at map position 130.4)[18] in pGV4000 is 1.3 ± 0.1 μm. The 0.5-μm deletion loop (Δ) in pTiT37 (ref. 4) and present in pGV3106 (at map position 124.3–125.3) (G. E., in preparation) was used as a reference point for the Tn*7* integration site. This mapping result agrees with the restriction endonuclease analysis (data not shown) of pGV3106.

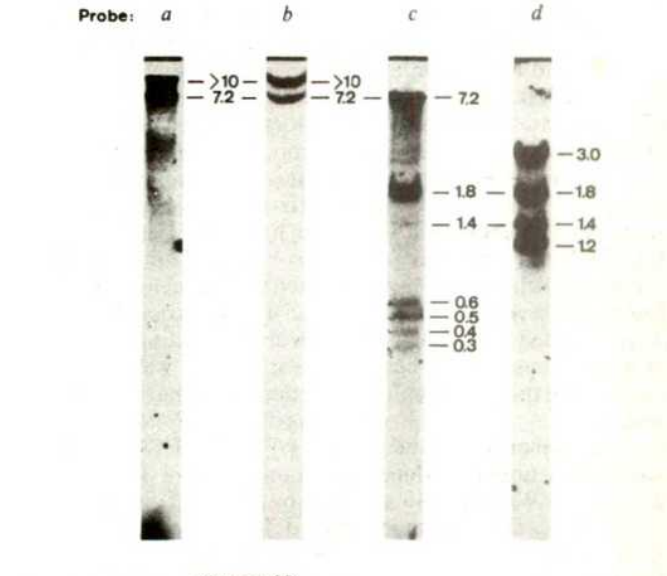
Fig. 2 Analysis of Tn*7* and Ti-plasmid related DNA fragments present in restriction endonuclease digests of tobacco tumour DNA. W38T37::Tn*7*-1, a bacterium-free tumour tissue culture, was started from a tumour induced by strain GV3171 on *N. tabacum* cv Wisconsin 38, essentially as described previously[16]. After 5 months of *in vitro* culture on hormone-free medium, samples of the tissue were extracted with 25 ml buffer (Tris 50mM *p*H 8.2, EDTA 100 mM, diethylammonium diethyldithiocarbamate (DIECA) 100mM, triisopropyl naphthalene sulphonic acid 2%, diethylpyrocarbonate 0.1%) per g lyophilized tissue. The mixture was brought to 0.3 M NaCl and extracted with an equal volume of phenol and chloroform. The aqueous phase was brought to 0.5 M NaCl and re-extracted with the same organic phase. After precipitation with two volumes of ethanol the crude DNA was further purified by CsCl gradient banding (starting density 1.55). After dialysis it was concentrated to about 1 mg ml^{-1} by ethanol precipitation. The DNA was digested to completion with restriction endonuclease *Eco*RI. Digested DNA (20 μg) was separated by electrophoresis through a 0.8% agarose slab gel and transferred to a nitrocellulose filter[19]. The filter was hybridized by Southern's[19] method to cloned Ti-plasmid fragments derived from the T region of pTiC58 (ref. 17) and to ColE1::Tn*7* plasmid DNA, labelled *in vitro* with ^{32}P by nick-translation[21]. ColE1::Tn*7* plasmid DNA was used as a probe in lane *a*. The extent of the cloned pTi fragments used as probes for the hybridizations of lanes *b*, *c* and *d* is indicated on top of the physical map of the T region of pTiT37. Lanes *a* and *b* demonstrate the presence in the tumour DNA of the complete Tn*7* sequence integrated in a sequence homologous to the 9.4 × 10^6 MW *Eco*RI fragment of pTiT37. The localization of the integration site of Tn*7* in the T-DNA segment based on these data and confirmed by similar hybridization experiments with *Hin*dIII digests of the tumour DNA (data not shown), corresponds to the integration site of Tn*7* in pGV3106 (Fig. 1). Lanes *b*, *c* and *d* demonstrate that the T-DNA segment in this tumour line is identical, except for the *Eco*RI fragment of MW 9.4 × 10^6, to the T-DNA segment independently shown to be present in the BT37 tobacco tumour line induced by wild-type pTiT37 (ref. 4). Numbers adjacent to bands and numbers in each segment indicate MW(×10^{-6}).



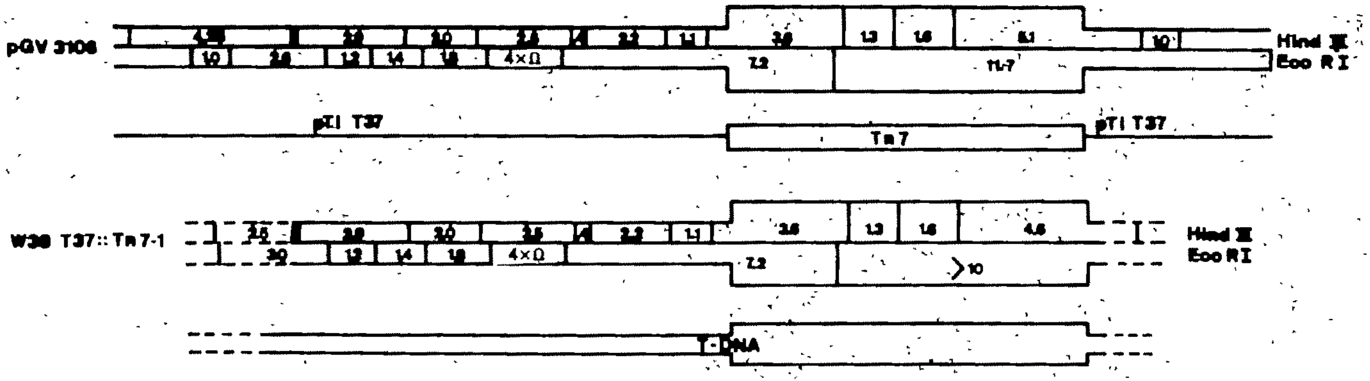


Fig. 3 The colinearity between the T region of the pTiT37::Tn*7* plasmid pGV3106 and the T-DNA segment in the tumour line W38T37::Tn*7*-1 induced by the *A. tumefaciens* strain GV3171 harbouring pGV3106. The figure is based on results obtained by Southern type DNA hybridizations as described in Fig. 2 legend.

GV15 was incubated for 24 h on minimal A[13] agar with the rifampicin- and erythromycin-resistant C58C1 derivative GV3102. Tn*7*-containing transconjugants were found at a frequency of 1.5×10^{-5} per recipient cell after plating on LB[13] medium supplemented with rifampicin (100 μg ml^{-1}), erythromycin (100 μg ml^{-1}) and spectinomycin (100 μg ml^{-1}). In 10% of these strains Ti plasmid could be demonstrated by its ability to degrade nopaline[8] and sensitivity to agrocin 84 (ref. 14). The remaining transconjugants expressed none of the Ti-plasmid markers and therefore probably harboured Tn*7* insertions in the cryptic conjugative plasmids of strain T37 Noc[r]1 (G. E., unpublished). Twelve transconjugants expressing both pTi and Tn*7* markers were inoculated on sunflower hypocotyl segments[15]. Nine were found to be pathogenic. Nopaline synthesis was demonstrated reproducibly by electrophoretic analysis[16] of the tumours induced by eight of these strains, but could not be detected in tumours induced by strain GV3171. The inability of strain GV3171 to induce nopaline synthesis was confirmed by analysis of tumours induced on potato, *Kalanchoë daigremontiana* and tobacco.

The Tn*7* insertion in strain GV3171 was localized on the mutant Ti plasmid (pGV3106) by restriction endonuclease analysis, and mapped in a DNA fragment homologous to the *Hin*dIII-23 fragment[17] of the standard nopaline Ti plasmid pTiC58 (data not shown). This localization was confirmed independently by electron microscopic heteroduplex analysis, which also showed that the Tn*7* inserted without detectable deletion (Fig. 1). This *Hin*dIII-23 fragment was subsequently shown to be homologous with the right-end border fragment of the T DNA[2,4] and thus to be part of the Ti-plasmid DNA segment which is normally transferred to plant cells. To confirm this result, several hundred Tn*1* and Tn*7* insertions in pTiC58 were screened for nopaline synthesis after induction of tumours. A single nopaline synthesis-deficient mutant was found and shown to be the result of a Tn*1* insertion in fragment *Hin*dIII-23 (ref. 18).

A bacterium-free tissue culture, W38T37::Tn*7*-1, was started from a tumour induced by strain GV3171 on *Nicotiana tabacum* cv Wisconsin 38. Analysis by Southern blot hybridizations[19] of a DNA sample isolated from this culture, using ColE1::Tn*7* (our isolate) DNA and various cloned segments of the nopaline plasmid pTiC58 as radioactive probes showed that the complete Tn*7* was present in the plant tumour genome, integrated at its original site in a normal-size T DNA (Figs. 2, 3).

Our results show that the Ti plasmid can be used as a vector for the experimental introduction and stable maintenance of foreign genes in higher plants. Furthermore, the demonstration that the Ti-plasmid DNA segment specifying nopaline synthesis in transformed plant cells is part of the T DNA, but not functionally required for the induction or maintenance of the neoplasmic state, supports the genetic colonization model of crown gall[2].

Transforming genes of neoplasms induced by avian lymphoid leukosis viruses

Geoffrey M. Cooper* & Paul E. Neiman†

* Sidney Farber Cancer Institute and Department of Pathology,
Harvard Medical School, Boston, Massachusetts 02115
† The Fred Hutchinson Cancer Research Center, Seattle,
Washington 98104

Oncogenic avian retroviruses can be classified into three groups: sarcoma viruses, acute leukaemia viruses and lymphoid leukosis viruses (LLVs)[1]. Sarcoma and acute leukaemia viruses transform fibroblasts and/or haematopoietic cells in culture and induce tumours with short latent periods in infected birds. In contrast, LLVs do not transform cells *in vitro* and require long latent periods before formation of neoplasms *in vivo*. The most frequent neoplasm induced by LLVs is malignant lymphoma of the bursa of Fabricius, but LLVs also induce other neoplasms,

including sarcomas, nephroblastomas and erythroblastosis[2]. The genomes of both sarcoma and acute leukaemia viruses contain specific genes responsible for viral oncogenicity[1,3–5], whereas the genome of LLVs apparently includes only genes required for virus replication. The genetic basis for the low oncogenic potential of LLVs is therefore obscure. The present experiments indicate that LLV-induced tumours contain transforming genes that can be detected by transfection of NIH 3T3 mouse cells. These transforming genes are not linked to LLV DNA sequences, suggesting that oncogenesis by LLVs may result from indirect activation of cellular transforming genes.

DNAs used as donors in transfection experiments were extracted from seven different LLV-induced chicken tumours, from LLV-infected non-neoplastic tissues of tumour-bearing birds and from tissues of uninfected birds. The tumours included a nephroblastoma, three metastatic bursal lymphomas, a cell line established from such a lymphoma and two neoplastic bursal nodules, which are the presumed precursors to metastatic lymphomas. LLV DNAs in the tumours and LLV-infected normal tissues used in these experiments have been characterized by restriction endonuclease analysis[6]. The bursal nodules and the nephroblastoma appeared to contain single complete exogenous LLV genomes integrated at a different site in each tumour[6]. The advanced metastatic lymphomas and the derivative cell line contained variable numbers of LLV DNA integration sites, some of which corresponded to incomplete proviruses (ref. 6 and unpublished observations). In addition, recent studies using a probe homologous to the terminal sequences of LLV DNA (see below) revealed additional exogenous LLV DNA sequences in these tumour DNAs that were only detectable by this selective probe (unpublished observations). Red blood cells and normal bursal and kidney tissues from LLV-infected birds contained exogenous LLV genomes in quantities similar to LLV-induced tumours[6].

Table 1 Transformation by DNAs of LLV-induced tumours

Donor DNA (tissue-bird no.)		Total colonies/ total recipient cultures	Colonies per μg DNA
Salmon sperm		0/36	<0.002
Uninfected:			
Bursa	2407	0/4	<0.01
Erythrocyte	2407	0/5	<0.01
Total		0/9	<0.005
LLV-infected normal:			
Bursa	2993	0/5	<0.01
	2999	0/3	<0.02
	B7655	0/8	<0.01
Erythrocyte	2902	0/7	<0.01
	2993	0/4	<0.01
	2999	0/10	<0.005
Kidney	3000	0/4	<0.01
Liver	2993	0/4	<0.01
	2999	1/6	0.01
Total		1/43	0.001
LLV-induced tumours:			
Nodule	2993	5/4	0.06
	2999	54/3	0.9
Metastatic lymphoma	2902	2/6	0.02
	B7362	38/21	0.09
	B7363	5/7	0.04
Lymphoma line	LSCC-RP9	9/5	0.09
Nephroblastoma	3000	24/3	0.4
Total		137/49	0.14

DNAs were extracted from normal and neoplastic tissues of chickens infected with LLV strain 5938 (bird nos. 2902, 2993, 2999, 3000, B7655, B7362 and B7363), from normal bursa and erythrocytes of an uninfected chicken (no. 2407) of the same flock as chickens 2902, 2993, 2999 and 3000 and from an early (6th) tissue culture passage of a cell line (LSCC-RP9)[25] established from a transplantable bursal lymphoma (LSCT-RP6) induced by LLV strain Rous-associated virus-2. LLV infection of birds B7655, B7362 and B7363 was described by Neiman *et al.*[26] and LLV infection of birds 2902, 2993, 2999 and 3000 by Neiman *et al.*[6]. High molecular weight ($>20\times10^6$) DNAs were assayed by transfection of NIH 3T3 mouse cells as previously described[13]. Salmon sperm DNA was included as a control in all experiments. Recipient cultures were inoculated with 20 μg DNA per culture and were transferred into soft agarose-containing medium 7 d after exposure to DNA. Colonies of transformed cells were counted after 2–3 weeks of further incubation at 37 °C.

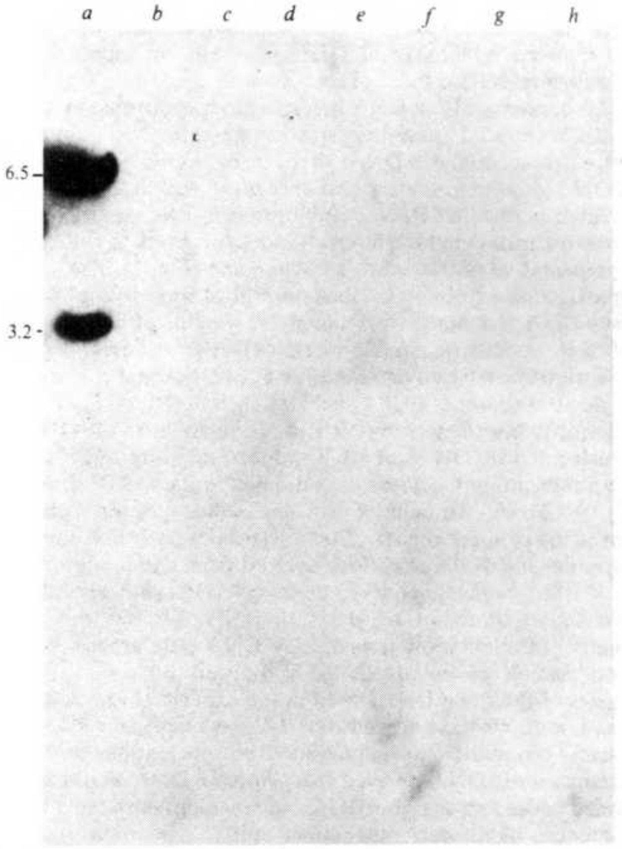

Fig. 1 Absence of LLV genomes in transformed NIH cells. DNAs of NIH cells transformed by Schmidt–Ruppin-D avian sarcoma virus DNA (lane *a*), NIH(BN-2993 DNA) cells (lane *b*), NIH(BN-2999 DNA) clone 1 cells (lane *c*), NIH(BN-2999 DNA)cl 2 cells (lane *d*), NIH(BN-2999 DNA) clone 3 cells (lane *e*), NIH(BL-B7362 DNA) cells (lane *f*), NIH(BL-LSCC-RP9 DNA) cells (lane *g*) and NIH 3T3 cells (lane *h*) were digested with *Hin*dIII, electrophoresed in 0.8% agarose gels and transferred to nitrocellulose filters as previously described[9]. Filters were baked and hybridized[10] to ^{32}P-cDNA (specific activity, $\sim4\times10^8$ cpm μg^{-1}) representative of the entire LLV genome which was synthesized by avian myeloblastosis virus reverse transcriptase from a template of Rous-associated virus-2 poly(A)-containing 35S RNA using oligomers of salmon sperm DNA as primers[27]. Filters were washed and exposed to X-ray film as previously described[10]. The molecular weights ($\times10^{-6}$) of LLV DNA-containing fragments are indicated.

The transforming activity of high molecular weight DNAs of tumours and normal tissues was assayed by transfection of NIH 3T3 cells, which have previously been shown to be transformable by DNAs corresponding to both viral and cellular transforming genes[7–13]. DNAs of all seven tumours, but not DNAs of either uninfected or LLV-infected normal tissues, induced transformation with efficiencies of 0.02–0.9 transformants per μg DNA (Table 1). These efficiencies were similar to the efficiencies of transformation by high molecular weight DNAs of cells transformed by avian sarcoma[9] and acute leukaemia[11] viruses and by DNAs of cells containing activated cellular transforming genes[12,13], but were 10–100-fold higher than the efficiency of transformation by fragments of normal cell DNA[13]. Thus, LLV-induced tumours, but not LLV-infected normal tissues, appeared to contain activated transforming genes that efficiently induced transformation of NIH 3T3 cells.

Several colonies of NIH cells transformed by LLV-induced tumour DNAs were grown to mass culture for further study. DNAs of these cells induced transformation in secondary transfection assays with similar efficiencies to the original efficiency of transformation by DNAs of LLV-induced tumours (~0.1 transformant per μg DNA) (Table 2) indicating they contained activated transforming genes. In contrast, transformation was not induced by DNAs of NIH 3T3 cells or spontaneously transformed NIH cells[9,13] (Table 2).

The content of LLV DNA in NIH cells transformed by DNAs of LLV-induced tumours was investigated by restriction endonuclease analysis. DNAs of the transformed NIH cells used as DNA donors in the experiments presented in Table 2 were digested with *Hin*dIII, electrophoresed in agarose gels, transferred to nitrocellulose filters[14] and hybridized to ^{32}P-cDNA representative of the entire LLV genome (Fig. 1). The sites of *Hin*dIII cleavage in viral DNAs are illustrated in Fig. 2. Two virus DNA fragments with molecular weights of 6.5 and 3.2×10^6 were readily detectable in *Hin*dIII-digested DNA of NIH cells transformed by avian sarcoma virus DNA and containing a single viral genome[9] (Fig. 1, lane *a*). In contrast, no LLV DNA sequences were detectable in any of the six lines of NIH cells transformed by DNAs of LLV-induced tumours (Fig. 1, lanes *b–g*), indicating that these cells did not contain LLV genomes.

LLV DNA contains a 300-nucleotide terminal repeat, consisting of approximately 200 nucleotides derived from the 3′ terminus and 100 nucleotides derived from the 5′ terminus of LLV RNA, which appears to be involved in synthesis, integration and expression of proviral DNA[15–18]. To determine whether terminal sequences of LLV DNA were associated with transforming genes of the LLV-induced tumours, *Hin*dIII digests of the same DNAs used in the experiment presented in Fig. 1 were also hybridized to ^{32}P-DNA of plasmid p53. This plasmid contains approximately 900 nucleotides of avian sarcoma virus DNA derived from *in vitro* DNA synthesis and cloned in the *Pst*I site of pBR322 and includes both the 3′ and 5′ sequences of the terminal repeat unit (K. Beemon, personal communications), and extends into the avian sarcoma virus *src* gene (unpublished observations, see Fig. 2). p53 ^{32}P-DNA hybridized to both *Hin*dIII fragments of DNA of avian sarcoma virus DNA transformed NIH cells (Fig. 2, lane *a*). Since the *Hin*dIII fragment of molecular weight 3.2×10^6 of this cell line is derived from the left-hand portion of avian sarcoma virus DNA and is homologous to p53 only at the terminal repeat unit (see Fig. 2), hybridization to this fragment shows the sensitivity of detection of these sequences. p53 ^{32}P-DNA also hybridized weakly to *Hin*dIII fragments of molecular weights 5.5 and 2.9×10^6 d in DNAs of all transformed cell lines (Fig. 2, lanes *a–g*) and in DNA of normal NIH 3T3 cells (Fig. 2, lane *h*). These fragments may represent normal mouse sequences homologous to *src*[19], since faint hybridization to these fragments was also detected with ^{32}P-cDNA representative of avian sarcoma virus RNA (unpublished observations). No additional LLV DNA sequences were present in NIH cells transformed by LLV-induced tumour DNAs (Fig. 2, lanes *b–g*), indicating that transforming genes of these cells were not associated with the terminal sequences of LLV DNA.

Thus, LLV-induced tumours contained cellular transforming genes, detectable by transfection of NIH 3T3 cells, which were not linked to LLV DNA. As transformation of NIH 3T3 cells was induced by DNAs of all seven tumours studied, including DNAs of two bursal nodules which represent an early stage of lymphoma development, it seems likely that activation of cellular transforming genes to a state in which they can be efficiently transmitted by transfection is significant in oncogenesis by

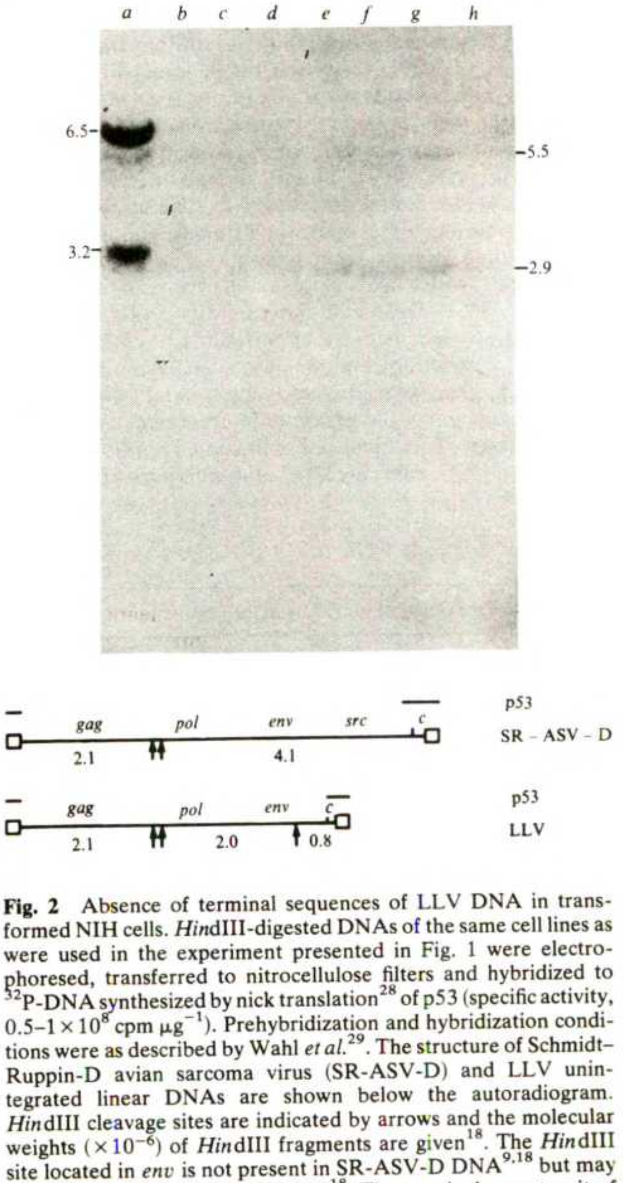

Fig. 2 Absence of terminal sequences of LLV DNA in transformed NIH cells. *Hin*dIII-digested DNAs of the same cell lines as were used in the experiment presented in Fig. 1 were electrophoresed, transferred to nitrocellulose filters and hybridized to ^{32}P-DNA synthesized by nick translation[28] of p53 (specific activity, $0.5–1 \times 10^8$ cpm μg^{-1}). Prehybridization and hybridization conditions were as described by Wahl *et al.*[29]. The structure of Schmidt–Ruppin-D avian sarcoma virus (SR-ASV-D) and LLV unintegrated linear DNAs are shown below the autoradiogram. *Hin*dIII cleavage sites are indicated by arrows and the molecular weights ($\times 10^{-6}$) of *Hin*dIII fragments are given[18]. The *Hin*dIII site located in *env* is not present in SR-ASV-D DNA[9,18] but may be present in some strains of LLV[18]. The terminal repeat unit of LLV DNA is shown as a box. The regions of viral DNA homologous to p53 are indicated above each map.

Table 2 Transformation by DNAs of transformed NIH cells

Donor DNA	Total colonies/ total recipient cultures	Colonies per μg DNA
Salmon sperm	0/28	<0.002
NIH 3T3	0/23	<0.002
NIH (spontaneous)	0/12	<0.005
NIH(BN-2993 DNA)	10/12	0.04
NIH(BN-2999 DNA)cl 1	23/18	0.06
NIH(BN-2999 DNA)cl 2	56/21	0.13
NIH(BN-2999 DNA)cl 3	48/16	0.15
NIH(BL-B7362 DNA)	17/15	0.06
NIH(BL-LSCC-RP9 DNA)	35/22	0.08

Salmon sperm DNA, NIH 3T3 cell DNA, DNA of spontaneously transformed NIH cells [NIH(spontaneous)] and DNAs of NIH cells transformed by DNAs of bursal nodule-2993 [NIH(BN-2993 DNA)], bursal nodule-2999 [NIH(BN-2999 DNA)clones 1, 2 and 3], bursal lymphoma-B7362 [NIH(BL-B7362 DNA)] and bursal lymphoma LSCC-RP9 ([NIH(BL-LSCC-RP9) DNA] were assayed as described in Table 1 legend.

LLVs. That transforming genes of LLV-induced tumours are not linked to LLV DNA suggests that oncogenesis by LLVs is not a consequence either of expression of an LLV transforming gene or of formation of recombinant transforming viruses and, furthermore, does not support the hypothesis that transformation results from viral promoters acting on adjacent cellular genes[20]. Instead, our results suggest that oncogenesis by LLVs may involve indirect activation of cellular transforming genes, possibly as a consequence of virus-induced mutations or gene rearrangements leading to abnormal gene expression. These events might be similar to those occurring in some chemically transformed mouse cell lines[12] or in the activation of potential transforming genes of normal cells during transfection with normal cell DNAs[13]. If the viral genome is not required for the maintenance of neoplastic change in LLV-induced tumours, the variability of LLV DNA in the metastatic bursal lymphomas, and the absence of detectable viral DNA in some lymphomas induced by analogous feline retroviruses[21], is not surprising.

The mechanism of activation of transforming genes in LLV-induced tumours is highly speculative. The pathogenesis of lymphomas induced by LLV suggests a process which includes several pre-neoplastic and neoplastic stages[22]. In addition, lymphomas pathologically identical to those induced by LLV occur at low frequency in the absence of exogenous LLV infection[23]. LLV may act thus at an early pre-neoplastic stage to expand the population of cells in which transforming events occur, which is consistent with the mechanism proposed by McGrath and Weissman[24] for induction of T-cell lymphomas by analogous retroviruses of the AKR mouse. LLV infection might also increase the frequency of genetic changes leading to transformation as a result of the activity of enzymes involved in integration of LLV DNA or by packaging transcripts of cellular genes in LLV virions followed by synthesis and integration of homologous DNAs in secondarily infected cells. Finally, the specificity of LLVs for transformation of bursal lymphocytes suggests that these cells provide a preferential site for LLV replication or that a bursal cell population provides a particularly sensitive target for genetic changes leading to transformation.

We thank K. Beemon for her gift of plasmid p53, W. Okazaki and L. B. Crittenden for the LSCC-RP9 cell line, S. Okenquist and L. Silverman for technical assistance, and D. M. Livingston for helpful comments on the manuscript. These studies were supported by grants CA21082 and CA20068 from the NCI.

In the refinement of the X-ray diffraction structures of molecules, it is conventional to introduce atomic 'temperature factors' of the Debye–Waller form to characterize the widths of the electron density peaks corresponding to the atoms[1]. Although these factors are known to include a variety of contributions other than thermal fluctuations of the atomic positions[2], recent progress in the refinement of protein structures has led to inferences concerning atomic mobilities from the temperature factor data for several proteins[3–10]. Atomic position fluctuations can be calculated independently by the molecular dynamics method, in which the classical equations of motion for the atoms of an equilibrated protein are solved on a computer[11–16]. We now show that the X-ray diffraction and dynamical simulation methods yield similar pictures of the atomic mobility in tuna ferrocytochrome *c*.

The temperature factors used here are from a new refinement[17,18] of the X-ray diffraction data collected at 293 K (ref. 19); the final *R*-factor is 17% at a resolution of 1.5 Å. The simulation results are from a new dynamics calculation carried out as described earlier[14], but with the following modification to improve initial equilibration. After the 12 ps of warming from a partially relaxed structure, atomic velocities were randomly re-assigned from a 300 K maxwellian distribution every 0.2 ps for an 8-ps period. The calculation was then continued as before, with 12 ps of unperturbed equilibration followed by 16 ps of actual simulation at 301 K.

The results of the new dynamics calculation are very similar to those found without the additional velocity randomization[14], but the average structure is somewhat closer to the X-ray result and the fluctuations about the average structure are somewhat smaller. Relative to the 1.5-Å X-ray structure[17], the average deviation of C^α positions is 1.27 Å, whereas that for all heavy atoms is 1.54 Å; the corresponding deviations in the previous dynamics calculation[14] are 1.42 Å and 1.73 Å. All these deviations are 0.1–0.2 Å smaller than those relative to the 2.0-Å X-ray structure[19]. The r.m.s. fluctuations of the atoms about their average positions are typically 10–20% smaller than in the previous dynamics calculation[14], but the structural correlations are unchanged (see below). In part, this decrease reflects a corresponding decrease in large-scale fluctuations: the r.m.s. fluctuations in radii of gyration are 0.047 Å for C^α atoms and 0.041 Å for all heavy atoms; the corresponding fluctuations in the previous calculation are 0.055 Å and 0.047 Å.

To compare the atomic position fluctuations found in the dynamical simulation with those found in the X-ray diffraction study, it is necessary first to subtract from the atomic temperature factors a contribution due to disorder within the crystal[3,4]. The atomic temperature factors B are given by[1–4]

$$B = (8\pi^2/3)(\langle\Delta r^2\rangle_{av} + \langle\Delta r^2\rangle_{ld}) \qquad (1)$$

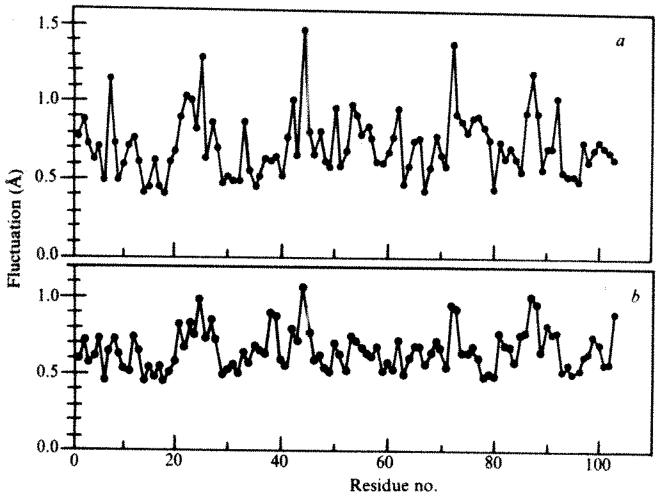

Fig. 1 Average r.m.s. atomic position fluctuation for each residue. *a*, Simulation result; *b*, X-ray result; the experimental values have been corrected uniformly for lattice disorder contributions (see text).

where $\langle \Delta \mathbf{r}^2 \rangle_{cv}$ is the mean-square dynamical fluctuation of the atomic position vector **r** due to conformational and vibrational motion, and $\langle \Delta \mathbf{r}^2 \rangle_{ld}$ is the mean-square fluctuation due to lattice disorder. With the simplifying assumption that only translational disorder need be considered, $\langle \Delta \mathbf{r}^2 \rangle_{ld}$ is the same for all atoms in the protein[4]. Here, $\langle \Delta \mathbf{r}^2 \rangle_{ld}$ was estimated by requiring that the average of $\langle \Delta \mathbf{r}^2 \rangle_{cv}$ over all interior atoms (that is, those atoms within 12 Å of the protein centre of mass)[14] obtained from the temperature factors be equal to the corresponding average of the mean-square position fluctuations in the simulation. The resulting value, $\langle \Delta \mathbf{r}^2 \rangle_{ld} = 0.22$ Å^2, is similar in magnitude to experimental estimates of this quantity for myoglobin crystals ($(\langle \Delta \mathbf{r}^2 \rangle_{ld} = 3\langle x^2 \rangle_{ld} = 0.14$ Å$^2)$[3,4]; the somewhat larger value found here is consistent with the fact that the myoglobin estimate is based only on iron atom data. The present comparison suggests that about half of the observed *B* factor value is contributed by thermal motion and half by other effects. In the following discussion, the r.m.s. position fluctuations $\langle \Delta \mathbf{r}^2 \rangle_{cv}^{1/2}$ calculated from equation (1) are compared with the r.m.s. position fluctuations from the dynamical simulation.

The magnitudes of the atomic position fluctuations derived from the X-ray temperature factors and from the dynamical simulation show the same correlations with the protein structure as were found in a previous simulation study[14]. The average r.m.s. fluctuations of the C^α positions are 0.58 Å (X ray) and 0.57 Å (simulation); the corresponding averages for all heavy atoms are 0.66 Å and 0.72 Å. To compare interior and exterior fluctuations, averages were calculated for atoms in spherical shells of 3-Å thickness centred at the protein centre of mass; the results are shown in Table 1. In the interior (shells with outer radii ≤ 12 Å)[14], the fluctuations are relatively small and increase slowly with shell size. In the exterior, the fluctuations increase more rapidly with increasing shell size; larger fluctuations occur in the simulation, reflecting the somewhat higher temperature and the neglect of the protein surroundings in the calculation. The atomic r.m.s. position fluctuations, averaged for each residue, are shown in Fig. 1; similar mobility patterns are evident, although the surface residues have larger fluctuations in the simulation. The most prominent differences are associated with the large peaks found in the simulation for exterior charged residues (for example, Lys), which are most strongly affected by the crystal and solvent environment.

Table 1 Average r.m.s. position fluctuations in shells of 3-Å thickness

Outer radius of shell (Å)	No. of atoms in shell	R.m.s. fluctuations X ray (Å)	R.m.s. fluctuations Simulation (Å)
6	41	0.54	0.51
9	148	0.56	0.53
12	284	0.60	0.61
15	262	0.71	0.83
18	96	0.85	1.09

The haem group is relatively rigid, with average r.m.s. fluctuations of 0.52 Å (X ray) and 0.46 Å (simulation). To assess the effect of the haem group on the mobility of nearby polypeptide atoms, a haem neighbourhood was defined by two cylindrical disks of 6-Å radius and 6-Å thickness lying on either side of the haem and coaxial with the iron[14]. The average r.m.s. fluctuations of the 61 heavy atoms in this neighbourhood are 0.54 Å (X ray) and 0.50 Å (simulation), compared with 0.60 Å (X ray) and 0.59 Å (simulation) for the other 374 heavy atoms of the protein interior. The average r.m.s. fluctuations are larger in the disk on the Met 80 side (0.57 Å, X ray; 0.52 Å, simulation) than in the disk on the His 18 side (0.51 Å, X ray; 0.49 Å, simulation). The additional flexibility on the Met 80 side may correlate with the larger structural changes observed on this side on oxidation of the protein[17].

Table 2 Average r.m.s. position fluctuations for various groups of atoms

Group	R.m.s. fluctuations X ray (Å)	R.m.s. fluctuations Simulation (Å)
C^α in helices	0.57	0.54
C^α not in helices	0.60	0.59
α atoms*	0.58	0.57
β atoms*	0.63	0.65
γ atoms*	0.72	0.78
δ atoms*	0.76	0.93

* Excluding proline residues.

Comparison of r.m.s. position fluctuation averages for other groups of atoms reveals additional correlations with the protein structure, as is seen in Table 2. In the backbone, there is somewhat less mobility in α-helical regions than in non-helical regions. In the side chains, the mobility tends to increase monotonically with increasing distance from the backbone.

The correlations of atomic mobility with structural features found here are in general agreement with simulation[11-13,15,16] and X-ray[4-10] results reported earlier for other proteins (compare with ref. 14). The detailed correspondence between the results from X-ray temperature factors and the molecular dynamics simulation for cytochrome *c* reinforces the view that valid information on the internal mobilities of proteins can be obtained from these complementary approaches.

Economics down on the farm

R.C. Lewontin

Farm and Food Policy: Issues of the 1980s. By Don Paarlberg. Pp.338. (University of Nebraska Press: 1980.) $16.50, £9.90.

AGRICULTURAL economists stand out among students of the "dismal science" by being uniquely conscious of history. The paradigm of bourgeois economics is an equilibrium theory that sees the present forms of production and exchange as eternal and without historical roots. Agricultural economists, however, are acutely aware of the rapid changes that have taken place in world agricultural production and in the relations of the agricultural producers to other economic sectors. Their problem is to incorporate these changes into the conventionally accepted explanatory modes of economics and political science that are, by and large, designed to explain the supposed unchanging character of modern capitalism. The explanation invoked combines demographic change, the conflict between interest groups and the effect of technological developments. According to this theory, population growth, especially urban growth, has put increasing pressures on farmers to produce more food. The farmer has responded by adopting labour-saving technology which has resulted in a further displacement of population to cities, a drastic reduction in the relative size of the farm population and, as a consequence, the loss of political power by what was formerly a dominant pressure group in national policies. *Farm and Food Policy* follows this line of analysis and attempts to use it to predict changes in American agriculture during the next few decades.

According to Paarlberg, there have been three major stages in farm policy history (what he calls three "agendas"). The first, ending in 1933, was a period of strong reliance on public funding of research, technology and education in agriculture, by which means the farm sector succeeded in reaping the benefits of technological change that had been created at public expense. The second, ending in the 1960s, was the support of prices paid to the farmer, by means of various government commodity programmes, at the same time holding down farmer costs by exempting the agricultural sector from labour laws, trade laws and certain taxes. Both of these policy agendas were a consequence of the numerical, and therefore political, power of farmers to establish themselves as a unique sector of American business with unique privileges. The loss of this numerical and political power in the 1960s has resulted in the loss of agriculture's unique position and the imposition of a third agenda from outside the farm sector. This last agenda supports the interests of farm labour, consumers, conservationists — the non-farm sector at large. Paarlberg's conclusion is that an equilibrium will be reached in the next decades just as the producer–consumer, capital–labour tensions between interest groups have equilibrated in the rest of the economy to the benefit of all parties concerned.

The only trouble with the conventional view of the political history of agriculture in the United States is that it does not correspond very well with what has happened.

First, pure demographic superiority has never meant political power for farmers. In 1786 the farmers of Massachusetts rose in armed rebellion to prevent the sitting of the Courts of Common Pleas which were bringing judgements against them for debt. Farmers comprised over 90% of the population, but the legislature and executive power were in the hands of the merchants and bankers, who put down Shay's Rebellion in a few months and collected what was owed them. There has been no significant period in American history when farmers have succeeded in dominating the state.

Second, the decrease of the farm workforce since 1900, from 40% to 4% of the total labour force, grossly exaggerates the change in the political voice of the agricultural sector. A large part of the relative decrease in farm population is a consequence of the absolute increase in urban population. The non-farm labour force has increased by a factor of five in the USA, while the farm population has fallen by about a factor of three. Much of the reduction in farm labour has been in tenants, sharecroppers and farm labourers who were generally the poorest sector of the farm population and without political power. In 1900, of 5.7 million farms, 2 million were tenancies. By 1970, while there were only 2.7 million farms left, tenants accounted for only 350,000. Moreover, there has been an immense increase in those who service and sell to the farmer — the merchants of farm machinery, of seed and fertilizers, of consumer goods in market towns, the mechanics and servicemen. These are now two to three times as numerous as farmers and are an integral part of the agricultural sector of the economy. Thus, farmers and those who sell goods and services to them remain numerous and locally concentrated. Despite their lack of economic and political power nationally, the farm sector has, and still does, exert considerable pressure locally where their concentration is high. This local concentration is important because, for example, state funds account for two-thirds to three-quarters of the money spent on agricultural research and education.

Third, agriculture has not been alone in socializing the costs of research by displacing it to public institutions. The degree of the socialization of research costs depends in each case on the point at which such socialization interferes with exclusive private control over the product. The cost of drug research is socialized by having most basic research and chemical trials carried out in public institutions supported by tax money, or by tax-exempt contributions from individuals. Only when the final compounding of the trade-name product is to be done will the drug companies themselves — sometimes — spend research money. Most basic research in metallurgy, chemistry, electronics, transportation, information theory and so on is supported publicly by tax funds or by tax-exempt gifts. The situation is the same in agriculture. Public institutions do the basic breeding research and produce public lines. The seed companies then change them slightly, if at all, give them a brand name and make the profit.

Fourth, it is by no means clear who has received importent benefits from socialized research in agriculture. Farmers try to reduce their labour costs, at the same time increasing their control over the labour process. Both these ends have been accomplished by changing from a labour-intensive to a capital-intensive system of production. For farming this has been the result of three major technological changes, none of which was the product of agricultural research. The first, beginning in about 1850 and ending in 1900, was the introduction of labour-saving machinery such as new plough designs, mowers, reapers, harvester combines and the like. All of these were invented and improved by industrial entrepreneurs. Further advance was limited because of the lack of the flexible traction power needed to pull large gang ploughs and combines. Beginning in about 1910 and extending until the Second World War, developments in the automotive industry (gasoline and diesel

THEY WANT TO LIVE FREE...

engines, the differential) gave the second great boost to labour productivity in agriculture. Finally, after 1945, the drop in the relative cost of fertilizers and other chemicals led to an immense increase in the use of agricultural chemicals. While none of these changes resulted from agricultural research, they all determined its direction. Plant breeding, for example, is largely devoted to making crop plants more responsive to fertilizers, and easier to harvest mechanically by reducing lodging, increasing morphological uniformity and making ripening simultaneous. The direction of agricultural research is determined by the existing forms of capital investment in production.

Who has benefited from these developments? Paarlberg assumes, conventionally, the consumer. His evidence is that Americans are spending, on the average, a decreasing proportion of their income on food, but this argument is spurious. As every economist (Paarlberg is one) knows, the demand for food, especially in prosperous countries, is virtually insensitive to income, so that as real incomes rise, food necessarily becomes a smaller and smaller proportion of expenditure. The real question is whether the price of food relative to the average price of other commodities has gone down. In 1913, the consumer price index of food relative to all other consumer items was 0.98; in 1967 (the base year) it was 1.00; and in 1979 it was 1.09. So much for cheaper food! Nor is it easy to show that farmers are better off. Paarlberg makes much of the increase in the value of farm real estate, but this is a paper increase that cannot be converted by the farmer into other assets because the market in farm real estate is a very thin one. In fact, the paper inflation of land value is a liability to the farm family because of the immense death duties that must be paid in cash that cannot be realized from continued farm operations. Like other small producers, most farmers consume all their surplus, so to the extent that farmers lead a better material life they have certainly profited. Driving an air-conditioned tractor is clearly better than sweating in the sun behind a mule. Yet the hours are just as long and the risks just as great. On the other hand, there is no doubt at all that the major beneficiaries of the technological revolution in agriculture have been the corporations that provide the farm inputs: chemical, seed and machinery companies, big grain merchants and those who lend money at interest.

Fifth, farmers cannot be treated as a homogeneous interest group sharing certain cultural features that arise from their unique way of life. Paarlberg portrays farmers as conservative, yet agriculturalists have been among the most politically radical groups in America, beyond such uprisings as Shay's Rebellion. In 1912 the Socialist Party had more paid members in Oklahoma than in New York, and Eugene Debs received more than 25% of the vote in the 23 counties of that state with highest tenancy levels and lowest incomes. The notion that mid-Western farmers are "conservative", despite their long record of populism, comes in large part from their rejection of the internationalist interventionist policies that were of clear advantage to industrial and banking capital and which were the hallmark of 20th century "liberalism". Tenant farmers who made up more than one-third of all American farm families until the Second World War cannot be lumped together with a 600-acre farmer who owns all his land and capital equipment. The political behaviour of farmers at any time reflects not some unique "way of life" but the way each farmer confronts the system of production and exchange of which he is a part.

Far from being unique, the history of agriculture in the United States is, in its main features, the history of American capitalist development. There has been a constant pressure to reduce labour costs and increase control over the labour process, a socialization, where possible, of the costs of technological development, a growth in the size of enterprises, a decrease in their number, and a growing monopoly control over production and exchange. Large corporations do not own the bulk of farmland and are not likely ever to do so because it is a poor use of capital, but that does not mean that agricultural production is any the less under the political and economic control of large capital concentrations. The forms are different, but the substance is the same. ☐

NMR for experts

K.A. McLauchlan

NMR of Chemically Exchanging Systems. By Jerome I. Kaplan and Gideon Fraenkel. Pp.165. (Academic: 1980.) £11, $19.50.

THIS book does not provide an experimental account of rate processes studied by NMR, nor does it give simple recipes for extracting rate data from observations. Instead it constitutes an extensive account of the application of density matrix theory to chemically exchanging systems. Much prior knowledge of NMR theory is assumed, notably of the nuclear spin Hamiltonian, the properties of spin operators and the rotating frame. This approach is on occasions too demanding; for example, some of the important density matrix equations as applied to magnetic resonance are simply quoted rather than derived in their entirety.

To start with, the Bloch equation and

density matrix approaches are shown to yield similar results for a single absorption peak. This early section of the book is the least successful since it abounds with small errors, which make it difficult to follow. Cross-referencing is not always correct and symbols are confused: bold type is used sometimes for vectors and sometimes for operators (which also appear in script and in the text typeface). The density matrix is defined as an operator rather than as a representation of an operator and its usefulness and relevance is not established at an early stage. A student would be better advised to turn to C.P. Slichter's *Principles of Magnetic Resonance* (Springer-Verlag, 2nd edn 1978) for a clearer introduction.

Once into its stride, however, this is an immensely useful and unique book for anyone wishing to see in detail how to apply the theory to real systems. It covers relaxation theory (including quadrupole effects), chemical reorganizations of all descriptions in first-order and close-coupled situations, the lineshapes of exchanging systems at high and low RF fields, double resonance lineshapes (including with exchange) and, briefly, transient effects. Application of density matrices to 2D spectroscopy receives no attention. Each chapter concludes with a useful summary and bibliography.

This book is intended for "the serious student of NMR" who has a considerable understanding of his subject, and at that level will be of value. ☐

K.A. McLauchlan is a Lecturer in Physical Chemistry at Oxford University and a Fellow of Hertford College.

A holistic approach to the classification of behaviour

Susan D. and Leslie L. Iversen

Chemical Influences on Behaviour. Edited by K. Brown and S. J. Cooper. Pp.670. (Academic: 1980.) £39.20, $90.50.

THE editors of this volume have brought together a collection of review articles relating to the effects of 'chemicals' — including hormones, nutrients before and after birth, neurotransmitters and psychotropic drugs — on behaviour. The aim is to provide the student with an introductory discussion of chemical influences on growth and development of the CNS, neuro-endocrinology, behavioural homeostasis and the effects of chemicals on a range of sensory and cognitive functions. The preface states that "the coverage is not intended to be comprehensive but rather serves to introduce the field of chemical influences on behaviour by carefully chosen examples, and to illustrate the continuity in research methods and the common problems of interpretation". Unfortunately this continuity will not be immediately obvious to the student, but it would be a difficult goal to achieve in a text of this kind.

The range of material in the book is unusual, cutting across traditional barriers of specialized interest. Computer simulation of behavioural homeostasis (F.M. Toates) is an unusual bed-fellow for an ethological topic such as chemical communication between animals (K. Brown). Students should find this range of material fascinating. Efforts have been made in some chapters to discuss methodological and other problems in the design of experiments, and Cooper's chapter on drug interaction studies is particularly useful, as the problems of working with drug cocktails and combinations are rarely discussed.

Three chapters, by Booth, Toates and Blundell, and Latham are dedicated to an analysis of food and water homeostasis. They are all excellent, and when read together illustrate how a combination of research methods applied to a clearly defined problem can yield substantial advances in understanding the organization and control of behaviour.

For the past 50 years studies of eating and drinking have been dominated by efforts to find the brain centres controlling the behaviour. While it is clear that certain hypothalamic and limbic lesions dramatically disrupt such behaviour, these lesion models have, during the past 20 years, contributed little more to our knowledge. Fresh advances have come only relatively recently by paying meticulous attention to the whole physiological balance of the organism, where the brain lies on an axis of control and is not the 'genie in the lamp'. It is useful to compare studies of feeding with those on drinking, where physiologists have always been strongly represented in the research effort. The delicately balanced nature of water control mechanisms has forced experimentalists to consider the homeostatic balance of the whole organism. This approach has paid off handsomely in the elaboration of the extracellular dehydration control of thirst by Fitzsimons (reviewed here by Blundell and Latham). This concept has been extended, most successfully, to investigations of the chemical messengers involved and their sites of action in the brain. Similar research on the control of food intake is poised to follow, as Blundell and Latham illustrate.

Rodgers provides a useful review of aggression from the behavioural, neuroanatomical and neuropharmacological viewpoint. The relationship between the sensory and emotional responses to noxious stimuli, the pain/anxiety continuum, provides a challenge to research. The catecholamine and indolamine chemical transmitter pathways

New Studies in Biology

119 Medical Mycology
Mary P. English
The only undergraduate book on medical mycology which introduces the subject through a study of the interactions between fungus, host and environment in selected mycoses.
Paper £2.50 64 pages

120 The Respiration of Higher Plants
Helgi Öpik
A concise account of the biochemistry and physiology of the respiration of higher plants incorporating current ideas. Elementary concepts are explained and only a basic knowledge of biochemistry is assumed.
Paper £2.50 64 pages

121 Ecology of Insect-Plant Interactions
Peter J. Edwards and Stephen D. Wratten
This book describes the complex interactions between plants and animals that feed on them, and considers the ecological and evolutionary significance of these relationships.
Paper £2.50 64 pages

122 The Ecology of Streams and Rivers
Colin R. Townsend
An unusual description of the ecology of running waters focusing on the general principles which determine the distribution of organisms in streams and rivers.
Paper £2.50 72 pages

123 The Biochemistry of Pollution
J. H. Ottaway
A discussion on the biochemical theory underlying the causes of fresh-water, marine, atmospheric and terrestrial pollution.
Paper £2.50 64 pages

of the hypothalamus and limbic system are involved in the emotional responses of aggression. But these same areas of brain have a high content of endogenous opioid transmitters, the endorphins. The endorphins in the brain stem are involved in the mediation of pain; their existence in forebrain may suggest a physiological axis of pain and anxiety. This is another area of research ripe for exploitation — the behavioural methods for studying responses to pain and aggressive responses are well developed; the chemical and anatomical axes of the spinal cord and brain are defined. It is now timely to ask what the functional relationships are between pain, anxiety and emotional behaviour.

In certain other areas there is less reason for optimism. If we consider the processes of learning and memory, it could be said that we are still struggling for the first rung of the ladder. Whilst it is recognized that there are methodological difficulties in studying memory — these can be overcome with appropriate controls (see Pilcher on state dependency) — there are more serious problems of interpretation: for example, in distinguishing deficits of retrieval from consolidation. We know that certain limbic areas are involved in the processing of information for memory storage, and we know that a wide range of endogenous and exogenous chemicals modify memory. But we still lack insight into the organization of the normal processes involved.

Much of the information in this volume could be found in a comprehensive textbook of physiological psychology, but there the material would be classified by brain site. The hypothalamus chapter, for example, would include eating, drinking and aggression. The achievement of this volume is that it provides another way of classifying behaviour: on physiological–chemical axes. This is not as novel as it seems; the terms pituitary–gonadal axis and pituitary–adrenal axis, used by Brain in his chapter titles, are traditional concepts in research related to sex hormones and behaviour, and to the relationship between ACTH, steroids and stress. But the same concepts could be applied to all behaviour. The brain and the body are inseparable and each possesses an integrated hierarchy of control. The endogenous neurotransmitter systems of brain and body provide a major force for integration. It is hardly surprising that so many chemicals modify behaviour since neural signalling depends so heavily on chemical relays, and it is with these tools and a conception of the whole organism that we may one day come to understand normal and abnormal behaviour. ☐

Susan D. Iversen and Leslie L. Iversen are Assistant Director of Research, Department of Experimental Psychology, and Director of the MRC Neurochemical Pharmacology Unit, University of Cambridge.

Asteroid revolution

D.E. Brownlee

Asteroids. Edited by Tom Gehrels. Pp.1181. (University of Arizona Press: 1979.) $19.95.

THE formation processes which created planets in the Solar System had at least one apparent failure. The failure occurred in the transition zone between the terrestrial and Jovian planets, and the surviving debris is known as the asteroid belt. Planetary formation was aborted at an early stage, presumably due to the proximity and rapid formation of Jupiter, the most massive planet in the Solar System. The majority of asteroids are believed to be composed of early Solar System materials which have been relatively well preserved for the age of the Solar System. They are the major source of meteorites and are a precious resource of information on the origin of the Solar System.

Ten years ago, measurable properties of asteroids were basically limited to orbits, broadband colours and brightness variations. Since then asteroid science has experienced a genuine revolution, with new observational techniques and new ideas producing a wealth of information relating to the composition and physical nature of asteroids as primitive Solar System bodies. The revolution is documented in this remarkable book, produced and edited by T. Gehrels and M.S. Matthews, with contributions from a significant fraction of the scientists active in asteroid research. The book is the product of a conference held in Tucson, Arizona, but by no means is *Asteroids* an ordinary proceedings volume. Instead of a loosely organized compilation of each participant's research results of the previous six months, this is a carefully created volume composed of review articles which cumulatively provide comprehensive and coherent coverage of existing knowledge of asteroids.

The book contains very few omissions, little repetition but extensive cross-

The Moss Flora of Britain and Ireland by A. J. E. Smith, first published in hardback in 1978, has been issued as a paperback by Cambridge University Press. Fully illustrated with line drawings by Ruth Smith, and containing an artificial key and full descriptions of taxa, the paperback edition costs £12.50.

referencing. Compilation of a 1181 page multi-author book with these attributes is obviously the result of careful planning and detailed iterative editing. Among the topics covered are orbital evolution, collisions, regolith development, reflectance spectroscopy, mineralogy, meteorite properties, formation from the solar nebula and possibilities for exploration by spacecraft.

Reading the volume, one is impressed by the diversity of techniques used to study asteroids. For example, asteroid diameters are now determined by measurement of polarization as a function of phase angle, the ratio of optical and infrared brightness, speckle interferometry, radar and occultations. Prior to 1970 diameters could only be estimated by visual telescopic observation. The most spectacular development described is the application of accurate spectral reflectivity measurements to reveal information on surface mineralogy. The measurements, combined with crystal field theory and laboratory data, have shown that asteroids are complicated bodies with diverse physical properties and surface mineralogy. One of the challenging goals for future theories on the origin of the Solar System will be to explain how such diversity could have been produced in what probably was only a small fraction of the solar nebula. Another exciting aspect of the reflectivity work is the attempt to identify specific asteroid parent bodies for various meteorite types.

Asteroids is a comprehensive and definitive book that will be of value to a variety of readers. For the specialist it will probably be the major reference source until future developments add a major increment to existing knowledge; such an advance will possibly not occur until a multi-asteroid spacecraft mission can be flown. For the newcomer to asteroid work the book will be invaluable because it contains numerous suggestions for future research. It also contains 140 pages of tabulated data for a large number of asteroids; this remarkable compilation contains information on orbital parameters, spectral reflectances, polarimetry, radiometry, light curves, magnitudes, diameters and discovery circumstances. In addition to active researchers, *Asteroids* will appeal to a much wider audience because of the review nature of the contributions. To smooth the mismatches that often occur in such an interdisciplinary field, a glossary is also included.

Although this is an excellent book it does, of course, have some shortcomings. Fortunately, these are of a relatively minor nature. A mineral defined in the glossary is misspelled and a few of the glossary definitions are not well thought out. In the text some of the material on meteorites is not as comprehensive as it could have been and does not reveal to the general reader the elements of controversy that exist in certain areas. In almost all other aspects, however, *Asteroids* is a real gem and remarkably enough for a book of its size is inexpensive enough to be a painless addition to one's personal book collection.

D.E. Brownlee is Associate Professor of Astronomy at the University of Washington, Seattle, and Associate in Geochemistry at the California Institute of Technology, Pasadena.

Children's skills with a difference

Peter Bryant

Beyond Universals in Cognitive Development. By David Henry Feldman. Pp.204. (Ablex: New Jersey, 1980.) $17.50

THERE is a character in Flaubert's short tale *A Simple Life*, who on being shown a map of America where her adopted son was at the time asked if she could see his house on the map and then if she could see him. Here is a dramatic if extreme illustration of the fact that people's skills with maps vary widely. This sort of variation between people is David Feldman's starting point and maps happen to be his main example.

His basic argument is impeccable. People's skills vary wildly. Some people play chess well, others are excellent gardeners and so on. Yet studies of the development of skills in children have concentrated on the few which virtually all adults possess. The understanding of number, the ability to make and understand logical inferences, even reading and writing are achievements which we take for granted in other adults, and yet these are at the centre of studies of child development. We spend very little time on studying how adults become so different from each other.

Feldman's approach is to look for similar variability among children, and he looks at two topics. The first is the way in which children draw maps. He divides this skill into a number of components and shows that different children forge ahead with different components. So much seems to be empirical fact. What causes this variability is still a matter for speculation, of which there is a great deal in this book.

His second example is creativity, but here because the measures of this elusive quality have been so unsuccessful Feldman's account is much less impressive. But he is right to point out that we have concentrated too much on universal features on human development and too little on the variations. □

Peter Bryant is Watts Professor of Psychology at the University of Oxford.

New Studies in Biology

124 Light and Plant Life
J. M. Whatley and
F. R. Whatley, FRS
An overall view of the effects of light on plant growth and development, from germination and seedling establishment, to flowering and senescence.
Paper £3.40 96 pages

125 Lipids and Polysaccharides in Biology
Anna J. Furth
This book describes exciting, new aspects of polysaccharide and lipid biochemistry, emphasizing the range of basic medical and biological problems that could be elucidated by structure-function studies of these somewhat neglected cell components.
Paper £2.60 72 pages

Coming in November:
126 Bioenergetics of Autotrophs and Heterotrophs
John W. Anderson
The book demonstrates that the principles of bioenergetics provide a unifying concept for understanding the metabolic activities of organisms, their interdependence and the cycling of elements by organisms.
Paper £2.50 64 pages

Coming in December:
127 Invertebrate Respiration
Rufus M. G. Wells
In this study, invertebrates are seen not as merely 'lower' animals, but as displaying control and regulatory capabilities which must cope with greater environmental exigencies than those of the vertebrates.
Paper £2.60 approx 72 pages

128 Immunobiology
Christopher J. Inchley
A concise introduction to the cellular basis of immune response in man and other animals, written from a biological viewpoint.
Paper £2.75 approx 88 pages

How to change the Nobel Prize rules

It is never the right time to raise questions about the institution of the Nobel Prize. For much of the year, most people are uninterested. The Nobel committees, of course, beaver away throughout the year and it is just possible that there are some in the world outside who, after a hard day in the laboratory, allow themselves to drift to sleep wondering whether what they have just done will one day produce a telegram from Stockholm. For most people, however, the phenomenon of the Nobel Prize is a seasonal phenomenon — perhaps fittingly something to do with the run-up to Christmas. And this, of course, is the season when the telegrams go out.

The danger of raising questions about the institution of the Nobel Prize at this stage is that the entirely proper pleasure of the recipients may be undermined. It is therefore right and proper that last week's prizewinners and their friends should know that their awards have generated just as much pleasure, and deserve congratulation as wholehearted, this year as in the past. Indeed, last week's award to Dr Frederick Sanger should prove that it is possible to distinguish between the merits of the prizewinners and the merits of the scheme. There can be few who are not delighted that such a modest man, yet such an able and imaginative scientist, should have been awarded his second prize.

So what can be wrong with an institution capable of such enlightened decisions? Is there not inherent virtue in an organization whose doings stimulate the pursuit of excellence? Why should there be anxieties about the Nobel Foundation when, by the careful management of its endowment and the diligent pursuit of its procedures, it has become a conspicuous adornment of the scientific profession? And if the institution of the Nobel Prize has stimulated later benefactors to found charities whose work consists of the award of prizes in other fields, from mathematics to immunology, is that not a sign that the market for scientific prizes is buoyant — benefactors seem to like endowing prize funds and scientists to enjoy receiving prizes? There is force in all these implicit arguments. The doubts are harder to define.

One complication is that of envy. Especially in these egalitarian days, there are constant grumbles that the singling out of individuals, however distinguished, for special honour is offensive. Discovery, the argument goes, is often a matter of luck — of being in the right laboratory at the right time. And if it turns out that a person makes an outstanding contribution to the development of his field, might that not merely reflect the value of the groundwork done by his predecessors? After all, it was no less a person than Newton who confessed that "if I have seen further than others, it is because I have stood on the shoulders of giants".

This line of argument is sadly inappropriate, even discreditable. Nobody these days will deny the importance of the climate in which research is carried out in fostering discovery. Teamwork is important. So too is the way in which people brought together, apparently often by accident, in productive laboratories derive extra benefit from being there rather than in some relatively backward place. From the generality of the scientific profession (as of any other creative profession), some able men and women are distinguished by their creativity, clarity of mind and sheer drive. It is proper that these qualities should be recognized for what they are — disproportionately powerful stimulants of discovery. Prizes are one way of recognizing such outstanding qualities, and should be valued.

Such doubts as there are about the prize-giving system are thus largely second-order effects. The Nobel Prizes are most often discussed because they are known widely outside the profession and because they are commonly supposed to deal with the whole of science under the three rubrics of physics, chemistry and "medicine and physiology". (Peace, literature and economics are dealt with separately.) It is therefore important that the scope of the Nobel system is by no means as catholic as it is usually supposed to be. The gap left by the exclusion of mathematics from the terms of Alfred Nobel's will has now been more than amply filled by the annual Field Prize, but it remains an anomaly bordering on the nonsensical that, for example, David Hilbert would not have been awarded a prize under the present rules. It is stranger still that growing fields such as astronomy and the earth sciences should on the face of things be excluded. Although the appropriate committees have in the past few years found ways of counting as physicists Vine and Matthews (because they measured magnetic anomalies on the sea floor) and a number of radio-astronomers (no doubt because radioastronomy sprang from physics laboratories), it is hard to see the Nobel Foundation screwing up its courage to award a prize to, say, Hubble (the astronomer) or Napier (the meteorologist). Whether Darwin would have qualified is an open question.

On the face of things, these complaints are not complaints against Nobel Prizes as such but at the scope of the present system. There is more than that to be said, however. When Alfred Nobel wrote his will at the end of the nineteenth century, he and his advisers could not have known how the balance of science would shift in the succeeding years. They set out to define a set of prizes covering the whole of the science they knew. Their intentions have been overtaken by events. The result is that some fields of science are well covered and others only marginally. The consequences are potentially harmful for the reputation of the prizes which are awarded, if only because of the sense of fickleness that is engendered. By all accounts, the Nobel Foundation is aware of this problem but insists that it would be impossible to amend the terms of Nobel's will. Can that be so? Other charitable foundations are constantly having to change the terms of their trust deeds by applications to the courts so as to fulfil their founders' wishes more adequately. Why should the Nobel Foundation be prevented from following suit?

Modest reform along these lines would help make the Nobel Prize system seem more equitable, taking one field of science with another, but this is not the only respect in which the fairness of the system has been called into question. In the past few years, there have been several occasions when only one member of a small team responsible for some important development has been awarded a prize. This practice appears especially unfair when the team consists only of two people and the prize is awarded to the more senior. Some years ago, there was something of a public controversy in Britain about the award of a prize to Dr Anthony Hewish for the discovery of pulsating stars when his graduate student, Miss (as she then was) Jocelyn Bell went unsung. Both the principals came out of the affair with credit, as no doubt would emerge from any new controversy Dr W. Gilbert (one of this year's winners) and Dr A.M. Maxam (whose name is linked with that of Dr Gilbert in the scientific literature for their development of their novel nucleotide sequencing technique, but who has not his year been given a prize). Like judges in a beauty contest, the Nobel committee brings disappointment as well as pleasure. Strict fairness is unattainable, but there is a sense in which the growth of the practice of close collaboration between groups of scientists may be a threat to the credibility of the system.

A still more serious danger is that the Nobel committees will

0028-0836/80/430667-02$01.00

from time to time let their pent-up sense of mischief get the better of them. In other fields, and in the award of the literature prize in particular, they are prone to let rather temporal considerations get the upper hand. An award to a distinguished writer seems the more delicious (from Stockholm) if the result should be problems with an exit visa from, say, the Soviet Union. There could be just an element of that tail-twisting in this year's prize (shared with Sanger and Gilbert) to Dr Paul Berg of Stanford University, who is, of course, a molecular biologist of the highest standing and the first to join two pieces of DNA together synthetically and also a distinguished teacher. But Dr Berg has also been, perhaps unwillingly, one of the advocates of the regulation of genetic manipulation. Nobody will begrudge Dr Berg his prize, and nobody in his senses will deny that the progress of science is effected not merely by startling discoveries but also by the genial influence of men and women who help to ensure that a new subject is widely known, properly understood and regarded with enthusiasm. This, for what is is worth, was the late J. Robert Oppenheimer's influence in physics in the 1930s, but he died without a Nobel Prize. Nobel's will may be intact, but have the rules been subtly changed?

That such questions are asked of the Nobel Foundation is a measure of its success. For better or worse, the Nobel Prize has come to stay. The need now is to make sure that it creates more pleasure than grumbling disappointment. Broadening the terms of reference of the will would help. A more explicit statement of the reasons for making an award, and a more explicit recognition by the Nobel committees of the teamwork involved in novel discoveries, would often help to disembarrass those who are awarded prizes and who are frequently heard to say "It's not for me but for my lab". Indeed, there is even a case for thinking that the Nobel Foundation might itself give expression to that sentiment by making the award, as at present, to the distinguished scientist but sending the cheque to his institution.

Making British science policy by stealth

The present British government, noted for (and proud of) its empiricism, appears to have taken an axe (or at least a chopper) to the foundations of British science policy in the past decade without much caring what the consequences will be. Since 1971, the word Rothschild has been (among other things) the code word for a doctrine — that, in the planning of applied research, decisions about what to do and how to spend can sensibly be made only by the ultimate user of the results of the research. But who is the potential user of the results of publicly financed research? Constitutionally, Rothschild recognized, the strict answer must be the taxpayer. In theory, however, taxpayers' interests are represented by government departments. So what more natural than that government departments should be required to work out, between themselves and the Treasury, what proportion of their resources should be spent on research and then to arrange that the work should be undertaken by the contractor offering the best terms? This was the argument accepted by Mr Edward Heath's government in 1971. Different fractions of the budgets of the Agricultural and Medical Research Councils and the Natural Environment Research Council were transferred to the appropriate sponsoring ministries. (The budgets of the Science Research Council and of the Social Science Research Council were, for a supposedly provisional period, left untouched.)

Now (see opposite page) the system is beginning to break down. The Department of Health and the Medical Research Council appear to have decided that Rothschild's omelette had better be unscrambled. The attractions to both parties are clear enough. The department will rid itself of some tedious administration (and may in due course get rid of even more). The council will grow modestly in size (which is probably not an important consideration) and, more to the point, will know more accurately where it stands financially from year to year. Undoubtedly a great many things would, under the proposed transfer of funds, be carried out more efficiently than in the past. It is, for example, anomalous that the Department of Health should have commissioned the study of the side-effects of the use of pertussis vaccine directly from a group of academic physicians, while the council has on its staff or on its books a galaxy of distinguished epidemiologists better able to plan a study of the kind required than almost anybody else. Plainly, part of the weakness of the Rothschild doctrine has been that in some fields of enquiry there is not merely just one customer but just one contractor as well.

For the council, there is only one serious drawback in the proposed arrangements. If the department is planning to hand over at least half the money it now spends on applied medical research, it is only right that the council should accept the responsibility for deciding how these should best be spent. In other words, the council will have to work out for itself some way of identifying the needs of the department and ultimately of the National Health Service. For what it is worth, one of the council's weaknesses in the heyday of its growth in the 1950s and 1960s was its stolid disinclination to take responsibility for such problems. Now, plainly, its inclinations have changed. It is to be hoped that it will succeed. Certainly a failure to do so will mean further upheaval. On balance, however, there is every reason to hope that the council will be able to rise to the occasion and be the better for having part of its interest in the long-term development of applied research however untidy it may be.

The drawbacks, such as they are, will be found principally at the Department of Health but also in the principles on which public policy on research now rests. Evidently — this is the experience of the past decade — the Department of Health has been at a loss to know how to function efficiently as a customer for research. To use the Rothschild imagery, the department has had money to spend but has not known clearly what it wanted to spend it on. At this stage, it is probably too late to know whether the department has deliberately (or even unconsciously) dragged its feet in setting up the "strong" chief scientist's department that was an essential ingredient of the Rothschild prescription. It is, however, a curious turn-up for the book that the council should now be thinking of taking on responsibility for operational research in health care, apparently because the department does not keenly sense the operational need of the health services. Rothschild would say that that is precisely what is wrong. The trouble with the traditional departments is that they consider research to be a kind of commodity, like string or sealing-wax, that can be bought in from time to time as the fancy strikes the administrators and as the funds allow. Part of Rothschild's point was that government departments should be forced to take a more constructive interest in the potential of research. That battle is on the way to being lost.

The consequences of this new development for the British government's wider conduct of research are harder to foresee. No doubt the administration will be saying that the special arrangement for medical research does not mean that the Rothschild principle has been breached, but the members of the other research councils will be less than human if they do not now sense a quickening of ambition, a tendency towards what the Soviets call revisionism. The Minister of Health, when he comes to describe the new deal in the House of Commons, should therefore be asked to explain why medical research is such a special case. That may be more difficult than he thinks. For although agricultural research appears to have fitted well into the Rothschild framework, it has for some time been clear that the application of the principle to the affairs of the Department of Industry is far from satisfactory. The "requirements boards" intended to simulate customers for research are not a great success. The lack of an obvious contractor has been a serious drawback. Sadly, the time may be approaching for yet another inquiry into the management of research in Britain.

Reorganization of UK medical research

MRC recovers funds from Rothschild?

A plan for reversing the Rothschild disposition of funds for British medical research is to be considered by the Medical Research Council (MRC) at its meeting today (23 October). The proposal, which has already been agreed by the Cabinet and was notified to the Advisory Board for the Research Councils on Monday of last week, may involve an increase of £12 million a year in the annual budget of the MRC, now running at £56 million a year.

Both the Department of Health and MRC at the official level appear to have arrived amicably at the proposal now being decided. One argument in its favour has been the difficulty experienced in the past several years in operating an effective Chief Scientist's Department within the Department of Health. Officials of MRC have also been swayed in the direction of the proposed arrangement by the recognition that, over the past decade, the funds available for contract work from the Department of Health and the Scottish Home and Health Department have been a declining proportion of the total budget for medical research in Britain.

The council will be expected at its meeting today to strike a balance between the benefits of a larger annual budget and the commitment it will now be expected to make to applied medical research. The proposal being considered involves no explicit strings, but representatives of the Department of Health will expect to be listened to more seriously in future if the council elects to take the funds now offered. If the council accepts, the Minister of Health intends to announce its decision next Tuesday in the House of Commons.

J.L. Gowans, MRC secretary

Formally, the Department of Health cannot off its own bat transfer funds from its own budget to that of MRC, which is dependent on the Department of Education and Science for its annual budget. This is why the feasibility of the proposed transfer of funds has had to be approved by the Cabinet before it could carry conviction with the council. But the redisposition of funds also entails an issue of principle — the abandonment of Lord Rothschild's "customer--contractor principle", at least as far as medical research is concerned.

The Rothschild doctrine, made public in 1971 and promptly accepted by the Conservative government of the day, recommended that 25 per cent of the then MRC budget should be progressively transferred to the Department of Health in the succeeding five years and that the department should use the funds concerned to commission research, not necessarily from the MRC.

One prominent feature of the Rothschild recommendations was the suggestion that each government department should be equipped with a "strong" chief scientist's department capable of making informed judgements of the department's need for research and of deciding how (and by whom) these objectives would best be met.

At the outset, MRC was more vigorous than the other research councils in its opposition to the Rothschild proposals. MRC also stands out among the research councils for the difficulties it has found in working out a smooth relationship with its sponsoring departments. Committees set up to suggest promising directions for applied medical research have been frustrated either by the lack of funds or the imprecision of their terms of reference. Research commissions by the Department of Health to MRC have generated uncomfortably large files of paper, while the council has been left with the sense that a substantial part of its annual spending is soft money.

At the Department of Health, difficulties have arisen because of the lack of full-time officials with a background in research. The chief medical officer has statutory responsibilities for the health of the population, and may find a conflict of interest between his day-to-day responsibilities and the planning of research. The National Health Service, presumably the prime customer in Rothschild's sense, is, however, administratively separate from the Department of Health proper.

An affirmative decision by the council at its meeting today will require that MRC equip itself to plan and execute programmes in applied medical research ranging from clinical research to the conduct of social surveys related to the effectiveness of medical care in Britian. The prize for success could well be a budget enlarged not merely by the £12 million of Rothschild money but a substantial slice of the further £14 million spent each year by the Department of Health and the Scottish departments on commissioned research with contractors other than MRC.

Genentech makes splash on Wall Street

Washington

"One of the most spectacular market debuts in recent history." That was how the *Wall Street Journal* described the first day of public trading in shares in Genentech, the San Francisco company which has been among the leaders of those aggressively pursuing the commercial exploitation of recombinant DNA technology.

Initially the company has proposed to offer one million shares at between $20 and $30 each. But demand was so great that an initial price of $35 was fixed for members of an under writing syndicate through which the shares were made public last week. An extra 100,000 shares were made available, providing the company with an investment — once brokerage commissions had been deducted — of $36 million.

During the day of frantic over-the-counter trading, in which more than half of the shares were resold by their original purchasers, the price rose at one point to $89 a share, eventually dropping back to $71. As the company has 7.5 million shares, this gives it a value of more than $500 million.

On paper, the Wall Street dealings have made multimillionaires of Genentech's two founders, Mr Robert Swanson, its president and chief executive, and Dr Herbert Boyer, vice-president and professor of biochemistry at the University of California, San Francisco.

Both own just under a million shares in the company. The principal shareholder is Lubrizol Incorporated of Cleveland, which previously bought 1.5 million shares in the company at $10 each. Kleiner and Perkins, an east coast venture capital firm, hold almost a million shares. The remainder are divided between directors and employees of the company.

Some employees have benefited from originally being paid in shares rather than cash. Robert Scheller, for example, a graduate research student at the California Institute of Technology, was given 15,000 for helping with research on human growth hormone four years ago. The stock is now worth more than $1 million.

The prices reached by the shares during the first day of public trading were con-

0028-0836/80/430669-02$01.00

siderably higher than most market analysts had anticipated. Two factors contributed. The first was a widespread expectation among investors that genetic engineering is the cornerstone of a future billion dollar industry, and Genentech is the only one of half a dozen small research companies to have gone public.

The second factor was a recent change in the tax law which has helped to restimulate the supply of venture capital. In 1969, Congress introduced legislation raising the effective rate of tax on long-term capital gains from 25 per cent to 48 per cent.

Many investors moved from the stock market to tax shelters, one result being a virtual drying up of new high-technology firms in the mid-1970s. In response, Congress cut the long-term capital gains tax back to 28 per cent in 1978, contributing significantly to the fact that the number of new companies is increasing rapidly again.

Thus, despite recent government warnings about declining investment in technological innovations, there was no shortage of bidders for other Genentech stock. Many brokerage houses were unable to obtain any shares at all in the initial allocation; others who had requested 50,000 or more only received a few hundred.

At the same time, federal officials have taken steps to try to prevent the shares from being oversold, frightened that a backlash could cause investment capital to dry up again. Thus the public offer of the Genentech shares was held up for several days, apparently after a ruling from the Securities and Exchange Commission that more details about the company's operations should be made public.

A revised prospectus issued by the company revealed that in the first half of 1980, Genentech had a revenue of $3.8 million, of which most came from research contracts, and earnings totalled only $80,000. Almost two-thirds of the contracts came from three pharmaceutical companies — A.G. Kabi of Sweden, Eli Lilly and Hoffman La Roche — with whom Genentech is working on human growth hormone, insulin and interferon respectively. The prospectus also revealed that the three companies will not be required to pay any royalties to Genentech after their research agreements expire. Although the agreements are described as "long-term", no further details are given.

Although several Wall Street analysts have claimed that the enthusiasm for the Genentech shares showed that the stock market was reviving, others added notes of caution. Half-way through the first day of trading, shares dropped from $80 to $74 following warnings from a senior partner of a major investment house that the explosive activity might be a "danger signal" and that "it will attract issues of lesser quality where an attempt will be made to create the same aura of scarcity".

European universities

No room below

European universities seem uniformly to be heading for demographic trouble. According to a 15-nation study commissioned by the European Science Foundation (ESF), European universities have too many academics in the younger age groups and consequently too small a rate of recruitment to university staffs. To make things worse, there is a prospect of falling student numbers as a consequence of low birthrates since 1970.

The report urges "concrete corrective action" to avoid an "irreparable" loss of research talent in the immediate future and, in the longer run, a shortage of trained scientists for the economy. The rate of new recruitment to most university teaching and research staffs is estimated at less then half the 3 per cent per annum required to maintain a flat age distribution.

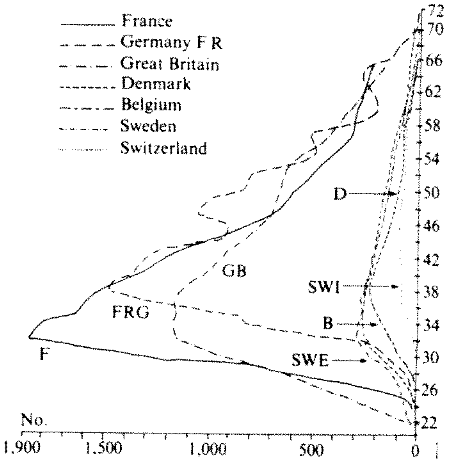
The decline of the European birthrate since 1970 is potentially a political threat to the universities. The report points out that unless a greater proportion of the age group elects for university education, enrolments will fall, teacher–student ratios will rise and governments will be tempted to cut university budgets.

Superficially, France may be the most seriously affected, with the most unbalanced age distribution among present academic staffs (see graphs). In 1977, 46 per cent of French uiniversity teaching staffs were aged 30–40, and retirement rates will average only 1.3 per cent a year over the next five years. But France is also among the most active in correcting the problem. In 1975, the Centre National de la Recherche Scientifique set itself a target of creating 3 per cent new posts a year within a staff of some 8,000 researchers. After a shaky start in 1978–79, recruitment seems likely to rise once more to 3 per cent, with consequent benefits for mobility among scientists.

Switzerland is at the other end of the spectrum. Retirements from the universities generate a 2.3 per cent annual demand for replacements in 1981–85, and thereafter more than 3 per cent.

In Germany, replacement demand is estimated at 1.5 per cent a year between now and 1985. The falling birthrate — down by 40 per cent in the period 1967-77 — will be especially troublesome. The "Heisenberg scheme" introduced in 1978 to increase the academic pool by 1 per cent a year, leaves much to be desired. Pay is relatively poor, contracts terminate after 5 years and in any case the most able get the few professorships on offer and leave the scheme.

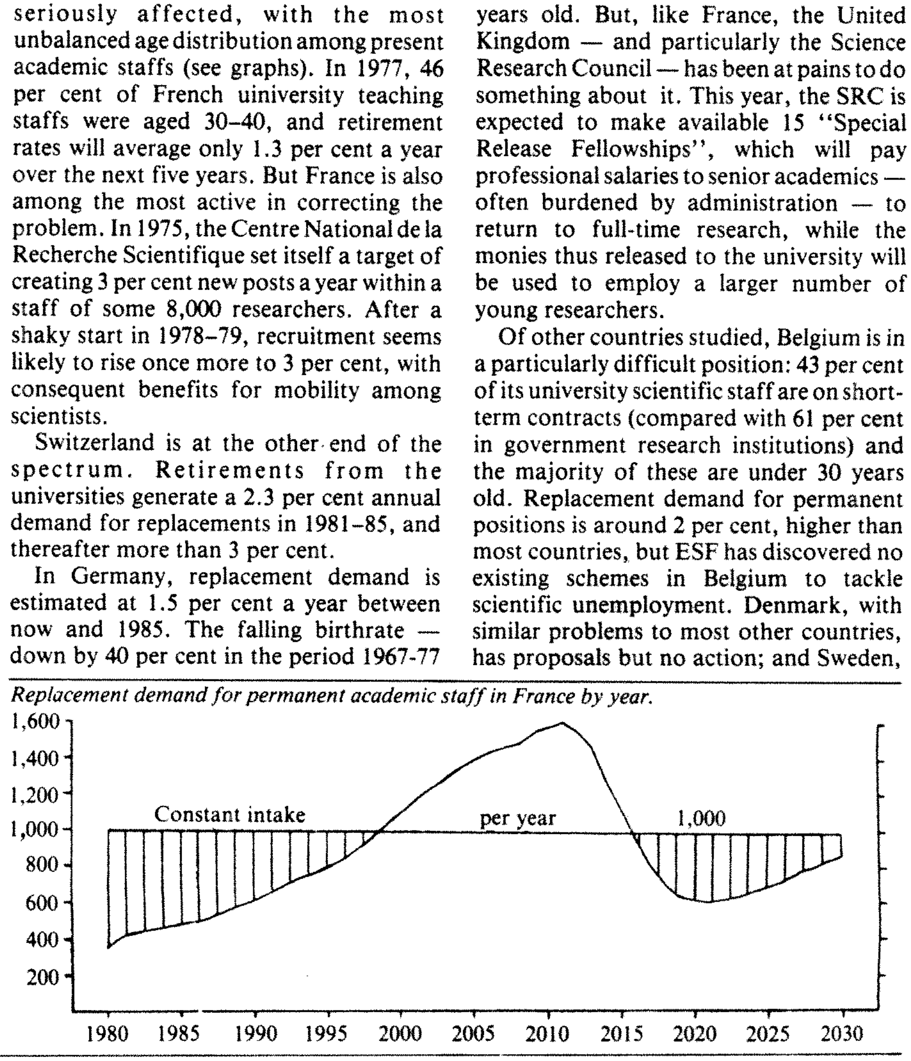
Stock of permanent academic staff universities in seven European cou s.



In the United Kingdom, the annual replacement rate is expected to be around 1.6 per cent, not reaching 3 per cent until the end of the century. Some 54 per cent of UK university staffs are between 30 and 45 years old. But, like France, the United Kingdom — and particularly the Science Research Council — has been at pains to do something about it. This year, the SRC is expected to make available 15 "Special Release Fellowships", which will pay professional salaries to senior academics — often burdened by administration — to return to full-time research, while the monies thus released to the university will be used to employ a larger number of young researchers.

Of other countries studied, Belgium is in a particularly difficult position: 43 per cent of its university scientific staff are on short-term contracts (compared with 61 per cent in government research institutions) and the majority of these are under 30 years old. Replacement demand for permanent positions is around 2 per cent, higher than most countries, but ESF has discovered no existing schemes in Belgium to tackle scientific unemployment. Denmark, with similar problems to most other countries, has proposals but no action; and Sweden,

Replacement demand for permanent academic staff in France by year.



0028-0836/80/430670-01$01.00

Norway and Austria provided no information to ESF about the measures they were undertaking.

The net result must be a fair degree of pessimism about the future of academic employment in Europe. The report makes 19 recommendations, few of them novel. The report also makes it plain that scientific mobility is also very low in Europe compared with the United States. Anxiety about jobs seems to have kept people at home. In the United Kingdom, for example, successful applications for the Royal Society European Fellowship exchange scheme fell from 91 in 1976 to 61 in 1979 (although the reverse traffic has kept up at about 90). **Robert Walgate**

Carcinogen regulations

US labs exempt

Washington

Following protests from both university and industrial scientists, the Department of Labor's Occupational Safety and Health Administration (OSHA) seems to be softening its stand on the control of toxic substances in research laboratories. Until recently, OSHA had been insisting that laboratories should be treated no differently from other workplaces in which individuals are occupationally exposed to hazardous substances.

A case in point is OSHA's new cancer policy, which was introduced at the beginning of this year: once a substance has been classed as a carcinogen based on defined scientific criteria, measures must be taken to reduce exposure levels to the lowest that is technologically feasible — and eliminate them if possible.

Labour unions have supported OSHA's argument in the past that laboratories cannot be considered any safer than factory environments, and that the same regulations should therefore be applied to both. Union officials point to reports in the scientific literature which suggest that laboratory workers may be at increased risk with respect to carcinogens, and that cancer rates are high among certain professions, particularly chemists.

University scientists, however, have complained that regulations designed to reduce exposure to chemicals in an industrial environment may be inappropriate and unnecessarily expensive when applied to research laboratories using the same substance.

Additional problems arise from the fact that laboratory work may involve exposure to small quantities of many different chemicals, and that some of these might be difficult to subject to rigid classification.

Although OSHA's new cancer policy received much comment from the chemical industry when it was first proposed, little was heard from the scientific community until the public review process was well under way. (Many laboratories were unaware of the proposals' application to them.) As a result, when the revised policy was published in January, no specific attempt was made by the agency to exempt research laboratories from its scope. In a preamble to the policy, however, OSHA said that consideration would be given to setting separate standards for laboratories.

Now, under growing pressure from various agencies, including the National Science Foundation (NSF) and the Office of Science and Technology Policy (OSTP), the agency has begun to explore ways of moving in this direction. OSHA officials are working on a proposal, due to be published sometime in the new year, setting out possible procedures for the control of toxic substances in laboratories.

Their proposals are likely to conform closely to the recommendations of the *ad hoc* committee set up by the National Research Council of the National Academy of Sciences (NAS) to look at possible alternatives to the original OSHA cancer proposals as well as other aspects of handling toxic substances. Publication of the committee's report is expected soon.

The committee, initially financed by the American Chemical Society, the Alfred P. Sloan Foundation and the Manufacturing Chemists Association, with later federal support from the NSF, the National Institutes of Health (NIH) and the Environmental Protection Agency, is expected to propose that emphasis be given to developing general laboratory safety regulations rather than the substance-by-substance regulations favoured by OSHA for industrial settings. The committee has in particular been keen to explore approaches which would be more flexible and less costly than those required under OSHA's present regulations.

Also due for publication in the near future are new guidelines that have been prepared by NIH covering the use of potential carcinogens in in-house laboratories. According to Dr Emmet Barkley, director of NIH's new Office of Research Safety, the guidelines (which include provisions for safety plans and medical surveillance) would be triggered whenever either OSHA regulates a chemical or an institute determines that a chemical is a carcinogen.

NIH's guidelines could be used as a model for other research laboratories, if OSHA sticks to a substance-by-substance form of control. However if — as seems more likely — greater emphasis is placed on general laboratory safety guidelines, the NAS report would probably provide the starting point, since this strategy would be a major departure for OSHA.

Another idea on which OSHA is thinking of asking for public comment is the setting up of an advisory committee to comment specifically on the safety measures required in research laboratories. More controversial is likely to be the role played by labour unions, which have been minimally involved in negotiations so far.

David Dickson

1980 Nobel prizes

The Nobel Foundation has in the past two weeks announced in Stockholm the names of the recipients of Nobel Prizes as follows:

Chemistry

Dr Frederick Sanger (MRC Laboratory for Molecular Biology, Cambridge, UK) for the development of a technique for obtaining nucleic acid molecules.

Dr Walter Gilbert (Harvard University, Cambridge, USA) for the development of a different technique for obtaining the sequence of nucleic acid molecules.

Professor Paul Berg (Stanford University, California) for "research in nucleic acids and genetic manipulation".

The Sanger and Gilbert techniques have turned out to be complementary. Sanger uses a single DNA strand to synthesize random lengths of complementary DNA; Gilbert's technique entails the degradation of single strands of DNA in such a way as to generate a mixture of random polynucleotides always including some fixed recognition point.

Professor Berg is known to have been the first to use naturally occurring enzymes to synthesize composite DNA molecules in which two pieces of natural DNA were spliced together.

Medicine and physiology

The prize, which is shared three ways, was awarded for different aspects of the research leading to present understanding of the human histocompatibility gene system (HLA). The recipients are:

Dr George Snell (Jackson Laboratory, Bar Harbor, Maine), responsible for the recognition of the mouse analogue of the HLA system, known as H2, and for the development of appropriate strains of inbred mice.

Professor Jean Dausset, (University of Paris) whose chief contribution was the recognition of the human histocompatibility antigens.

Professor Baruj Benacerraf (an Argentinian working at Harvard University) was chiefly responsible for the identification of the system of genes responsible for the HLA antigens.

Physics

The 1980 physics prize has been awarded for the discovery of what is called "CP violation" to **Professor J.W. Cronin** (Chicago University) and **Professor Val Fitch** (Princetown University).

Their discovery was the experimental observation of the decay of a neutral meson into two charged pions (*Phys. Rev. Lett.* 13, 138; 1964). The outcome was the recognition that in the interactions or spontaneous transformations of elementary particles, parity (left or right-handed geometrical symmetry) need not be conserved.

0028-0836/80/430671-01$01 00

Almost 8,000 scientists, including 32 Nobel laureates, have signed a "personal moratorium" pledge in support of Andrei Sakharov, Yurii Orlov and Anatolii Shcharanskii, it was announced last week. The moratorium pledge was organized by the "SOS" campaign — original "Scientists for Orlov and Shcharanskii" but extended in January to include Sakharov on his exile to Gor'kii. All three were linked with the work of the Helsinki Watch Committee.

The pledge, which replaces an earlier "personal boycott", binds the signatories not to visit the Soviet Union nor to receive Soviet scientists in their laboratories from 15 May 1980 (the second anniversary of the Orlov trial) until the end of the forthcoming Madrid review conference on the progress of the Helsinki process — unless, in the meantime, Orlov and Shcharanskii are released from labour camp and Sakharov is restored to full liberty, including the right of residence in Moscow. A total of 6,100 scientists and engineers in 44 countries have signed the SOS pledge, while similar but independent pledges in France and Switzerland have so far attracted 1,200 and 600 signatures respectively.

Orlov tee-shirts on show

The organizers now plan to deliver an information dossier to the delegations of the 33 countries signatory to the Helsinki Final Act before the conference officially opens on 11 November.

According to Dr John Charap (Queen Mary College, London) who took the chair at a meeting in London last week to report progress, the moratorium and previous boycott pledges have significantly cut Soviet exchanges with the West. In 1979, he said, short-term US–USSR exchanges of personnel had numbered 783 US and 662 Soviet scientists. In the first half of 1980, partly as a result of the pledges, these figures had fallen to a mere 72 US and 117 Soviet scientists.

Since the pledges are essentially personal, it is impossible, of course, to stop Soviet scientists visiting Western establishments, even if there has been a large response to the campaign by the scientists employed there. CERN, for example, still receives a significant number of Soviet visitors, although a large number of the scientists there have organized and signed their own pro-Orlov moratorium. Here, the signatories to the pledge simply refuse to conduct the visitors around their laboratories. When such visitors are expected at CERN, laboratory walls and notice boards display posters bearing simply Orlov's photograph and name, while many staff don T-shirts with the slogan "Free Y. Orlov".

The organizers of the moratoria emphasize that they are not "cold warriors". Nobel laureate H. Christian Anfinsen of the US National Institutes of Health said last week "We have traditionally pushed for togetherness but now we are deciding to hold back because of our concern for human rights".

All moratoria so far have been partial. They do not bind the participants, for example, not to speak to Soviet scientists at international conferences outside the Soviet Union, or not to correspond with Soviet colleagues. Several signatories report tacit sympathy for the campaign among Soviet scientists.

What the organizers hope for is not, however, entirely clear. They stress the harm that Soviet science will suffer, although the Soviets, in their turn, stress that Soviet science is self-sufficient and that moratoria can only harm the West. Dr Charap said last week that the Soviet government needs Western contacts in order to build up its economy, and that such contacts and exchanges are dealt with under "Basket two" of the Helsinki accords. If the Soviet Union wishes to benefit under "Basket two", he said, it must be prepared also to implement "Basket three", which deals with human rights.

The Western attitude to the Helsinki Final Act has always been that the detente process is indivisible, while the Soviets have preferred to deal separately with the three "Baskets" and especially "Basket one" (arms control). The public speaking of the moratorium organizers is intended to stiffen the Western stand at Madrid on the human rights issue.

Last week's simultaneous meetings in London, Washington, Geneva and Paris were, however, timely for another reason. A few days before, Shcharanskii's mother, Mrs Ida Milgrom, reported that her son had collapsed on 23 September in his Perm labour camp and had been rushed to the prison hospital for emergency treatment of abdominal pains. And in London, John McDonald, QC, announced that Orlov had been put into the punishment area of his labour camp in the Urals, apparently for complaining that he was not receiving his mail and that the guards, drunk on duty, had beaten him up. His right to a visit from his wife this August was withdrawn, and she will not now be able to see him until August 1981. However, said Mr McDonald, Mrs Orlova is afraid that her 57-year-old husband will be unable to survive the present six months punishment regime. **Vera Rich**

Ariane failure known

A faulty fuel injector in one of four rocket motors led to the failure of the second launch of the European Ariane rocket on 23 May this year.

This is the conclusion reached by the European Space Agency, which said last week that the fault caused the rate of burning fuel in the engine to oscillate 2,000 times per second soon after the launching.

A review group of independent experts has recommended that the Société Européen de Propulsion (SEP), which built the engines, should make future injectors to finer tolerances, and select good ones by ground firing tests before they are fitted to a launch vehicle.

The injector mixes fuel with oxidant at the top of the engine. It consists of a cylinder equal in diameter to the engine, with 5-cm-thick walls pierced by hundreds of angled holes which direct streams of oxidant onto streams of fuel. Variations, within manufacturing tolerances, of the geometry of the holes seem to be capable of inducing instabilities in the burn – although the fluid dynamics of this is still not understood.

Experiments with engines at SEP in Vernon, near Paris, showed up the fault. Apparently, manufacturing tolerances have slipped since the 200 test firings, although with hindsight low amplitude oscillations have now been discovered in the data.

The third launch — with ground-tested injectors — is now scheduled for mid-March 1981. The fourth and last test flight would be in June 1981, and the first operational flight in October the same year, if all now goes well. The programme would then proceed with the dates planned before the failure of the second launch. **Robert Walgate**

Soviet science

Relations forsworn

Old wounds will be opened at the salt domes of Gorleben, Lower Saxony, early next year when a new inquiry begins on the disposal of spent nuclear fuel. But this time it will not be a staged confrontation, as happened last May, of nuclear and non-nuclear experts. Now the licensing authority, the Physicalisch-Technische Bundesanstalt of Braunschweig, will present the case from the platform and protesters will have to speak from the floor. And protesters will not be getting financial support from the state.

The previous inquiry led to the rejection of the proposals, for reasons which the prime minister of Lower Saxony, Herr Albrecht, insists were political, not technical. The plan then was for a final disposal facility for all West German nuclear waste, but this has now become a plan for the temporary storage of up to 1,500 tonnes of spent fuel in transport con-

0028-0836/80/430672-02$01.00

tainers, constantly cooled in a deep pit. A similar proposal is being made at Ahaus, 100 km from Gorleben, but the inquiry there will take place later.

Both proposals are backstops, not permanent solutions to the problem of nuclear waste in Germany. The spent fuel ponds of the existing 12 GW of nuclear power plants are full (allowing space for emergency core dumping), and spent fuel is being transferred to the French reprocessing firm Cogema. But that 500 times per year contract expires in 1984, when French capacity will be fully committed on domestic work.

One alternative being considered is what is called compact storage at existing ponds, using barium shields to absorb neutrons and to kill potential fusion chain reaction. The result could be a five- to sevenfold increase of storage capacity but only in the face of political opposition. As part of nuclear power station site construction (or modification), compact storage must be approved by public inquiry.

Compact storage has nevertheless been agreed for the six nuclear reactors now under construction, which will bring German nuclear power capacity to 21 GW by 1984, so that the issue is only relevant for existing reactors but is there critical. Legally, reactors whose fuel cannot be disposed of safely must be shut down. With the possible ending of the Cogema contract in 1984, West Germany may have to shut down 12 GW of nuclear power.

The sites of Ahaus and Gorleben are thus safety valves, and the planning process has been started in good time in deference to the inevitable opposition. At Gorleben, the chief opponent will be Helmut Hirsch, who organized the opposition at the previous inquiry. Backed by a consortium of environmental groups, he will be arguing that extended storage in transport casks is unsafe.

"The whole scheme is improvised" he said last week. Two years ago, he claimed, the nuclear industry had admitted that there was no recognized system of safe dry storage. In the new proposal, the fuel would become hotter in ponds, perhaps hotter even than in a reactor, and the mechanical stresses involved would lead to corrosion and collapse of the fuel cladding. Hirsch also emphasized that the containers will have to be actively cooled, so that safety will depend on the continuity of the power supply to the plant. The nuclear industry counters that Hirsch's scenarios are extremely improbable.

The long-term deep storage of reprocessed and glassified high active waste seems still a long way off. Indeed, the prospect has become even more uncertain since the last inquiry, for the East German government has now weighed in with complaints about the risks of siting a deep storage facility close to the border, where the prevailing winds would carry emissions to the East rather than the West.

Baltic oil pollution

Finns fight spill

Finland's Department of Environmental Protection is to set up a new marine biological research and rescue programme to deal with oil spills. This announcement by the Ministry of the Interior follows publication of a report on the damage caused by the oil slick from the *Antonio Gramsci*, which went aground in the Gulf of Riga in February 1979. Although the damage on this occasion was relatively slight, the report found Finnish preparations inadequate to deal with a major slick disaster. The new programme, which will cost an estimated FM 400,000 (£57,000) to implement, will include both oil-fighting and clean-up measures and longer-term research on toxic after-effects.

The oil from the *Antonio Gramsci* first entered Finnish waters at the end of March 1979, striking the edge of the sea ice just south of Utö. It then drifted away towards Sweden, but returned at the end of May and came ashore in the Aaland Islands until 4 June. After emergency clean-up measures, a survey was made during July and August on the impact of the oil on fish, seal and bird populations, and on the littoral and benthic ecologies.

Some 1,200 sea birds had perished in the disaster, and a further 500 were soiled. By the time the survey was made, fish life was found to be virtually unaffected. (The islanders had apparently continued to eat the fish without ill-effects.) However, ichthyologists found a significantly higher rate of abnormal tails in the fish examined, although it was not clear that this was the result of oil from the *Antonio Gramsci*.

There was, however, considerable benthic deposition of oil, with the consequent threat of accumulation in food chains. Six months after the incident, there were still traces of oil in mussels.

Finland's unpreparedness for post-spill rescue and clean-up measures is in remarkable contrast to its concern with pollution prevention. The pride of the Finnish passenger fleet, the *Finnjet* ice-breaker ferry, operates as a totally closed environment, with special port facilities for the discharge of sewage and bilges, while her onboard sewage treatment plant has been estimated to cost some £1,000 a day in lost cabin/cargo space alone.

Moreover, under the terms of the Helsinki Convention for the Protection of the Marine Environment of the Baltic Sea, Finland has special responsibility for pollution due to oil spills. Although the convention only came into force on 3 May 1980, there has been joint research and monitoring programmes between the participant countries for several years. A major programme for open-sea monitoring of biomass as an indicator of pollution is already under way. Finland, however, like all other participant countries, is experiencing some delays in getting started; in Finland's case, this is due to lack of carbon-determination facilities in institutes on the coast.

One country which is not taking part in the biomass monitoring programme, although it is a signatory to the Helsinki Convention, is the Soviet Union. The reason for this is mainly that the biomass working group needs to be able to meet at relatively short notice, shorter than the time needed for Soviet experts to obtain visas to attend. Therefore, when, at a working group meeting at the Gdynia Sea Fisheries' Institute last May, monitoring of the Baltic was partitioned between the participant countries, the Soviet offshore waters became the responsibility of Finland and the GDR.

It would seem, furthermore, that the Soviet Union is unable to meet its full commitment regarding damages from the *Antonio Gramsci* affair. The Finns set the total bill at some 15 million Finnmarks, but have agreed to settle for about 25 per cent of this sum, the one million rubles which is the maximum compensation permitted under Soviet law.

Frosch moves on

Washington

Dr Robert Frosch, administrator of the National Aeronautics and Space Administration (NASA) since 1977, is the latest to join the exodus of science administrators from the federal government.

Following the departure in June of Dr Richard Atkinson, director of the National Science Foundation, and the widely expected appointment of the President's Science Advisor, Dr Frank Press, as president of the National Academy of Sciences (NAS), Dr Frosch has announced that he will become the first president of the American Association of Engineering Societies. on 20 January next year.

Before joining NASA he was associate director for applied oceanography at Woods Hole Oceanographic Institution, and has also been Assistant Secretary of the Navy for research and development. His three and a half years at NASA have seen the agency struggling increasingly against the escalating costs of the space shuttle programme, which is now biting deeply into the space research budget.

Dr Press's appointment is almost settled. His was the only name put forward by the academy's nominating committee, and no serious challenge is expected. Dr Press's appointment would have to be reviewed by a federal ethics committee, established last year to consider the exemption of science administrators from a new law forbidding an ex-government employee from accepting funds from his old agency for two years after leaving government service, but this is not expected to raise difficulties.

CORRESPONDENCE

Science in Spain

SIR — The present status of science in Spain is unworthy of an advanced society that values its standing in the community of nations. It is incumbent upon a modern state to develop a balanced policy of support for basic and applied science; a policy for the advancement of science must be the concern of government as much as economic, educational, foreign and military policy. Unfortunately our administration is derelict of this obligation; it is disregarding the creative aspects of science in favour of short-term pragmatism, typical of a colonial society.

As a matter of intellectual dignity, of national prestige and of responsibility to future generations, this situation must not persist. As Spanish scientists we demand that the administration respect our right to pursue our scientific interests, and we assume the responsibility for generating a scientific establishment that is both of value to our society and a credit to our country.

The efforts committed to this endeavour will be justifiable only if the resulting science and technology are competitive at the international level. In order to be competitive, technology must be original, and because of its modern complexity it depends on complete and continuous access to basic research. It is impossible to generate a competitive technology without a parallel reinforcement of research in basic science.

The extent of the task that confronts us can be evaluated by examination of the commitment to science in other countries in the European Community. The initial investment required to approach their levels is modest, both in absolute terms and in comparison with the cost of other national programmes. However, this effort must begin immediately, because the deterioration of our scientific institutions, the demoralization of our scientists and the loss to other countries of the most able, especially among the young, increases daily.

In order to invigorate our science, the university departments must become centres of scientific excellence, with a balanced dedication to preparing new professionals and to research. Moreover, because of the complexity of modern scientific investigation it is necessary not only to reorganize and strengthen existing research centres, such as the Research Council, the Nuclear Energy Commission and the Agricultureal Research Institute, but even to create new ones.

Our country cannot be expected to reach a satisfactory level of cultural and economic development or a minimum of political independence, if we do not soon recognize that progress depends on knowledge. State administrators must become aware of the necessity of stimulating sound scientific research and of the historical responsibility they have in this endeavour.

The above *Manifesto* has been signed by, among others, 134 professors, 25 associate professors of the University of Madrid, 23 research professors and 14 investigators of the Spanish Research Council, heads of departments or institutes in the areas of humanities, natural sciences, medicine and technology in nineteen major cities of the country (Barcelona, Bilbao, Córdoba, Granada, La Laguna, León, Lérida, Madrid, Málaga, Murcia, Oviedo, Pamplona, Salamanca, Santander, Santiago, Sevilla, Valencia, Valladolid and Zaragoza) besides 21 investigators, heads of research groups in the Spanish Atomic Energy Commission and several medical institutions.

Nuclear electricity

SIR — The article 'Nuclear generating costs compared' (*Nature* 21 August, p.753) states that the analysis of relative costs given in the 1979/80 Report of the Central Electricity Generating Board (CEGB) "is likely to be much quoted in the months ahead, when plans are being laid for the further development of the British nuclear power programme". This is certainly true and it is therefore a pity that the report's figures were reproduced without question. In fact, for the purposes of comparison, the figures are almost totally misleading.

The apparent lower cost of nuclear (Magnox) electricity (1.30 pence per kWh against 1.56 pence per kWh for coal) is entirely an artefact of inflation. If currency had been stable over the lifetime of the Magnox stations (or if inflation had been corrected for in the accounts) the order would have been reversed. In 1980 prices the approximate corrected costs are 2.5 pence per kWh for electricity from nuclear stations and 1.9 pence per kWh from coal-fired stations[1].

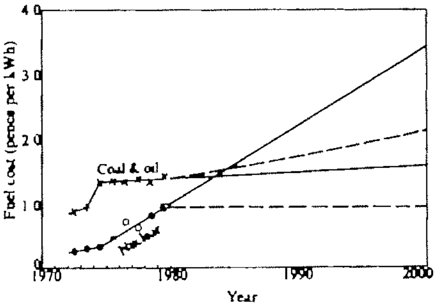

Fig. 1 Fuel costs from the 1979/80 CEGB Statistical Yearbook, Tables 9 and 10, from 1972/3 to 1979/80 in pence per kWh corrected to 1979/80 prices using the Retail Prices Index., Crosses, coal and oil combined, circles, nuclear 1980–2000 extrapolations. solid line, linear; dashed line, CEGB extrapolation for net effective cost calculations

The full calculation can only be undertaken when the CEGB decides that its present policy of withholding the data from which Table 1 in the *Nature* article was calculated is counterproductive, but all the indications are that the real cost of nuclear electricity in 1979/80 was well over 50 per cent greater than that from coal-fired stations.

When we come to future costs (Table 3 in the *Nature* article) the figures are calculated in 1980 £'s But here the figures are equally misleading for different reasons. Richard Marshall (*Nature* 18 September, p.184) has dealt with the CEGB's optimistic figures in the light of actual operating experience with regard to load factors. An equally optimistic view is taken of nuclear fuel costs relative to those of coal. Figure 1 shows the real costs of nuclear fuel for the last eight years. This rose quite rapidly for the first three years but then shot up at a rate of 0.12 pence per kWh per year to 0.94 pence per kWh in 1979/80. The increase shows no sign of slowing down and if it continues nuclear fuel costs will overtake those of coal in the mid 1980s.

It is significant in respect of future fuel costs that the 1979/80 CEGB Report records with satisfaction that an understanding has been reached with the National Coal Board to take 75 million tons of coal a year provided that the real price of coal does not increase for five years, but "the terms of a contract with British Nuclear Fuels Ltd for reprocessing oxide fuel from the advanced gas-cooled reactor (AGR) stations have yet to be negotiated".

It is extraordinary that the CEGB has nevertheless nowhere, either in its reports or in the evidence to the Select Committee, discussed the alarming increase in real nuclear fuel costs (over 10 per cent per year for the last five years) but has concentrated on postulated increases in the real price of coal up to the end of the century. This hypothetical increase is actually incorporated into Table 3. The figure of 2 38 pence per kWh for 'inclusive fuel costs' of a coal-fired station is composed of two parts. 1.36 pence per kWh is the approximate current fuel cost in March 1980 prices and the remainder, 1.02 pence per kWh, is entirely dependent on the assumption about increases in coal costs up to the year 2000. If real future costs for coal are assumed to remain stable this part would be zero.

No such addition to current costs occurs with nuclear fuel. The figure of 0.61 pence per kWh in March 1980 prices hardly covers the increase due to inflation from the 0.55 pence per kWh given for Hinkley Point B in 1979/80 average prices, let alone any allowance for the rapid rise in real costs. There is no provision for "present value of future real increases in the price of fuel" in the nuclear case and this means that it is assumed there will be no real increases in the price of nuclear fuel over the 25-year lifetime of the station.

It is on the basis of such wild assumptions that the net effectiveness cost calculations over the whole lifetimes of the stations have produced the apparently favourable results for nuclear power.

It is difficult to see why the CEGB did not present the obvious calculation — the estimated cost in pence per kWh for each station in its year of commissioning in 1980 costs and prices — and then make the various points relevant to possible alterations in these costs in the future. But then these considerations would have been explicit and generally understandable, whereas wrapped in the computer program for finding net effective cost they are almost immune from criticism.

NEWS AND VIEWS

The economics and management of commercial fisheries

from Robert M. May

THE blockade of Channel ports by French fishing boats this summer will have forcibly reminded many unfortunate travellers that managing the fisheries of Northern Europe is no simple task.

As will be argued below, the major problems are economic, social and political rather than scientific. The scientific problems are, however, formidable. To begin, data for fish populations[1] and the intrinsic dynamical behaviour of the populations[2-4] are both subject to many kinds of stochastic effects. Thus, even when the millennium dawns and fisheries managers completely understand the biology underlying recruitment processes, predictions about stock densities and recommended catch levels are likely to remain probabilistic rather than deterministic statements[5,6]. This probabilistic character infuses much of the biological sciences[7], contrasting with the crisp determinism of most of classical physics and engineering; a contrast leaving many people with the uncomfortable feeling that such areas of biology are 'unscientific'.

The millennium lies a long way off for fisheries scientists, and many fundamental biological problems remain unsolved. One problem concerns the relation between stock and recruitment[1-8]. For whales, other marine mammals and some fish there is a rough — a very rough — understanding of the relation between the size and age composition of the population and the recruitment rate. But for most fish (including essentially all the commercially important species in the North Sea) recruitment appears to be approximately independent of stock density down to some threshold level, below which recruitment appears to collapse suddenly; at present, there is no *a priori* way of determining this threshold, although it may be (and this is debatable) that it has been discovered *post hoc* in 7 major clupeoid fisheries that have collapsed[9] (North Sea herring, Norwegian spring spawning herring, Hokkaido-Sakhalin herring, Pacific sardine, Far Eastern sardine, Southern African sardine, Peruvian anchovy). Another set of problems arises from the simultaneous harvesting of several different species that interact within a complicated ecosystem[1-10,11]; such problems are becoming more important with overfishing of many conventional fish species and the search for new kinds of food from the sea.

These scientific problems are the subject of several recent reviews[6,8,11,12]; the book edited by Gulland[1] is particularly good. The difficulties are often compounded by inadequate reporting of catch data. For instance, the International Council for the Exploration of the Sea (ICES) working group on hake stocks this year decided to double Spain's official figure for their hake catch (taken under license in EEC waters), on the basis of the number of unlicensed Spanish vessels sighted in the Bay of Biscay by the French authorities. Moreover, the agreed rules are not always obeyed: again to use hake as an example, French and Spanish fisheries in the Bay of Biscay in 1979 exceeded the total allocated catch (TAC) by some 10,000 tonnes, using small-meshed nets such that 80 to 90 per cent of the catch was below the internationally agreed minimum size of 25cm. Although the reasons given in defense of such infringement are often that the TAC set by ICES or other international bodies is not scientifically sound (even Le Monde[13] writes of "foreign competition (using) so-called scientific arguments, such as, for example, slashing quotas of catches in authorized fishing areas . . ."), the real reason lies in the economics and politics of the situation. To this I now turn.

In the past, most marine fish stocks have been exploited as 'common-property' resources; fishermen (unlike farmers, miners, or lumbermen) do not usually own the primary resource base from which their income is derived. In such common-property, open-access situations, there ensures what Hardin[14] has called a 'tragedy of the commons', as fishermen are forced to compete for their share of the catch taken from a finite resource stock. Even after the establishment of international management commissions which seek to prevent excess depletion of stocks (or rehabilitation of overexpolited stocks) by restrictions on fishing gear, closed seasons and areas, total catch quotas and so on, there remains a basic tension between[12] "the interests of the individual ('will an additional vessel make a profit') and of society as a whole ('will an additional vessel result in an increase in the value of total catch that is greater than the cost of the vessel')." In this way, competition within common-property fisheries has repeatedly led to overexpansion of fishing capacity and "dissipation of economic rent", even in those cases where management has succeeded in preventing depletion of the fish stocks.

With the introduction of 200-mile Exclusive Economic Zones (EEZ) by coastal states, most of the world's fish stocks are now susceptible to rational management; by the end of 1979, 99 per cent of all commercial fish catches were contained within the new EEZs. The UN Food and Agriculture Organization (FAO) has noted[12] that this global movement to patterns of national "sole ownership" marks "a time of fundamental change and tremendous opportunity . . . to move in an orderly way to develop processing capacity and markets based on a stable supply, and in general to look forward to great and continuing benefits from the resource". Partly motivated by these opportunities, there has been an upsurge in interest in methods for the economic regulation of commerical fisheries[12,15-19].

In particular, Clark[17] has analyzed models for fisheries, incorporating the microeconomic decisions made in the operation of individual vessels, in order to understand the consequences of various methods of regulation. These include total catch quotas, vessel licenses, taxes on catch (or effort) and transferable catch (or effort) quotas allocated to individual vessels.

Setting aside the technical problems associated with a licensing programme (who gets licenses, at what cost and under what limitations of transferability, etc.), it is important to realize that licensing by itself does not resolve the common-property problem of fisheries. The usual experience of licensing programmes has been that[20] "licensed vessels have been progressively replaced by larger, more powerful vessels with increased capacity for catching and storing fish on board." Such expansion in capacity typically necessitates additional regulation: the size and horsepower of vessels may be controlled, restrictions may be placed on gear or detection equipment, fishing grounds may be closed at specified times, and so on.

Similar problems beset regulation by

Robert M. May is Class of 1877 Professor of Zoology at Princeton University.

0028-0836/80/430675-02$01.00

total catch quotas. Both licenses and total quotas can prevent depletion of stocks, but they almost inevitably lead to the kind of overexpansion of fishing capacity that causes many of the problems in the North Sea. As Clark[20] summarizes it, "In practice, this process usually manifests iself in terms of a progressive shortening of the fishing season, with the entry of more and larger vessels, which become capable of capturing the annual quota in fewer and fewer days of fishing. When the regulation is by means of gear restriction, closed seasons, and the like, the resulting fleet expansion will tend to overcome the regulation, which will then have to be revised, initiating further expansion."

In short, any regulatory process that leads to fishermen competing for the catch may force individuals to act in ways contrary to the overall economic efficiency of the fishery.

A system that allocates quotas to individual vessels has the fundamental advantage of counteracting these competitive features. Clark notes that such allocated quotas are frequently used to manage other common-property resources, such as water supplies and grazing land[20]: "The owner of a quota knows that (barring unforeseen circumstances) he will be able to take his quota regardless of the activities of other users. On the other hand, he is prohibited from exceeding his quota. With this knowledge, it is then to his benefit to exploit his quota in the most economically efficient manner. The main incentives for wasteful expansion of fishing capacity and other inefficient activities are thus eliminated."

The quota certificates or licenses should, furthermore, be transferable. They would thus acquire a monetary value, keyed to fish prices and the costs of fishing, which would encourage efficiency and also would[20] "resolve the problem of permitting new entrants — although entry would of course be open only to those who could afford to buy up an existing quota license".

Clark[17] has also given a proof that taxes or royalties on catch or effort are formally equivalent to allocated quotas. In practice, however, this formal result should not be taken too literally; quotas by their nature provide a direct control over catches, and thence over stock density, whereas taxes act indirectly. Control of the total catch rate via taxes or royalties requires knowledge of the price of fish, the cost of fishing effort, and in general depends on the behavioural responses of fishermen, all of which are subject to serious imprecision and uncertainty.

For international fisheries, the allocated quota system may be extended by setting national quotas, which serve to divide fishing rights among the nations involved. Then each nation can apportion its quota, allocating fishing rights to individual fishermen or firms.

There remain, of course, many technical difficulties in the implementation of any scheme of allocated quotas. These include: the set of scientific problems noted above; problems in dealing with the intrinsic variability of many fish stocks; the management of multiple-purpose fishing fleets and multi-species catches; and the inevitable problems of enforcement. Further complexities enter when one gives explicit attention to the "concentration profile" characterizing the way a fish population is distributed in space or time[18]. Thus the economics and population dynamics of harvesting a stock that is uniformly distributed in the sea will differ from those for a stock that aggregates in a relatively few large schools; exploitation will always tend to follow the concentration profile, focusing first on the highest concentrations. Depending on the shape of the concentration profile, this can complicate the economics and management of the fishery.

In general, however, there appears to be a feeling[12] that the establishment of EEZs has provided a "finite opportunity — a window in time — in which the world community and the coastal states can work together to place these new national fisheries on a solid groundwork of management", and that the best available regulatory instrument is a system of transferable catch (or effort) quotas allocated to individual fishermen or vessels. □

Roles of RecA revealed

from Steve Sedgwick

AT first glance it seems improbable that a single protein can perform genetic recombination, regulate its own synthesis, and switch-on expression of several other operons. However it is now evident that the recA protein of *Escherichia coli* has all of these capabilities. Not surprisingly the activity and regulation of this protein are currently under intense scrutiny.

In a series of recent papers, groups led by C. M. Radding[1] and I. R. Lehman[2] have shown that purified recA protein will stimulate the formation of DNA structures resembling putative recombination intermediates. One such structure is the D-loop where a single DNA strand pairs with a complementary region in a locally denatured section of double stranded DNA. D-loops may represent an early stage in recombination where a single DNA strand invades a homologous duplex to initiate strand exchange. A series of partial reactions, all requiring recA, occur in D-loop formation. At low concentrations recA protein binds to single stranded DNA. At higher concentrations it binds to double stranded DNA using ATP as a cofactor. A three stranded complex then forms in which double stranded DNA is unwound. Finally ATP is hydrolysed and recA protein dissociates. If hydrolysis takes place at a region of homology between single and double stranded DNA a D-loop can form. Heterologous and homologous single strands stimulate unwinding, perhaps explaining how recA protein seeks for homology between DNA molecules. Unwinding occurs without topoisomerase (nicking-closing) activity and so requires a free DNA end or superhelical turns so that DNA strands can rotate around each other.

RecA protein will also join double stranded DNA circles to make figure-of-eight structures, provided that one of the circles has a single strand gap[3,4]. A joining reaction analagous to D-loop formation has been proposed where initial pairing occurs between an unwound section of duplex DNA and single stranded DNA in the gap of the second molecule[3]. Nevertheless, some uncertainty remains whether D-loop formation really reflects an event in recombination between duplex DNA. First, DNA crosslinking does not reduce the yield of figure of eight molecules even though it impairs strand separation and presumably, D-loop formation[4]. Second, binding of recA protein to gapped DNA is not restricted to single strand regions and extends into much of the double stranded portion of the molecule[5]. Howard-Flanders and colleagues suggest that duplex DNAs bound with recA protein can form four stranded synapsis structures[4].

Steve Sedgwick is in the Genetics Division, National Institute for Medical Research, Mill Hill, London.

0028-0836/80/430676-02$01.00

They refer to theoretical work showing that a helical arrangement of four DNA strands with four-square base pairing can be formed without strand breakage[6].

Indications that recA protein has a regulatory role, switching-on expression of its own and other genes, first came from observations on the physiological response of *E. coli* to DNA damaging treatments. It was found that the recA gene, and a second gene, lexA, were needed to induce synthesis of large amounts of recA protein and a variety of new physiological responses. The induced responses have been called SOS functions because some aid cellular recovery. Better known SOS functions are the induction of prophages to enter a cycle of lytic growth, induction of new DNA repair systems, induction of mutations, and induction of filamentous growth. Biochemically, λ induction is best understood and occurs by recA protein proteolytically cleaving the λ repressor protein[7]. The λ repressor is then unable to bind to λ operator sites and prevent transcription. It has been hypothesised that the recA gene, and genes for the other inducible processes, also have repressors sensitive to recA proteolysis.

Direct evidence for an array of operons regulated by recA and lexA has now been presented by Kenyon and Walker[8]. By using a specialized Mu-lac transducing phage developed by Casadaban and Cohen[9] they made random insertions of the *lac* structural gene into the *E. coli* chromosome. Bacteria were selected which became lactose positive after DNA damaging treatments. These bacteria presumably have a *lac* gene fused into a transcriptional unit whose expression is induced by DNA damaging treatments. So far five different loci have been identified where recA and lexA functions are needed for induction of gene expression. Surprisingly one of these loci appears to be the *uvr*A gene, a component of the exision repair process, long considered to be distinctly separate from recA and lexA pathways of repair.

Extensive genetic evidence indicates that expression of the recA gene is switched off by the product of the lexA gene, possibly acting as repressor. This is the regulatory state of a normal cell and provides a low basal level of recA protein sufficient to perform genetic recombination and recombinational DNA repair. Little *et al*[10] have shown that recA protein switches on expression of its own gene by inactivating the lexA protein. *In vitro* they found that lexA protein was proteolytically cleaved by purified recA protein in a reaction essentially identical to recA proteolysis of λ repressor. Lex A 3 mutants are unable to induce recA protein synthesis and have a lexA protein insensitive to proteolysis. It seems that recA protease activity is triggered by interaction with a signal molecule, possibly single stranded DNA or a short oligonucleotide, which accumulates in DNA damaged cells.

An additional twist to this story, described by Brent and Ptashne[11], is that lexA protein switches off transcription from the lexA promotor. Thus the lexA gene has negative autoregulation. Increased lexA protein levels also switch off expression of certain other genes such as those causing filamentous growth.

To summarise, evidence for the following control network is emerging. LexA protein represses expression of its own gene, the recA gene, and genes for some SOS functions. Other SOS functions are switched-off by their specific repressor molecules. DNA damage activates protease activity in the basal recA protein. RecA protease cleaves the lexA protein switching on expression of the recA gene and SOS genes under the direct control of lexA. Other SOS functions are derepressed by recA proteoysis of their specific repressors.

The structural basis of recA protease and recombinase activities has now begun to be examined. As a first step the amino acid sequence of the protein was determined from the nucleotide sequence of the recA gene, combined with partial sequencing of tryptic fragments[12]. The gene contains 1,059 coding bases specifying a 352 amino acid protein with a calculated molecular weight of 37,842. The nucleotide sequence contains several regions resembling 'vestigal' insertion sequences with characteristic direct repetition of 8-11 bases. An intriguing speculation is that the recA gene evolved through a process involving transposition. The amino acid sequence indicates the presence of central β sheet flanked by partially α helical segments. The amino terminus contains sequences of amino acids reminiscent of active sites of known serine proteases. It is worth noting that four recA mutations primarily affecting the induction of SOS functions were earlier mapped in this region[13]. The carboxy terminus of recA protein is rich in aromatic and basic amino acids believed to be important in DNA binding, and so might be concerned with recombination functions. A more detailed understanding of active site domains should come with the sequence analysis of different alleles of the recA gene. Finally, the announcement that recA protein has been crystallized and subjected to X-ray diffraction analysis promises an intimate dissection of this protein's structure in the near future[14]. □

Charon's diameter

from David W. Hughes

OCCULTATION observations have been the mainstay technique for the measurement of planetary diameters for a considerable time now, and the discovery of such things as the Uranian satellite belt in 1977 and a binary asteroid in 1978 are obvious bonuses. The principle is simple. A planet passes in front of a distant star and blocks out the starlight for a specific time. Measurement of that time interval gives the angular size of the chord of the planetary disc in that direction. If this is done from a range of observatory positions on Earth the size and shape of the planetary disc perpendicular to the line of sight can be obtained. The method is technically quite difficult because it relies on extremely accurate knowledge of stellar and planetary positions and the use of highspeed photometers at the focal planes of large telescopes.

Whether or not an occultation of Charon, Pluto's satellite, would occur was difficult to predict. Gordon Taylor of the Royal Greenwhich Observatory reported that an occultation by Pluto or Charon of a 13th magnitude star in Virgo would possibly take place at about 0h on April 7, 1980. Subsequently it was predicted that Pluto would be about 1 arc sec away from the star and no occultation would be seen. Then it was noticed that Charon would be on the 'star side' of its orbit around Pluto and would be within about 0.2 arc sec of the track. As an error in the known position of Charon of ± 0.2 arc sec is quite possible Alistair R. Walker of the South African Astronomical Observatory decided to attempt the observation. His success is reported in a recent edition of *Monthly Notices of the Royal Astronomical Society*, **192**, 47P, 1980.

The occultation was monitored using a 100 cm telescope coupled to a pulse counting photometer which could operate at 1 ms per reading without difficulty. Twin

channels were used, one looking at the star which was to be occulted, the other at a nearby reference star. The data was taken using an integration time of 2 sec. Sky conditions were excellent and the occultation took place at 23h 39m 28s on April 6, 1980 and lasted for 50 seconds. This duration corresponded to 0.055 arc sec or 1,200 km at the distance of Charon. Unfortunately, no other observations were made in the southern hemisphere (no occultation was observed from England) so the chord length of 1,200 km must simply be taken as a minimum value for the diameter.

Another clue to the size of Charon lies in the fact that it is 1.7±0.1 magnitudes fainter than Pluto. Unfortunately, the magnitude, which is a direct measure of the brightness, depends not only on the illuminated surface area but also on the reflectivity. There is no specific reason why the reflectivity of Pluto and Charon should be the same. Other satellites are not noted for having similar reflectivities to their planets.

The dominant constituent of the surface of Pluto is methane ice. By assuming that Charon has a similar covering and that its density is greater than 0.35 g cm^{-3} Walker concludes that its diameter lies in the range 1,350 to 1,800 km.

Pluto and Charon thus seem to form a 'double planet' with probable diameters of 3,600 and 1,650 km respectively. The mass ratio is about 10:1, an extremely low value for the ratio between the mass of a planet and its primary satellite. Whether this is significant or not is a matter for future conjecture but it does bring to mind a point stressed by R.A. Lyttleton (*Mon. Not. R. astr. Soc.*, **121**, 551; 1960) when discussing the origin of the solar system. The fissional break up of a rotating protoplanet results, according to Lyttleton, in two main fragments with equal densities, the mass ratio of these portions being at least 8:1, but not greatly more than this. Unfortunately, Lyttleton points out that the two fragments separate at more than the escape velocity and cannot remain gravitationally bound to each other. So the origin of the Pluto–Charon double planet is still a mystery. □

Opioid peptides: search for the precursors

from Michael J. Brownstein

In 1975 Hughes and his colleagues unraveled the structures of two opioid peptides — methionine-enkephalin and leucine-enkephalin — that they had isolated from brain extracts[1]. They pointed out that the amino acid sequence of methionine-enkephalin was contained within another larger peptide, β-lipotropin[2], and they suggested that the latter might be a methionine-enkephalin precursor. It is known that β lipotropin does give rise to at least one family of opioid peptides, the endorphins, but, although methionine enkephalin can be enzymatically liberated from the largest of the endorphins (β-endorphin), recent evidence suggests that both methionine- and leucine-enkephalin are produced by a quite different route.

Methionine-enkephalin and β-endorphin are found in separate populations of cells both in the central nervous system and the periphery. For example, β-endorphin, but not methionine-enkephalin, is found in high concentrations in the intermediate and anterior lobes of the pituitary where it is synthesized as part of a 31,000 molecular weight protein ('pro-opiocortin') that also gives rise to adrenocorticotropic hormone and α-melanocyte-stimulating hormone[5]. Again, very high levels of methionine-enkephalin and leucine-enkephalin, but not β-endorphin, are present in chromaffin cells of the adrenal medulla[6]. Finally, it is quite clear that leucine-enkephalin must be synthesized separately from β-endorphin because its amino acid sequence is not present in pro-opiocortin[7].

Table I. Opioid Peptides

Trivial Name	*Source*	*Structure*	*Ref.*
Methionine-Enkephalin Related Peptides			
Methionine-enkepahlin	pig brain	H-Tyr-Gly-Gly-Phe-Met-OH	1
Pro-methionine enkephalin	Pig hypothalamus, human adrenal medullary tumor	H-Tyr-Gly-Gly-Phe-Met-Arg-OH	12
—	bovine adrenal medulla bovine striatum	H-Tyr-Gly-Gly-Phe-Met-Arg-Phe-OH	9
Molluscan cardioexcitatory neuropeptide (FMRFamide)	clam ganglia	$H\text{-}Phe\text{-}Met\text{-}Arg\text{-}Phe\text{-}NH_2$	8
—	trypsinization of bovine adrenal medullary proteins	H-Tyr-Gly-Gly-Phe-Met-Lys-OH	10,11
—	trypsinization of bovine adrenal medulary proteins	H-Tyr-Gly-Gly-Phe-Met-Arg-Arg-OH	10,11
β-endorphin	camel pituitary	H-Tyr-Gly-Gly-Phe-Met-Thr-Ser-Glu-Lys-Ser-Gln-Thr-Pro-Leu-Val-Thr-Leu-Phe-Lys-Asn-Ala-Ile-Ile-Lys-Asn-Ala-His-Lys-Lys-Gly-Gln-OH	3
Leucine-Enkephalin Related Peptides			
Leucine-enkephalin	pig brain	H-Tyr-Gly-Gly-Phe-Leu-OH	1
α-neo-endorphin	pig hypothalamus	H-Tyr-Gly-Gly-Phe-Leu-Arg-Lys-Arg-Pro-$(Gly_1\ Tyr_2\ Lys_2\ Arg_1)$	15
Dynorphin-(1-13)	pig pituitary	H-Tyr-Gly-Gly-Phe-Leu-Arg-Arg-Ile-Arg-Pro-Lys-Leu-Lys-OH	16

In the years since the enkephalins were first described a number of peptides with opioid activity have been discovered. Most of these contain either the methionine-enkephalin sequence (H-Tyr-Gly-Gly-Phe-Met-OH) or the leucine-enkephalin sequence (H-Tyr-Gly-Gly-Phe-Leu-OH).

As shown in the table some of the unique enkephalin-related molecules are generated by incubating adrenal proteins in the presence of trypsin[10,11]. These include H-Tyr-Gly-Gly-Phe-Met-Lys-OH and H-Tyr-Gly-Gly-Phe-Met-Arg-Arg-OH. In addition, methionine-enkephalin, leucine-enkephalin, H-Tyr-Gly-Gly-Phe-Met-Arg-OH[12], and H-Tyr-Gly-Gly-Phe-Met-Arg-Phe-OH[9], are found in tryptic digests of adrenal medullary proteins. The larger molecules that give rise to the above peptide species are being isolated and analyzed. In the bovine adrenal two possible precursors with molecular weights of 3,000 to 5,000 have been already described[13] and are shown in Table 2.

Note that trypsin, which cleaves on the carboxy terminal side of basic amino acid residues, would liberate a single leucine-enkephalin molecule from the upper peptide and a single methionine-enkephalin molecule from the lower one. Trypsin would also release H-Tyr-Gly-Gly-Phe-Met-Arg-OH and H-Tyr-Gly-Gly-Phe-Met-Lys-OH from the upper and lower peptides respectively and methionine-enkephalin could be made from either of these molecules by removing

the arginine or lysine by a carboxypeptidase B-like 'trimming enzyme'.

In human adrenal tumours there are two 2,000 molecular weight peptides that yield methionine-enkephalin when they are treated with trypsin and carboxypeptidase B (see ref. 11). The relationship of these two peptides to one another and to the 3,000-5,000 molecular weight bovine adrenal peptides described above is uncertain. It is clear, however, that 2,000 to 5,000 molecular weight human and bovine peptides are too small to be translation products themselves. They are more likely to be parts of a larger molecule; and, in fact, 8,000 to 50,000 molecular weight molecules have been detected in the brain and adrenal that either bind directly to opiate receptors or enkephalin antibodies or do so after treatment with trypsin[10,13,14].

Table 2: Two precursor molecules from the bovine adrenal gland which could give rise to enkephalins.

$\text{H-}\overset{1}{\text{Ser}}\sim\overset{\text{Lys}}{\text{Arg}}\text{-Tyr-Gly-Gly-Phe-Met-Arg}\sim\overset{\text{Lys}}{\text{Arg}}\text{-Tyr-Gly-Gly-Phe-}\overset{39}{\text{Leu}}\text{-OH}$

$\text{H-}\overset{1}{\text{Tyr}}\text{-Gly-Gly-Phe-Met-Lys}\sim\overset{\text{Lys}}{\text{Arg}}\text{-Tyr-Gly-Gly-Phe-}\overset{33}{\text{Met}}\text{-OH.}$

Recently, Lewis and his coworkers have isolated a 50,000 molecular weight protein from adrenal medulla that they think is an enkephalin precursor able to produce both methionine-enkephalin and leucine-enkephalin. The molecule contains methionine-and leucine-enkephalin sequences in a ratio of about 7 to 1, and could also contain α-neoendorphin[15] or dynorphin[16] (see Table 2), but (assuming that there is only one mole of leucine-enkephalin per mole of precursor) not both of them. It is also possible, of course, that α-neoendorphin, dynorphin, and methionine/leucine-enkephalin are all made in separate groups of cells and that there are precursors distinct from the postulated methionine/leucine-enkepahlin precursor. This could account for the report that there are separate leucine-enkephalin and methionine-enkephalin containing cell populations in the brain[17].

To establish a precursor-product relationship between the 'big' enkephalins that have been discovered and the small forms, pulse labeling studies will have to be undertaken. Workers in a number of laboratories have shown that radiolabeled amino acids can be incorporated into methionine-and leucine-enkephalin *in vivo* by the rat brain[18], and *in vitro* by striata slices[19], dissociated spinal cord cells[20], myenteric plexus explants[21], and adrenal medullary chromaffin cells[22,23]. In addition, Rossier and his colleagues[23] have shown that a 22,000 molecular weight methionine-enkephalin containing protein is synthesized in advance of methionine-enkephalin and may give rise to it. Much more work needs to be done to characterize the enkephalin precursor(s) and to show how they are metabolized into active peptides. The regulation of this process also needs to be studied in detail[22].

When the biochemistry, anatomy, and pharmacology of the various opioid peptides are better understood, the reason for their diversity may be more obvious. □

Big eyes

from M.J. Disney

HISTORY shows that in astronomy, scientific advance rides on the back of technical progress. The last major step forward in optical telescope design was conceived in 1928 and completed in 1950 with the commissioning of the Hale 5-metre telescope on Palomar Mountain. Since then the emphasis has been on light detectors, which have improved 100 fold in sensitivity and which now respond to about 50 percent of the light collected. The scope for further significant improvement is therefore limited, for which reason interest has again turned to attempts to increase collecting areas. To that end a large workshop was held earlier this year at Kitt Peak National Observatory in Arizona.

Astronomers rely on optical spectroscopy to determine the redshift, distance, composition, luminosity, rotation-speed and temperature of sources. The spectral resolutions needed to supply these data require a light gathering capacity hundreds of times greater than that sufficient to merely detect the objects. To obtain detailed information from the clouds of faint galaxies that we can already see an ambitious increase in telescope size will be required. Many conference participants felt that a collecting area equivalent to a single 25 metre diameter mirror was a reasonable goal at which to aim.

Ideally, such a massive optical telescope should be placed in space where, free of atmospheric seeing problems, it would reach its diffraction limited performance. The 2.5-metre Space Telescope to be launched in 1983 will provide increased spatial resolution but its light gathering power may still not be sufficient for spectroscopic analysis of extended objects like galaxies. As the Space Telescope will cost 500 million dollars the launch of an even larger telescope seems out of the question.

The costs for conventional ground based instruments seems to increase approximately as the 2.6 power of diameter, so that more than 2 billion dollars would be needed for a 25 metre conventional telescope. However, technological developments, particularly

thin mirror construction, polishing of fast (that is highly curved) primaries, computer aided design and control, and the alt-azimuth concept with its favourable affects on dome size, will enormously decrease the costs of future telescopes per metre of aperture. A 2-metre for less than $2.5m complete is now a certainty and proposals for a 14-metre at the price of a conventional 4-metre are being discussed in detail.

With falling costs, single institutions may be able to contemplate a big telescope for themselves. The University of Texas is considering a thin mirror (20 cm) 7-metre monolith for less than 25 million dollars; the University of California, a segmented 10-metre mirror for somewhat more. Domes can prove expensive items in the budget: at 2 million dollars the rotating asymetric dome of the 3.6-metre equivalent Multi-Mirror Telescope, now in use on Mt Hopkins, is probably a realistic pointer towards the future.

The high cost of the conventional telescope springs largely from the mass needed to maintain optical rigidity. Very large telescopes must depart from this philosophy and rely instead on the active interrelation of light thin structures. The reflecting area will either be segmented or divided into a number of separate mirrors aimed at a common focus: lasers may be used for active alignment of the components (a scheme already being tested on the Multi-Mirror Telescope) although simpler, computer-based, electromagnetic linkages between segments now look quite adequate.

The dome costs, which are considerable, rise at something like the cube of the telescope length, so there is much more pressure to construct primary mirrors as fast as F/1.75 instead of the customary F/3. Such a trend will also help to shrink the starfield onto miniature modern detectors such as CCD's, but useful angular field of view will then also shrink due to aberrations. While opticians are now confident they can devise these fast mirrors using computer-controlled polishing machines, astronomers are uneasy at the loss in field of view. It is true that big telescopes are largely used for on-axis spectroscopy, in which field-size is unimportant. However, at the conference J.R.P. Angell (Steward Observatory) demonstrated the dramatic changes we can expect from optical-fibre techniques. He used fibres for the simultaneous conduction of light from 16 widely spaced cluster galaxies down the slit of his spectrograph; thus once again highlighting the usefulness of a wide field. The battle between the big-fielders and little-fielders has scarcely begun.

The alternative to a single large instrument of revolutionary design is an array of smaller ones, adding either their light or their post-detector signal. The problems of long horizontal light beams and multiple reflections probably make a light adding design suitable only for interferometry. Any array of small instruments must reduce unit costs to the point where a very large area can be operated at a reasonable price. To reach the goal of 25 m for around $150m the choice is either a fully instrumented 2-metre unit at $1m, or a 4-metre at $4m. The Kitt Peak proposal for an Advanced Technology Telescope of 2 metre size incorporates fast thin-mirror automatic setting and guiding for a projected cost around $1.7m. How far 'mass' production could bring this down further is still uncertain. In France, A. Labeyrie (CERGA, Grasse) is operating the first of his concrete, onion-shaped 1.5-metres, which, due to their weight do not need a dome and can cost a mere $120,000 per square metre of collecting area.

With infra-red astronomy making great strides it will obviously be sensible if infra-red and optical astronomers can contrive to share telescopes. There was much debate on this issue, but with no clear result, mainly because infra-red astronomers see the need for at least two different kinds of instrument. There seems to be no doubt that the diameter of the image is disturbed by atmospheric 'seeing' as a function of wavelength, following a $\lambda^{-1/5}$ law as predicted by the theory of homogenous turbulence. Given a telescope of sufficient diameter to be diffraction limited, the atmosphere will allow 0.5 arc second seeing at 10 microns.

This, combined with the long awaited infra-red imaging CCD's, calls for a single aperture telescope of 10-metres or more, whose structure does not radiate significantly into the beam. On the other hand, C. Townes (Bell Laboratories) and F. Low (University of Arizona) have demonstrated phase coherence at the same wavelengths for periods of up to an hour and want coherent arrays of smaller telescopes. It would seem that infra-red astronomy will now develop along the lines of radio astronomy with a request for both phased arrays and big single dishes.

The issues and questions raised by the conference come at an appropriate time. It does now seem likely that a 25-metre equivalent mirror can be built in any one of a variety of ingenious ways. It remains to be seen which is best and cheapest but astronomers will need to unite behind a single proposal before they approach governments for a sum that is likely to be nearer two than one hundred million dollars.

100 years ago

ON THE SKIN-FURROWS OF THE HAND

A large number of prints have been taken by me from the fingers of people in Japan, and I am at present collecting others from different nationalities.

My method of observation was at first simply to examine fingers closely, to sketch the general trend of the curves as accurately as possible, recording nationality, sex, colour of eyes and hair, and securing a specimen of the latter. I passed from this to "nature-printing," as ferns are often copied.

A common slate or smooth board of any kind, or a sheet of tin, spread over very thinly and evenly with printer's ink, is all that is required. The parts of which impressions are desired are pressed down steadily and softly, and then are transferred to slightly damp paper. I have succeeed in making very delicate impressions on glass. They are somewhat faint indeed, but would be useful for demonstrations, as details are very well shown, even down to the minute pores. By using different colours of ink useful comparisons could be made of two patterns by superposition. These might be shown by magic lantern. I have had prepared a number of outline hands with blank forms for entering such particulars of each case as many be wanted, and attach a specimen of hair for microscopic examination. Each finger-tip may best be done singly, and people are uncommonly willing to submit to the process. A little *hot* water and soap remove the ink.

When bloody finger-marks or impressions on clay, glass, &c., exist, they may lead to the scientific indentification of criminals. Already I have had experience in two such cases, and found useful evidence from these marks. In one case greasy finger-marks revealed who had been drinking some rectified spirit. The pattern was unique, and fortunately I had previously obtained a copy of it. They agreed with microscopic fidelity. In another case sooty finger-marks of a person climbing a white wall were of great use as negative evidence. Other cases might occur in medico-legal investigations, as when the hands only of some mutilated victim were found. If previously known they would be much more precise in value than the standard *mole* of the penny novelists.

I have heard, since coming to these general conclusions by original and patient experiment, that the Chinese criminals from early times have been made to give the impressions of their fingers, just as we make ours yield their photographs. I have not yet, however, succeeded in getting any precise or authenticated facts on that point. That the Egyptians caused their criminals to seal their confessions with their thumb-nails, just as the Japanese do now, a recent discovery proves. This is however quite a different matter, and it is curious to observe that in our country servant-girls used to stamp their sealed letters in the same way. There can be no doubt as to be advantage of having, besides their photographs, a nature-copy of the for-ever-unchangeable finger-furrows of important criminals. It need not surprise us to find that the Chinese have been before us in this as in other matters. I shall be glad to find that it is really so, as it would only serve to confirm the utility of the method, and the facts which may thus have been accumulated would be a rich anthropological mine for patient observers.

REVIEW ARTICLE

Compound eyes: old and new optical mechanisms

M. F. Land

School of Biological Sciences, The University of Sussex, Brighton BN1 9QG, UK

Over the last twenty years classical views of how compound eyes work optically have undergone a series of overhauls. Exner's central concept of an optically inhomogeneous lens cylinder has survived, and such devices are now made commercially. He was wrong, however, about some crustacean eyes. They produce images by a mirror mechanism that was not discovered until 1975, and which now shows promise as an optical system capable of development.

IN 1891 Sigmund Exner produced a monograph[1] on the optical mechanisms of insect and crustacean eyes that was a landmark not only in biology, but also in optical theory. The problem at that time was that image formation in many animals with compound eyes was not comprehensible in terms of conventional spherical surface refraction, as in a simple lens. This is particularly true of aquatic insects and crustaceans, where there is only a negligible refractive index difference between external and internal media so that ray-bending by a curved cornea is minimal, and also in those eyes whose corneal surfaces are flat anyway—some mantids, for example[2]. Exner's solution was ingenious and unconventional. He proposed that the optical elements of many compound eyes behaved as 'lens cylinders', that is, cylinders with a graded refractive index, densest along the axis and declining in an approximately parabolic manner towards the outside. Such structures have the property that a non-axial ray, striking the end of the cylinder normally, will be refracted continuously towards the axis (Fig. 1*d*, *e*). In fact, if the gradient is right, all parallel rays will be refracted to the same point on the axis, and parallel rays at an angle to the axis will be focused in the same plane, but slightly to one side. In other words, an inhomogeneous flat-ended cylinder would behave very much like an ordinary converging lens in its image-forming properties.

Inhomogeneous lenses were not an entirely revolutionary proposal, even in Exner's day. Matthiessen[3] had already proposed that the lenses of fish eyes had a variable refractive index, highest in the centre. He used this to explain why fish lenses had a much shorter focal length than a homogeneous lens with the same central refractive index (this would be about 4 radii, whereas real lenses have a focal length of about 2.55 radii, a figure that has come to be known as Matthiessen's ratio). It also

explained why fish lenses are free of spherical aberration, which would otherwise be severe. Speculation about the properties of optically inhomogeneous media goes back to Maxwell[4], who "stimulated apparently by the contemplation of his breakfast herring" (ref. 5), devised a fish-eye universe with the alarming property that all rays emitted from a particular point returned to it, after passing through a conjugate image[4–6].

Much of Exner's work was based on two animals which he chose for their differences and experimental convenience. They are the king crab (Xiphosura) *Limulus*, and the glowworm *Lampyris*.

Limulus

Limulus has a smooth cornea behind which is a series of ingrowths of the cuticle (Fig. 2*a*), each of which abuts onto a cluster of receptors. Exner found that there was an inverted image at the tip of each such ingrowth (Fig. 2*c*), and because of the smooth cornea concluded that this had to be produced by lens-cylinder focusing. In one particularly telling experiment he cut a parallel-sided slice through one of these structures, and showed that this still acted as a converging lens, though of longer focal length. Exner's lens-cylinder explanation of *Limulus* optics was challenged recently by Levi-Setti *et al.*[7], who suggested that focusing might occur not by inhomogeneous refraction, but by reflection from the walls of each projection. They pointed out that the shape of the projections resembled that of an 'ideal collector', a reflecting device originally designed by Winston[8] for the collection of faint radiation. However, such devices produce erect, not inverted images, and furthermore, the refractive index gradient in the *Limulus* cornea, measured by interference microscopy (Fig. 2*b*), is precisely that required for lens-cylinder optics[9], so that Exner's mechanism survived the challenge.

Superposition images

Limulus has an apposition eye, that is, one in which each receptor cluster has its own private optics, and receives an image from a small solid angle of external space (Fig. 1*a*). Many nocturnal insects and crustaceans have eyes with a similar superficial appearance, but a quite different optical structure (Fig. 1*b*), known as superposition eyes. They are characterized anatomically by a wide zone of clear material between the superficial optics and the receptor layer, which usually forms a hemisphere with a radius of curvature about half that of the eye itself[10,11]. One group of insects with eyes of this kind are the glowworms and fireflies (Lampyridae) and these have the useful feature that the optical elements are physically part of the cornea, so that by simply cleaning out the interior of the eye the optics of the whole array can be studied. Exner did this, and found that instead of a series of inverted images at the cone tips there was just one erect image. This image was formed by the array as a whole and lay relatively deep, in approximately the position occupied by the retina. I have repeated Exner's observation (Fig. 3), as have others[12,13]. Unfortunately, it is not easy to see an image in most insect eyes with 'clear-zones', moths for example, because the optical elements (or crystalline cones) are separate from the cornea and the array does not survive the abuse of cleaning. In choosing *Lampyris*, and for that matter *Limulus*, Exner clearly knew what he was doing.

The explanation Exner gave for superposition image formation is shown in Fig. 1*b* and *e*. Essentially, parallel light entering many facets superimposes in the image region, and because the whole system is spherically symmetrical the overall result is an erect image. For superposition to occur it is clear that each optical element must behave as an inverter—a telescope with an overall magnification of −1. Parallel rays entering each element are redirected in such a way that the emergent beam makes the same angle with the element's axis as the entering beam, but, unlike the situation in a simple lens, the emergent beam lies on the same rather than the opposite side of the axis (Figs 1*e* and 3*b*, *c*).

There are two ways in which such a device could be made: as a conventional telescope made from two curved surfaces, with a focus in the middle, or from a pair of lens cylinders like those in *Limulus* but placed end to end. The former alternative is possible in theory[1] but in insects the refractive indices are too low and the curvatures inadequate for this to be the correct interpretation. Exner chose the double-length lens-cylinder explanation for *Lampyris*. Rays are brought to a focus by the first half of the element, then unfocused and inverted by the second half. The correctness of this interpretation has now been verified for fireflies[14], some other beetles[15], moths[16], skipper butterflies[17] and euphausiid crustaceans[18], in each case by examining sectioned crystalline cones using interference microscopy and confirming the existence of an appropriate refractive index gradient (Fig. 4).

Exner did, however, make one serious mistake. He generalized his mechanism to all eyes with a similar structure. Figure 1*b* admits of one other explanation and that is that the optical elements are simply plane mirrors (Fig. 1*c*). I shall return to this later.

Man-made lens cylinders

Commercial interest in inhomogeneous cylindrical lenses did not begin until the late 1960s, and the thrust was not to produce devices with compound eye-like properties, but to make optical fibres that transmitted images, as opposed to simply transmitting intensity. It is clear that an extended lens cylinder will keep imaging and re-imaging an object placed against its end at regular intervals along its length (Fig. 3*d*), and this ability could potentially be used to convey at least as much information per unit cross-sectional area as the alternative; this would be an expensive coherent light-guide array. The exact refractive index gradient that an image-transmitting lens cylinder should have was worked out in the mid-1950s by Fletcher, Murphy and Young[19] who, incidentally, also derived the refractive index gradient for a Matthiessen fish lens. They give the following relationship between distance between foci ($2F$), axial refractive index (n_0) and refractive index (n_r) at a radial distance (r) from the axis

$$n_r = n_0 \operatorname{sech}(\pi r/2F)$$

This expression can be expanded[20] to give

$$n_r = n_0\left(1 - \tfrac{1}{2}a^2r^2 + \tfrac{5}{24}a^4r^4 - \tfrac{61}{720}a^6r^6 + \cdots + \frac{En}{(2n)!}(ar)^{2n} \cdots\right)$$

where $a = \pi/2F$, and En are the Euler numbers. If one ignores all terms beyond the r^2 term, the refractive index gradient

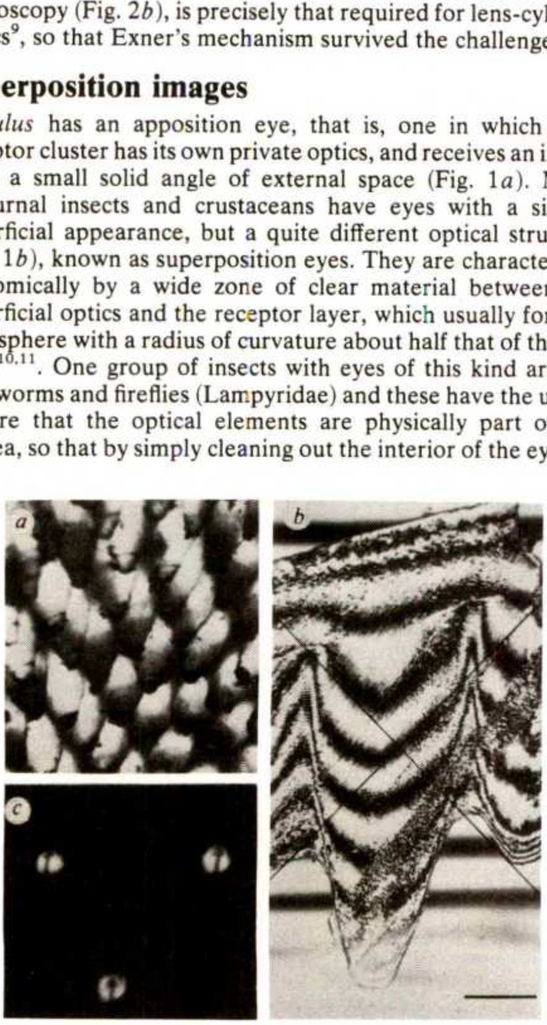

Fig. 2 Eye of *Limulus*. *a*, Crystalline cones projecting inwards from cornea. *b*, Interference micrograph of thin section of a cone. The fringe distortion is proportional to the local refractive index. Scale bar 100 μm. *c*, Inverted images of an arrowhead at the tips of the crystalline cones. (From Land[9].)

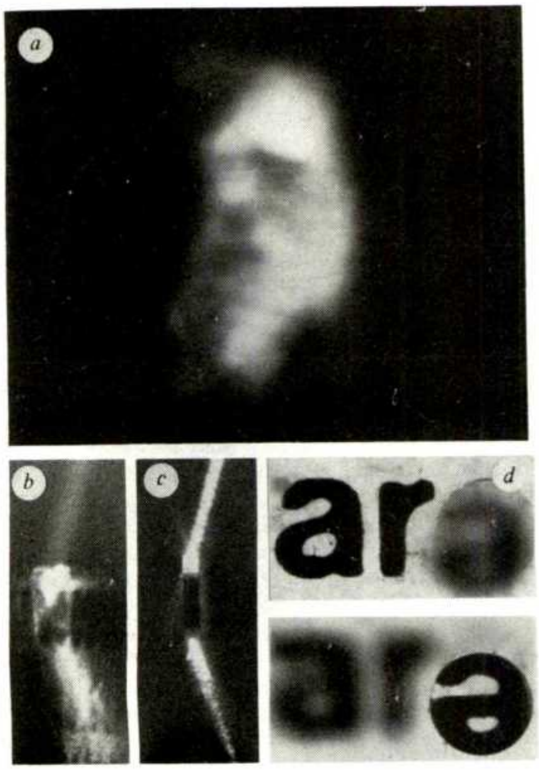

Fig. 3 Optics of refracting superposition eyes. *a*, Julia Cameron's portrait of Charles Darwin rephotographed through the cleaned cornea of a firefly. The eye was suspended in a hanging drop of water with the cornea in air. The image is erect, and the face is about 0.1 mm across. *b*, Bending of a light beam by a natural double length lens cylinder, a crystalline cone from a euphausiid crustacean. The beam is made visible with fluorescein and is 30 μm wide (from ref. 45). *c*, Light beam bent in a similar manner by a man-made SELFOC glass lens cylinder. Compare with the light paths in Fig. 1*b* and *e*. *d*, Lens cylinders also have the property of imaging an object at intervals of $2F$ (see text). The photograph shows the word 'are' with the same SELFOC as in *c* placed over the 'e'. The 'e' is re-imaged, inverted, at the upper end of the lens cylinder.

becomes a parabola, and it was this parabolic approximation that Exner's brother, Karl[21], derived in connection with biological lens cylinders (Fig. 4). Attempts to manufacture lens cylinders have also been made using diffusion processes which give rise naturally to parabolic gradients. In the 1960s attempts were made to use gas mixtures to produce lenses and waveguides[22]. Then in 1968 a glass lens cylinder (SELFOC) was produced and patented in Japan. It was made by heating a thallium-rich flint glass in a molten salt (KNO_3, at 500 °C) which leached out and replaced the heavy metal ions from the outside, thereby reducing the refractive index from 1.542 in the centre to 1.517 at the periphery[23,24].

More recently, plastic lens cylinders have been made by heating a high refractive index rod of soft polymerized plastic (diallyl isophthalate, $n = 1.57$) in a bath containing the monomer of a low index plastic (methylmethacrylate, $n = 1.49$)[25,26]. This gives a usable refractive index range that is similar to that of the glass lenses.

The future of man-made lens cylinders is unclear. They have good imaging properties over short distances—through one or two serial images (Fig. 3*d*)—but then aberrations of various kinds tend to degrade the image. The higher-order terms in the expansion for n, begin to become important, as does the fact that non-paraxial rays require a somewhat different index gradient from paraxial rays[20]. Chromatic aberration also accumulates, although this can be offset to some degree by a suitable choice of materials[26]. Given these problems, as well as those of manufacture, it is likely that aligned fibre bundles offer better prospects for long-distance image transmission than focusing lens cylinders. There should, however, be many other applications for versatile lens-like systems of very small dimensions.

Problems, and the light-guide heresy

During the 1960s, when commercial lens cylinders were at last being developed, their biological counterparts almost suffered extinction, as the following quotations show. Of lens cylinders: "It seems very doubtful if 'lens cylinder' properties will ever be found in a compound eye and therefore it would probably be better to discard the idea." (ref. 12). And of superposition optics: "There is no reason to suppose that this is true for any compound eye, and there are several reasons, given above, why the superposition image of the firefly is no more than an artifact of the cleaned retina." (ref. 27).

The revolt against Exner's principal ideas began with some careful observations by Kuiper[12], showing that in certain crustacean eyes there are no important refractive index variations in the crystalline cones, a conclusion subsequently verified by interference microscopy[28,29]. This would seem to rule out both lens-cylinder optics and superposition imagery. In their place Kuiper suggested that the important optical elements in this kind of eye were tracts or threads which crossed the clear zone, conveying images from lens systems in the region of the cornea to the deep-lying receptors. In support of this idea, he pointed out that these higher-index light-guide-like structures often became lined with pigment in the light-adapted eye, the function of which was to 'bleed' light out of the light guides by bringing high-refractive index material into contact with their sides. Effectively, Kuiper was suggesting that superposition eyes, in crustaceans at least, were really apposition eyes with a 'longitudinal pupil' mechanism for protecting the eye against high light intensities, rather than a superposition mechanism for increasing sensitivities at low intensities. Further support for this idea seemed to come from an interference microscope study by Allen[30], who claimed that in the hornworm moth the crystalline cones had a refractive index that was constant to less than 1%, and that the threads traversing the clear zone had an index of 1.523 (which would make them solid). These observations have not been confirmed, and indeed all subsequent work on insect superposition eyes[14–17], including moths, has led to opposite conclusions[11].

The present position is a satisfactory compromise. Most, if not all, insect eyes with clear zones do behave as proper Exner-type superposition eyes in the dark, with the threads that cross the clear zone interfering only minimally with the ray paths that contribute to the focused image. However, the effect of light adaptation is to cause pigment movement into the clear zone,

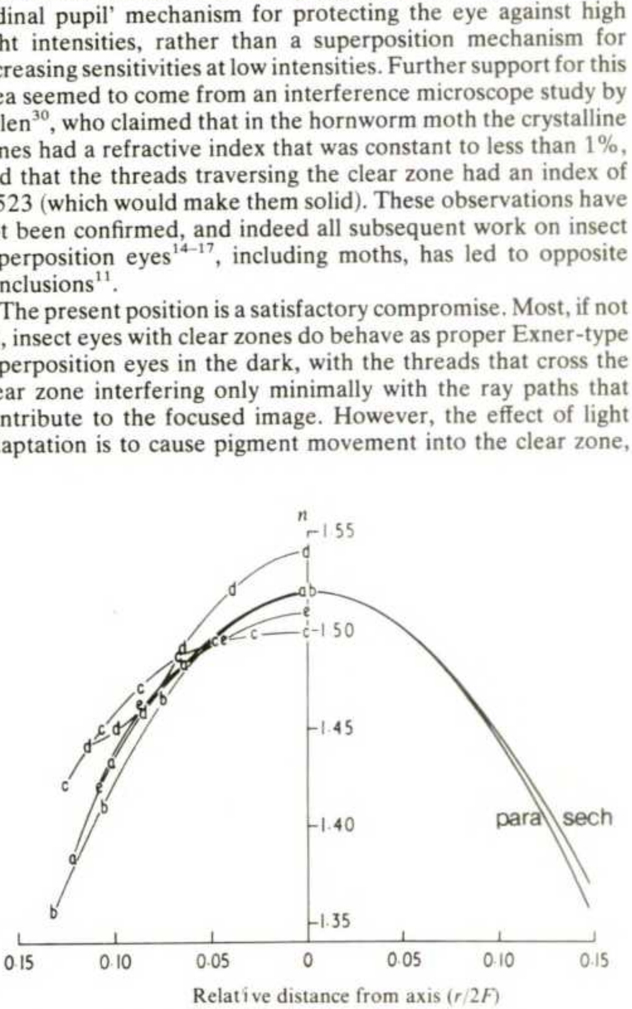

Fig. 4 Comparison of theoretical (right) and measured (left) refractive index distributions through crystalline cones. The theoretical curves show the difference between the Fletcher *et al.* equation[19] and Exner's parabolic approximation. Measured data are from: *a*, a euphausiid[18]; *b*, a firefly[14]; *c*, a moth[16]; *d*, a skipper butterfly[17]; *e*, *Limulus*[9]. The gradients have been normalized by taking the cone length as $2F$ for superposition eyes (a–d), and F in the case of the apposition eye of *Limulus* (e).

confining image-forming rays to the tract of thread joining each facet to its corresponding receptor bundle. Kuiper's light-bleeding mechanism, as well as simple pigment screening, probably both occur[31,32] and the net effect is that eyes with superposition optics at night have apposition optics by day. In moths one can watch this change happening. When suddenly illuminated in the dark, there is a large patch of 'glow' or eye-shine corresponding to the whole pupil of the superposition system, illuminated from within by light reflected from a tapetum behind the receptors (Fig. 5*d*). Exposure to light causes this patch to shrink to not much more than one facet, as pigment migrates inward and intercepts the oblique rays that would go to form the superposition image[32].

There remains, however, the problem that started the controversy. What happens in crustacean eyes without lens cylinders?

Reflecting superposition optics

Klaus Vogt provided the answer in a short note on crayfish eyes[33]. "Rays from an object point entering through different facets are superimposed not by refracting systems as in other superposition eyes but by a radial arrangement of orthogonal reflecting planes which are formed by the sides of the crystalline cones and purine layers surrounding them." Without being aware of Vogt's paper I reached the same conclusion about the eyes of a deep-sea shrimp[34]. If one looks at Exner's original figure[1,11] it is clear that the elements he drew could equally well be replaced by plane mirrors (Fig. 1*b*, *c*), and this is precisely what happens in certain crustacea, specifically the long-bodied decapods (shrimps, prawns, crayfish and lobsters, but not the true crabs). The structure of their eyes is very much like that of insect superposition eyes—a peripheral array of optical elements, a wide clear zone and a deep-lying hemispherical retina. They ought, anatomically, to be superposition eyes. The crucial difference is that the 'crystalline cones' are not crystalline—they are jelly-like with a refractive index of about 1.42—and neither are they conical. They are square in surface view (Fig. 5*a*, *d*), as shown perfectly accurately in Grenacher's plate of 1879 (ref. 35) (Fig. 5*b*).

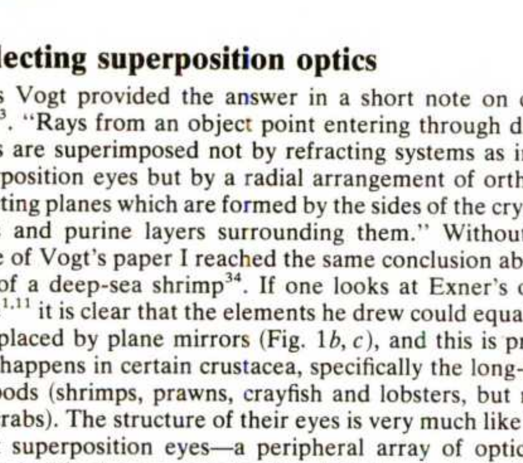

Fig. 5 Reflecting superposition optics. *a*, Surface of a crayfish eye showing the square array of mirrors; *b*, Grenacher's drawing[35] of an optical element from a shrimp; *c*, images formed by lenses in the cuticle of a crayfish eye, which prefocus the beams entering the mirror boxes[41]; *d*, adult eye of *Palaemonetes varians*, fully dark adapted, showing square symmetry and patch of eye-shine corresponding to the superposition pupil; *e*, 1st instar larva of *Palaemon serratus*, showing hexagonal symmetry and a small black pseudo-pupil characteristic of apposition eyes.

There is an elegant reason that eyes that use mirrors must have square facets. Figure 1*c* shows a two-dimensional diagram of an image-forming mirror array, but the question is: of what three-dimensional array would this be a section? One possibility is that it is a section of an axially symmetrical arrangement of tilted circular strips (Fig. 6*a*). Clearly, this will form an image of a distant point source located on the axis of the structure, but equally clearly it will not form an image of light originating from any other direction: the strips will not so much focus light as get in the way of it. What is required is an array that will behave like the strip arrangement, but for all directions. An array of square corners will do this. The reason is that a pair of mirrors at right angles to each other behave as though they were a single mirror that is always normal to the plane of the incident ray (Figs 1*f* and 6*b*): the complete angle through which the ray is reflected must add up to 180°. (One occasionally encounters corner mirrors in clothes shops—it is impossible to escape from one's image by moving around them.) Thus, provided most light entering the eye encounters two faces of each mirror box, all ray paths to the focus will be essentially identical to those of the two-dimensional diagram[29,36,37]. For a large-aperture eye like that of a crayfish each mirror box should be about twice as deep as it is wide, for the double reflection conditions to be met.

Not all eyes of the reflecting superposition type actually have mirrors. In the shrimp *Palaemonetes*, for example, reflection occurs at the faces of the mirror box by total internal reflection. With a refractive index of 1.41 inside the box, and a fluid outside with an index of about 1.33, the critical angle for total internal reflection is 71°, that is, rays making angles of up to 19° with the box wall will be reflected. This restricts the eye's effective pupil to about one-third of the eye diameter. To increase this the boxes are lined with a specular mirror in both crayfish and deep-sea shrimp. The mirrors are composed of a three-layer sandwich of one-quarter wavelength-thick plates alternating with tissue fluid[37], which is a common way for natural mirrors to be produced[38,39]. The nature of the material of the plates is not known in the crayfish, but in a pennaeid shrimp it is the pteridine isoxanthopterin[40].

A final refinement of the crayfish optical mechanism was found recently by Bryceson[41]. She noticed that each facet of the cleaned cornea is actually a long focus lens, with a focal length in water approximately equal to the distance from cornea to receptors (Fig. 5*c*). This has two implications. It means that the pencil of light passing through each mirror box is prefocused, so that it reaches the receptors as a fine beam, thereby improving image resolution. It also means that when the eye is in the light-adapted condition and each receptor only receives light from its 'own' facet[42], the focusing ensures a resolved image on that receptor and hence a narrow field of view. Interestingly, Kuiper had noticed inverted images in his original study[12].

Phylogeny and ontogeny

Mirror boxes with a hexagonal cross-section do not reflect light as shown in Fig. 1*f* and 6*b*, and so cannot be used in reflecting superposition eyes. Therefore, hexagonally faceted eyes do not use this mechanism, whereas square-faceted eyes probably do. Corneal geometry can thus be used as a reliable indication of an eye's optical type, and, since this is likely to be an evolutionary conservative character, of its ancestry as well[43,44].

An examination of the higher crustacea shows that square-faceted eyes are found only in the Decapoda, and there only in the long-bodies forms. The crabs (Brachyura) and hermit-crabs (Anomura), but interestingly not the squat-lobsters (also Anomura), have hexagonally faceted eyes of the apposition type, without a clear zone[43,44]. Equally interesting is the fact that the euphausiids, the shrimp-like krill usually grouped with the decapods in the super-order Eucarida, have both hexagonal facets and a clear zone. These eyes are very similar in their construction to the refracting superposition eyes of moths, and indeed their bullet-like crystalline cones bend light in the same way as in insect superposition eyes[45] and have a lens cylinder-

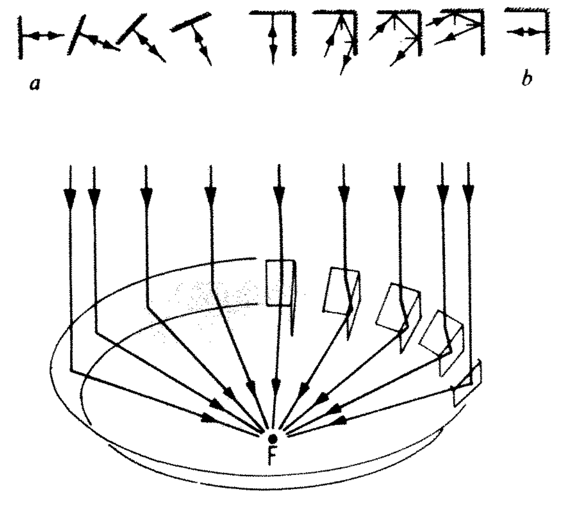

Fig. 6 A superposition focus can be formed either by set of tilted circular strips of mirror (*a*, left) or by a surface made of corner reflectors (*b*, right). Corner reflectors behave as though they are single mirrors at right angles to the plane of the incident ray (inserts above) so that the ray paths are almost the same as for the strips.

like refractive index profile[18]. The mysids (Peracarida), which look very much like euphausiids but differ from them in having a brood-pouch, also have refracting superposition eyes, although other peracaridans have apposition eyes. In the last century the euphausiids and mysids were grouped together as the Schizopoda, and my guess is that that grouping more accurately reflected their evolutionary affinity.

The decapods with reflecting superposition eyes do not start life that way (Fig. 5*e*). In their larval stages they have hexagonally faceted eyes with a typical apposition structure. In *Palaemonetes* it is not until about moult 15, when the animal is almost adult, that the facets square off and the superposition mechanism comes into operation. Presumably, the apposition type of eye is adequate for the upper ocean where the planktonic larvae live, just as it is in the light-adapted adults, but the deeper, dimmer waters the adults inhabit on maturity make it advantageous to use superposition optics, with their much greater light-gathering power. Larval crabs have eyes just like larval shrimps: the main developmental difference is that adult crab eyes retain the larval optical design. Again this makes sense, since most of them are shallow water or even terrestrial forms and would not need the superposition mechanism. It is as though the crab eye is derived from the crayfish eye by neoteny, the final developmental stage having been omitted.

This is somewhat perplexing for taxonomists. Eye structure links the mysids and euphausiids, which contemporary taxonomy does not. The reflecting superposition mechanism links all the long-bodied decapods, which are currently split between the Natantia and Reptantia[46] or the Dendrobranchiata and Pleocyemata[47]. It splits the galatheids (squat lobsters) from the pagurids (hermit crabs) and so divides the Anomura, and it suggests that the euphausiids and decapods are unrelated. Any one character is perhaps as fallible as any other as an evolutionary guide, but at least for eyes one can make the claim that once a design that works well has evolved it is most unlikely to be abandoned for an equally complicated but functionally equivalent one, as, for example, reflecting versus refracting superposition optics.

Although the decapods are alone among crustacea in possessing square-faceted eyes, there may be one possible parallel in insects. Horridge and Maclean[48] have described the eye of the Australian mayfly *Atalophlebia*, which has entirely square facets in its dorsal eye (in males the eyes are divided), square homogeneous crystalline cones and a wide clear zone. The optics are not well understood, but this ought to be a reflecting superposition eye. By contrast, the common European mayflies (*Cloeon*) have hexagonal facets and presumably refracting superposition optics. The Ephemeroptera are again a taxonomically difficult group, and it will be interesting to see whether eye structure is helpful here as well.

X-ray telescopes and other applications

Both types of superposition eye represent image-forming systems equivalent in many ways to conventional lenses and mirrors, but which have so far found few applications in optical technology. It is almost true to say that they have not properly been invented. In the case of refracting superposition devices it is clear that the task of making a large number of appropriate lens cylinders and aligning them accurately probably is not worth the effort, but for a reflecting system this is not necessarily true. One could imagine the construction of a reflecting array from strips of sheet metal, cut so as to interlock, or from a casting that was subsequently plated (there is a problem in trying to cover a sphere with squares—basically it cannot be done—but both geographers and lobsters have found ways round it). Such structures could have wide apertures, like crustacean eyes, and serve in applications like solar collectors, where condensing power rather than resolution is at a premium, or as emitters they could be useful for making large collimators, lighthouse lenses for example.

If the pupil is restricted, much higher resolution can be achieved, and it is this form that has produced the only important application so far, as an X-ray telescope[49,50]. X rays cannot be focused by refraction or by reflection at near normal incidence, which has meant that existing X-ray telescopes are all based on grazing incidence optics utilizing nested surfaces. Their design is basically similar to the tilted strips in Fig. 6*a*, and they suffer from the same drawback, a very narrow field of view. Angel[49] realized that the use of square cells as reflectors eliminates this problem, and has designed a telescope with a spatial resolution of 30 arc s. This degree of resolution is achieved by making the reflecting cells very long—about 100 times their width. Because they are reflecting devices, square-cell surfaces are usable over large parts of the electromagnetic spectrum, and provided the manufacturing problems can be overcome they should have a wide range of uses.

Guanine nucleotide-binding and autophosphorylating activities associated with the $p21^{\mathrm{src}}$ protein of Harvey murine sarcoma virus

Thomas Y. Shih, Alex G. Papageorge, Patricia E. Stokes, Maureen O. Weeks & Edward M. Scolnick

Laboratory of Tumor Virus Genetics, National Cancer Institute, National Institutes of Health, Bethesda, Maryland 20205

The purified $p21^{\mathrm{src}}$ protein of Harvey sarcoma virus shows a guanine nucleotide-binding activity and, in addition, at elevated temperature an autophosphorylating activity at a threonine residue using as phosphoryl donor GTP or dGTP but not ATP or dATP. These biochemical activities are unique among those associated with transforming proteins of RNA-containing or DNA-containing tumour viruses.

HARVEY MURINE SARCOMA VIRUS (Ha-MSV) is a replication-defective retrovirus with the potential to transform fibroblasts in cell culture and to induce solid tumours and erythroleukaemia in animals. It is a recombinant virus between genetic sequences of a helper-independent mouse type-C virus at both ends of the genomic viral RNA and inserted rat nucleic acid sequences[1-3]. Using antisera from rats bearing Ha-MSV-induced tumours, we have identified a 21,000-molecular weight (MW) protein (p21) coded for by the rat insert sequences in Harvey virus-transformed cells and in cell-free translation products of Ha-MSV virion RNA[4]. One form of p21 is phosphorylated in virus-transformed cells. Two major lines of evidence have led us to conclude that one of the forms of p21 is the transforming *src* gene product of Ha-MSV. First, the p21 encoded by a mutant (ts371) of the closely related Kirsten murine sarcoma virus (Ki-MSV), temperature-sensitive for the maintenance of transformation, is much more thermally labile than the p21 of the wild-type Kirsten virus[5]. Second, through transfection studies of the molecularly cloned Ha-MSV proviral DNA, its cloned subgenomic fragments and a series of Ha-MSV deletion-insertion mutants, the transforming *src* gene and the p21 encoding region have been localized to the 1,100-nucleotide rat sequences closest to the 5′ end of the viral genome[6-8]. The gene coding for an endogenous p21 also seems to be present in uninfected normal cells derived from a variety of vertebrate species. The antisera containing antibodies to the Ha-MSV p21 precipitated a smaller quantity of the 21,000-MW cellular homologue protein which is structurally and antigenically related to the Ha-MSV p21 and is itself highly conserved throughout evolution[9]. The major problem is, through what kind of molecular mechanism the p21 *src* transforms normal cells. Over 95% of the intracellular $p21^{\mathrm{src}}$ of a Ha-MSV-transformed MDCK dog cell has been localized to the inner surface of the plasma membrane by electron microscopic immunocytochemistry suggesting the cellular membrane to be a major site of action of this *src* protein[10]. Perhaps the most interesting property of the $p21^{\mathrm{src}}$ is its strong affinity for guanine nucleotides, implying that the transforming function of the $p21^{\mathrm{src}}$ may involve the metabolism of guanine nucleotides[11].

The $p60^{\mathrm{src}}$ gene product of Rous sarcoma virus (RSV)[12-15] and the T antigens of adenovirus[16] and polyoma virus[17] are associated in immunoprecipitates with an ATP-protein kinase activity which phosphorylates the immunoglobulin heavy chain. A tyrosine-specific phosphorylating activity has been found in immunoprecipitates of polyoma T antigens[18], Abelson murine leukaemia virus (MuLV) pl20 (ref. 19) and RSV $p60^{\mathrm{src}}$ (ref. 20). We report here a unique GTP-specific enzymatic activity of the partially purified Ha-MSV *src* protein which in solution without immunoprecipitation autophosphorylates the $p21^{\mathrm{src}}$ with $[\gamma\text{-}^{32}P]$GTP but not with $[\gamma\text{-}^{32}P]$ATP as phosphoryl donor. This enzymatic activity is clearly distinct from that of most of the other cellular protein kinases.

Purification of the p21 from NIH 3T3 cells transformed by Ha-MSV

Using antisera containing antibodies to the p21, a ^{3}H-GDP-binding assay specific to p21 has been developed[11]. Cellular extracts are incubated with ^{3}H-GDP and the antigen–antibody complexes precipitated by an absorbent, formaldehyde-fixed *Staphylococcus aureus*-containing protein A or protein A-Sepharose (Pharmacia). p21 in the immunoprecipitates is quantified by the ^{3}H-GDP bound to the p21 protein. This rapid assay allows purification of p21 from unlabelled cell extracts on a large scale. To preserve any enzymatic activity associated with p21, purification procedures used for most enzymes in

0028-0836/80/430686—06$01.00

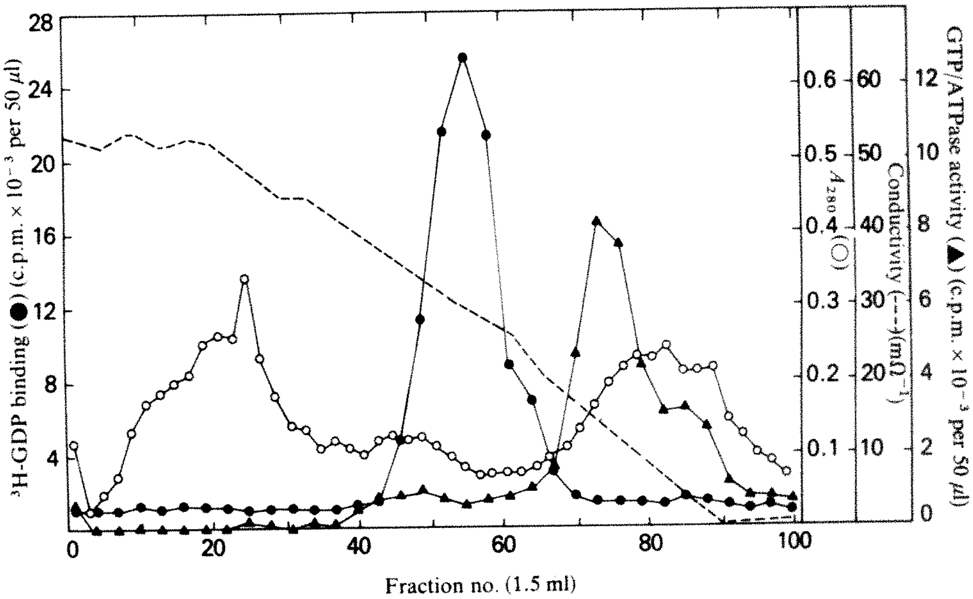

Fig. 1 Purification of the p21 by phenyl-Sepharose chromatography. 20 ml of hydroxyapatite-purified p21 (18 mg) in 0.09 M sodium phosphate, *p*H 6.8, was adjusted by adding 3.5 M ammonium sulphate to a final concentration of 0.8 M. It was loaded slowly on a small phenyl-Sepharose column (5 ml bed volume, Pharmacia) equilibrated with a starting buffer containing 0.8 M ammonium sulphate, 0.01 M sodium phosphate, *p*H 6.8, and 1 mM DTT at 4 °C. After washing in the sample with an additional 10 ml of the starting buffer, the column was eluted with 80 ml of a linearly decreasing ammonium sulphate gradient from 0.8 to 0 M in the same buffer at a flow rate of 0.2 ml min^{-1}. After completion of the gradient, the column was further eluted with 40 ml of the same buffer without ammonium sulphate and 1.5-ml fractions were collected. Immediately after measuring A_{280} and conductivity of the fractions, the fractions were dialysed against 50% glycerol in 0.01 M sodium phosphate, *p*H 6.8, and 1 mM DTT. The samples were stored at −20 °C, and no loss of p21 enzymatic activity was observed in this storage condition for at least 2 months. The p21 in column fractions was detected by a p21-specific ^{3}H-GDP binding assay as described in Table 1 using anti-p21 rat antiserum. In those conditions of assay, 7,300 c.p.m. represent 1 pmol of ^{3}H-GDP bound. As an illustration of the resolving power of the hydrophobic column, a cellular ATP/GTPase activity was also assayed by incubation with [γ-^{32}P]GTP across the gradient[34]. The ^{32}P-orthophosphate released by the enzyme reaction was extracted into the benzene/isobutanol organic phase as a silicotungstico-phosphomolybdate complex. In those assay conditions, 100 c.p.m. represents 1 pmol P_i produced in 20 min at 37 °C. ^{3}H-GDP-binding activity of the p21 (●); A_{280} (○); conductivity (- - -); ATP/GTPase activity (▲).

nondenaturating conditions were used. The membrane-bound p21 was solubilized by homogenizing cells in a buffer containing 1% Triton X-100. After high-speed centrifugation to remove nuclei and insoluble cell debris, the cell lysate was chromatographed on a hydroxyapatite column and eluted with a step-gradient of increasing sodium phosphate concentration. Most of the p21 was recovered in a fraction eluted between 0.005 and 0.09 M sodium phosphate. Essentially no detectable p21 was present in the flow-through material or fractions eluted with higher phosphate concentrations of 0.15 and 0.3 M. The specific binding activity of ^{3}H-GDP was increased 17-fold from the high-speed supernatant with a recovery of 172% total activity (Table 1). This increased activity was due to removal of substances interfering with the binding assay in crude extracts.

Hydroxyapatite chromatography is a valuable step in the purification scheme; it removes Triton X-100 and most other substances, such as lipid and nucleic acid. As p21 is mostly bound to membrane, chromatography based on hydrophobic interactions may be of particular value. Figure 1 shows the purification of p21 on a phenyl-Sepharose column. The hydroxyapatite fraction was applied to the column in 0.8 M ammonium sulphate and eluted with a decreasing gradient of ammonium sulphate which loosened the hydrophobic interaction. The p21 emerged as a single sharp peak at ~0.4 M ammonium sulphate at the minimum of the A_{280} profile. A cellular ATPase activity was detected at 0.2 M ammonium sulphate and was clearly separated from p21. As Table 1 shows, this step purified the specific GDP-binding activity of p21 by 16-fold. The overall purification from the high-speed supernatant of cell lysate was 265-fold with recovery of 93% total binding activity. To verify more directly that the purified GDP-binding activity represented the activity associated with the p21 protein, cellular proteins labelled in tissue culture with ^{35}S-methionine were purified by hydroxyapatite and phenyl-Sepharose chromatography. Both phosphorylated and non-phosphorylated forms of the p21 doublet were visualized by immunoprecipitation with antisera and SDS-gel electrophoresis from fractions eluted at 0.09 M sodium phosphate in the hydroxyapatite column and at 0.4 M ammonium sulphate in the phenyl-Sepharose column. The chromatographic profiles of the ^{35}S-methionine-labelled p21 on both columns were identical to that detected by the GDP-binding assay.

Table 1 Summary of p21 purification

Step	Total protein (mg)	Total GDP-binding activity (pmol GDP)	Specific binding activity (pmol mg^{-1})	Yield (%)	Step purification	Total purification
Total homogenate (50 g cells)	4,292	–	–	–	–	–
1. High-speed supernatant	2,523	2,291	0.9	100	1×	1×
2. Hydroxyapatite (0.09 M PO_4 fraction)	261	3,944	15.1	172	17×	17×
3. Phenyl-Sepharose (fractions 52–58)	9	2,131	241.0	93	16×	265×

All the purification procedures were performed at 4 °C. Approximately 50 g of Ha-MSV-transformed NIH 3T3 cells were lysed in 4 vol of lysis buffer containing 1% Triton X-100, 0.1 M NaCl, 0.005 M $MgCl_2$, 0.02 M Tris-HCl, *p*H 7.4, and 0.1 mM dithiothreitol (DTT). Cell lysis was assisted by two passages through an 18-gauge needle in a syringe. This is referred to as the total homogenate which was centrifuged at 150,000*g* for 30 min, and the pellets discarded. This fraction is the high-speed supernatant. For hydroxyapatite chromatography, the high-speed supernatant was dialysed overnight against the starting buffer (0.005 M sodium phosphate, *p*H 6.8, and 0.1 mM DTT) and was then loaded on a hydroxyapatite column (5 × 25 cm, Bio-Rad). The flow-through material was washed with the starting buffer until the A_{280} returned to the basal level. The fraction containing p21 was then batch-eluted with 0.09 M sodium phosphate, *p*H 6.8, and 0.1 mM DTT. The p21 was detected by a ^{3}H-GDP-binding assay[11]. Briefly, various amounts of column fractions were incubated at 4 °C with 10^{-5} M of ^{3}H-GDP (10 Ci mmol^{-1}) for 10 min in a final volume of 0.3 ml (1% Triton, 0.2 M NaCl, 0.005 M $MgCl_2$ and 0.02 M Tris-HCl, *p*H 7.4). Antisera or normal sera (7 µl) as controls were then added. After 90 min, the antigen–antibody complexes with bound ^{3}H-GDP were precipitated with 50 µl 10% (v/v) formaldehyde-fixed *S. aureus*. After several washings, the precipitates were dissolved by boiling in 0.30 ml of 2% SDS, 28 mM β-mercaptoethanol, 100 mM Tris-HCl, *p*H 7.8, 40% glycerol. ^{3}H-GDP dissolved in the supernatant was then counted. The ^{3}H-GDP binding activity of p21 was determined from the linear portion of the binding versus protein curves. The protein concentration was determined by the method of Lowry[33]. The hydroxyapatite fraction was stored in small aliquots at −170 °C, and subjected to only one cycle of freeze–thawing. Portions of this fraction were further purified by phenyl-Sepharose column detailed in Fig. 1 legend. The activity and yield shown above represent the total activity from the original 50-g cell pack.

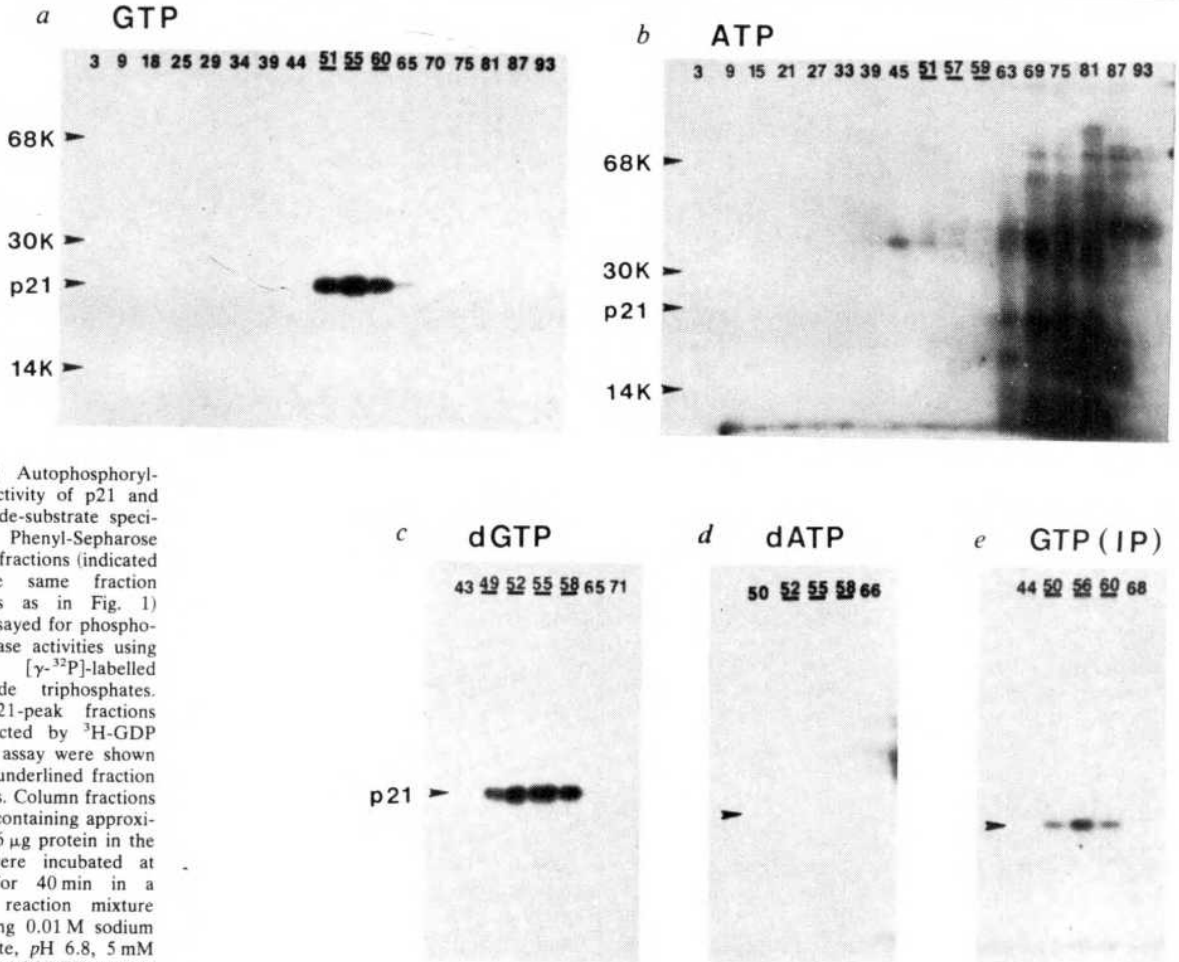

Fig. 2 Autophosphorylation activity of p21 and nucleotide-substrate specificity. Phenyl-Sepharose column fractions (indicated by the same fraction numbers as in Fig. 1) were assayed for phosphotransferase activities using various [γ-^{32}P]-labelled nucleotide triphosphates. The p21-peak fractions as detected by ^{3}H-GDP binding assay were shown by the underlined fraction numbers. Column fractions (40 μl) containing approximately 6 μg protein in the peak were incubated at 30 °C for 40 min in a 100-μl reaction mixture containing 0.01 M sodium phosphate, *p*H 6.8, 5 mM $MgCl_2$, 1 mM DTT, protein acceptors (5 mg ml^{-1}) as indicated, and various [γ-^{32}P]nucleotide triphosphates (~15 Ci mmol^{-1}) at a final concentration of ~4.7 μM. The exact condition for each experiment is indicated below. Except for the immunoprecipitation experiment (*e*), at the end of incubation the reaction was stopped by the addition of 0.5 ml cold 10% TCA. After standing at 4 °C for 60 min, the precipitated protein was pelleted by 10 min centrifugation in the Eppendorf microfuge. After being washed once more with 1 ml of 10% TCA at 4 °C, the pellets were dissolved by incubating at 95 °C for 3 min in 50 μl of 2% SDS, 0.2 M Tris-HCl, *p*H 8.0, 40% glycerol, 28 mM β-mercaptoethanol and 0.002% bromophenol blue. Proteins were separated by a 12% SDS-polyacrylamide gel electrophoresis (SDS-PAGE) as previously described[4]. The dried gels were autoradiographed for 18–72 h. The ^{14}C-labelled protein markers are bovine serum albumin (68K), carbonic anhydrase (30K) and lysozyme (14K). *a*, Column fractions were incubated with 2.7 μM of [γ-^{32}P]GTP (19 Ci mmol^{-1}, Amersham) in the presence of phosvitin (5 mg ml^{-1}, Sigma) which was visualized as a 40K band in Coomassie blue-stained gel. *b*, Column fractions were incubated with 5.6 μM of [γ-^{32}P]ATP (18 Ci mmol^{-1}, Amersham) in the presence of phosvitin (5 mg ml^{-1}). *c*, Column fractions were incubated with 1.8 μM of [γ-^{32}P]dGTP (25 Ci mmol^{-1}, ICN) in the presence of casein (5 mg ml^{-1}, Sigma) which revealed itself in the stained gel as a 25K band above the p21. *d*, Column fractions were incubated with 4.3 μM of [γ-^{32}P]dATP (10 Ci mmol^{-1}, ICN) in the presence of casein (5 mg ml^{-1}, Sigma). *e*, Column fractions were incubated with 9.3 μM of [γ-^{32}P]GTP (5 Ci mmol^{-1}, Amersham). After incubation, the p21 was immunoprecipitated by 7 μl of anti-p21 antiserum from tumour-bearing rats by a procedure previously described[4]. The immunoprecipitate was analysed by SDS-PAGE.

Nucleotide binding specificity of the purified p21

We have shown previously[11] that in crude cell lysates, the ^{3}H-GDP binding of p21 can be effectively inhibited by 20-fold excess of unlabelled GDP, GTP, dGTP, ppGpp, p[CH_2]ppG and to a lesser extent UTP but not by other nucleotide triphosphates, diphosphates, monophosphates and 3′,5′-cyclic phosphates. In crude extracts, the thermolability of the p21 encoded by the temperature-sensitive mutant of the closely related Ki-MSV can also be stabilized against thermal inactivation by 0.1 or 1 mM of GDP, GTP or dGTP. Using the purified p21 we examined the specificity by direct binding of ^{3}H-labelled nucleotides. As shown in Table 2, a constant amount of the p21 purified by phenyl-Sepharose was incubated with 4–12 μM of ^{3}H-labelled nucleotides; the bound nucleotides were immunoprecipitated as a complex with p21 by the antiserum. Only GTP, dGTP, GDP and to a lesser extent dATP demonstrate significant binding with normal serum. Nucleotides bound were approximately the same for GTP, GDP and dGTP, whereas dATP was only 24% of dGTP. Note that, in contrast to GTP, ATP gives no appreciable binding.

The nucleotide concentration for half-maximal binding was determined using p21 purified by phenyl-Sepharose in the ^{3}H-nucleotide concentration range from 2×10^{-9} to 10^{-7} M. In Mg^{2+}-containing buffer (5 mM $MgCl_2$, 0.2 M NaCl, 0.02 M Tris-HCl, *p*H 7.4), the concentration for half-maximal binding for GTP was observed at 8×10^{-9} M, for GDP at 7×10^{-9} M, and for dGTP at 9×10^{-9} M. The maximum amount of nucleotide bound was approximately the same for each of these three nucleotides. Although dATP gave appreciable binding, the concentration for half-maximal binding was ~5,000 times higher than that for dGTP. Contamination by dGTP of less than 0.02% could account for the dATP binding observed here. In buffers containing 5 mM EDTA and no added Mg^{2+} the same maximal extent of binding was observed but 100-fold higher concentrations of GTP were required for half-maximal binding.

These binding studies indicate that p21 is a quanine nucleotide-binding protein with strong affinity towards GTP, GDP and dGTP. Nucleotides of other bases and all monophosphates demonstrate much less significant binding to p21.

GTP-specific autophosphorylation of p21

The p21 immunoprecipitated from ^{35}S-methionine-labelled lysates of virus-transformed cells migrated as a doublet band in SDS-polyacrylamide gel electrophoresis; the lower band was a non-phosphorylated form of the p21, and the upper band was labelled with ^{32}P-orthophosphate *in vivo*. The high resolving power of the phenyl-Sepharose chromatography allowed us to study the possible enzymatic activities associated with p21. The guanine nucleotide-binding properties of p21 suggest that it may have enzymatic activity involving these nucleotide triphosphates. Small aliquots of the column fractions were incubated with various [γ-^{32}P]-labelled nucleotide triphosphates and the total proteins phosphorylated *in vitro* were then examined by SDS-polyacrylamide gels without prior immunoprecipitation. The results are shown in Fig. 2. Using [γ-^{32}P]GTP as a substrate (Fig. 2*a*), the only major protein phosphorylated across the column fractions is the ~21K band. This 21K band is most intense at the underlined fractions of numbers 51, 55 and 60, and coincides precisely with the p21 peak as determined by ^{3}H-GDP-binding assay seen in Fig. 1. That the 21K band is indeed the p21 protein is demonstrated by its immunoprecipitation with antisera containing antibodies to p21 (Fig. 2*e*) and its co-migration with the phosphorylated *in vivo* upper band of the p21 in SDS-gel electrophoresis (data not shown). It will be important to determine which form of the p21, the phosphorylated or non-phosphorylated, becomes autophosphorylated. In contrast to the results obtained with GTP, when [γ-^{32}P]ATP was used as phosphoryl donor, no p21 was phosphorylated at the peak fractions 51, 57 and 59 (Fig. 2*b*). The addition of 10 μM cyclic AMP had no effect on these patterns of phosphorylation. However, with [γ-^{32}P]ATP, extensive phosphorylation of various proteins are seen especially in fractions from 63 to 93, corresponding to the A_{280} peak seen in Fig. 1. This intense ATP-dependent protein kinase activity was well separated from the p21 peak in the phenyl-Sepharose chromatography. In Fig. 2*c*, it is seen that phosphorylation of p21 occurs at the same peak fractions by using [γ-^{32}P]dGTP as donor. The dGTP-dependent activity is similar to the GTP activity. The dATP-dependent reaction is also similar to ATP (Fig. 2*d*), and again no p21 phosphorylation is seen at the peak fractions. The lack of phosphorylation by [γ-^{32}P]ATP is not due to the phosphatase or pyrophosphatase activity in the preparation which selectively degrades ATP: most of the [γ-^{32}P]ATP or [γ-^{32}P]GTP remained intact after incubation with p21 for 80 min (Fig. 3). Compared with the control with no p21, very little ^{32}P-orthophosphate or ^{32}P-pyrophosphate was formed by incubation with the p21 preparation. Therefore, the phosphorylation reaction is very specific to GTP and dGTP and parallels the guanine nucleotide-binding specificity of the p21.

An important question is whether p21 phosphorylation is an autocatalytic reaction or p21 is simply a substrate for a contaminating protein kinase. Various commonly used protein kinase substrates were included in the reaction mixtures, for example phosvitin (40K) in Fig. 2*a* and *b* and casein (~25K) in Fig. 2*c* and *d*. No GTP/dGTP-dependent phosphorylation of these protein kinase substrates was seen at the p21 peak fractions. Also, the autophosphorylation reaction of the p21 *per se* was not affected by the presence of casein or phosvitin. No GTP-specific kinase activity of the p21 fractions was observed with calf thymus histones, protamine or a synthetic poly-L-tryosine-L-glutamate copolymer (data not shown). Other characteristics of p21 phosphorylation, such as relative insensitivity to EDTA, *N*-ethylmaleimide (NEM) and other agents, distinguish the autocatalytic reaction from most cellular protein kinases. Furthermore, the nucleotide specificity of the phosphorylation reaction is consistent with the nucleotide-binding specificity of p21. Thus it seems that GTP is a substrate for p21 and it is unlikely that p21 phosphorylation is due to a contaminating cellular protein kinase in the purified preparation.

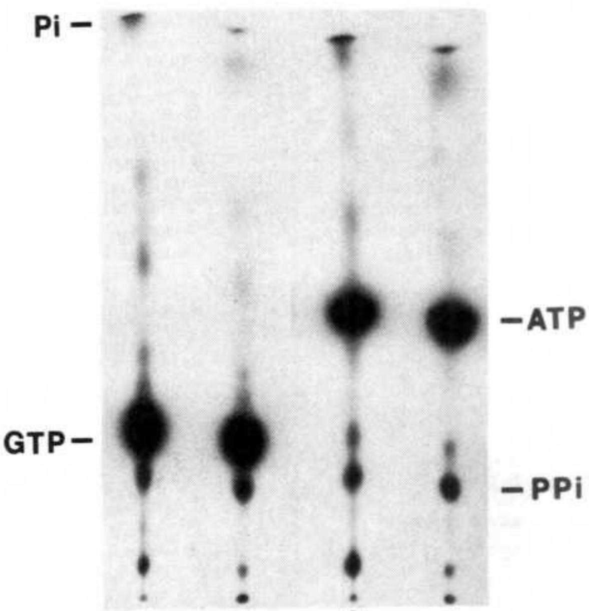

Fig. 3 Analysis of remaining [γ-^{32}P]GTP and [γ-^{32}P]ATP substrates after incubation with the purified p21. [γ-^{32}P]GTP (1.5 μM, 37 Ci mmol^{-1}, NEN) or [γ-^{32}P]ATP (2 μM, 22 Ci mmol^{-1}, NEN) was incubated at 30 °C for 80 min in the presence and absence of p21 purified by phenyl-Sepharose in conditons identical to those described in Fig. 4*A* legend. At the end of the reaction, 2 μl of each reaction mixture was spotted on a PEI-thin layer plate (Brinkmann). Ascending chromatography was in 0.75 M KH_2PO_4, *p*H 3.4. Authentic markers of GTP, ATP, P_i and PP_i were run on the same plate. Lane 1, [γ-^{32}P]GTP without p21; lane 2, [γ-^{32}P]GTP with p21; lane 3, [γ-^{32}P]ATP without p21; lane 4, [γ-^{32}P]ATP with p21.

Table 2 Nucleotide binding specificity of p21

^{3}H-labelled nucleotides	Bound pmol	
	Anti-p21 serum	Normal serum
GTP	2.00 ± 0.09	0.21 ± 0.01
ATP	0.11 ± 0.01	0.09 ± 0.01
UTP	0.09 ± 0.03	0.09 ± 0.00
CTP	0.05 ± 0.01	0.05 ± 0.01
dGTP	2.40 ± 0.09	0.14 ± 0.01
dATP	0.58 ± 0.05	0.06 ± 0.00
dTTP	0.08 ± 0.04	0.02 ± 0.00
dCTP	0.05 ± 0.03	0.03 ± 0.00
GDP	2.71 ± 0.33	0.24 ± 0.03
ADP	0.18 ± 0.04	0.16 ± 0.07
UDP	0.23 ± 0.09	0.24 ± 0.11
CDP	0.27 ± 0.13	0.22 ± 0.08
Cyclic GMP	0.05 ± 0.03	0.03 ± 0.00
Cyclic AMP	0.04 ± 0.01	0.03 ± 0.00
Cyclic CMP	0.03 ± 0.01	0.01 ± 0.00

The p21 purified by phenyl-Sepharose column (10 μg) was reacted with 7 μl of antiserum or control normal serum in ^{3}H-GDP binding assay conditions as described in Table 1 legend. The nucleotide concentration was at 4–10 μM at a specific radioactivity of 10–24 Ci mmol^{-1} (NEN). A triplicate determination was performed for each nucleotide and the average values and their standard deviations are listed.

Characterization of the p21 autophosphorylation reaction

Figure 4*A* shows the time course and temperature dependence of the autocatalytic reaction. The p21 band becomes more intense with incubation at 30°C for increasing periods of time. The reaction is relatively slow and persistent even after 80 min of incubation. Although nucleotide binding occurs readily at 4°C, autophosphorylation is strongly dependent on incubation temperature. Almost no phosphorylation reaction is seen at 4°C and the phosphorylation reaction rate is higher at 37°C than at 30°C. These characteristics are consistent with a *bona fide* enzymatic reaction. Band intensity was related to the amount of p21 protein, but the exact stoichiometry of phosphorylation is not yet determined. Figure 4*B* demonstrates the reaction rate as a function of [γ-^{32}P]GTP concentration. The p21 bands were cut off from the gels and the radioactivity counted. By double reciprocal plots of the incorporated c.p.m. against GTP concentration, the K_m for Mg^{2+}-GTP was estimated to be $\sim 2\times10^{-7}$ M

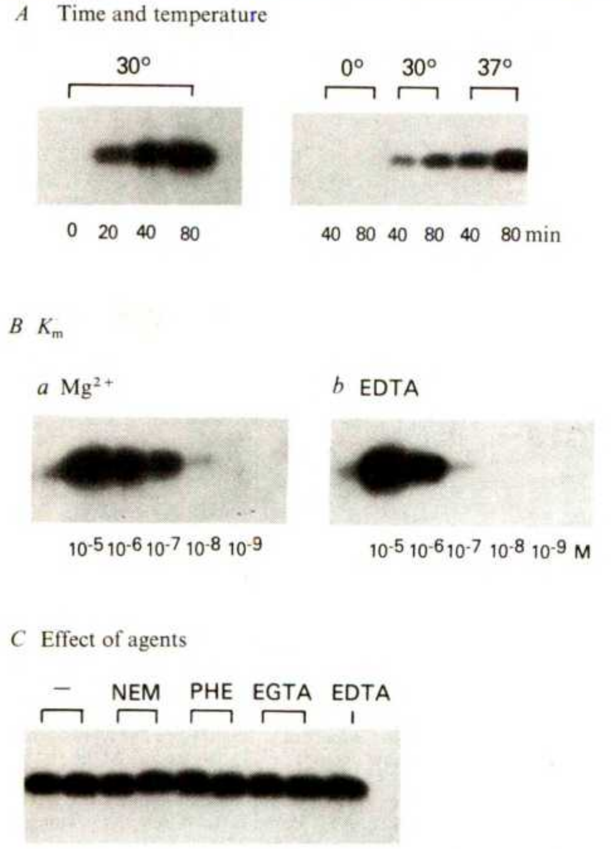

Fig. 4 Characterization of the p21 autophosphorylation reaction. *A*, Time course and temperature dependence of the reaction. The p21 peak fraction (1.5 μg) from the phenyl-Sepharose column was incubated at 30 °C for 0, 20, 40, or 80 min in the first experiment, and at 0 °C, 30 °C or 37 °C for either 40 or 80 min in the second experiment. The reaction mixture (50 μl) contained 5 mM $MgCl_2$, 0.01 M sodium phosphate, *p*H 6.8, 1 mM DTT and 0.5 mg ml^{-1} casein. The reaction was started by addition of [γ-^{32}P]GTP (37 Ci $mmol^{-1}$, NEN) to a final concentration of 1.5 μM. The reaction was stopped by 10% cold TCA. The precipitated protein was analysed by SDS-PAGE as described in Fig. 2 legend. Autoradiography was for 18 h with Dupont intensifying screen. Similar results were obtained if 0.01 M Tris-HCl, *p*H 7.5, was used instead of the phosphate buffer. *B*, Effect of [γ-^{32}P]GTP concentration. The purified p21 (0.8 μg) was reacted at 37 °C for 60 min with the following concentration of [γ-^{32}P]GTP (364 Ci $mmol^{-1}$, ICN): 10^{-5}, 10^{-6}, 10^{-7}, 10^{-8} and 10^{-9} M. *a*, Mg^{2+}-containing buffer of 5 mM $MgCl_2$, 0.01 M sodium phosphate, *p*H 6.8, and 1 mM DTT. *b*, Mg^{2+}-free buffer: the same composition without $MgCl_2$ and with 2.5 mM EDTA. *C*, The effect of various agents. The purified p21 (1.5 μg) was incubated in 50 μl of reaction mixture containing 0.01 M sodium phosphate, *p*H 6.8, 1 mM DTT, 0.5 mg ml^{-1} phosvitin and 1.5 mM of [γ-^{32}P]GTP for 80 min at 37 °C. In addition, various agents were added before incubation: *N*-ethylmaleimide (NEM, Sigma) at 2.5 mM or 5 mM; 1,10-phenanthroline (PHE, Sigma) at 2.5 mM or 5 mM; EGTA (Sigma) at 2.5 mM or 5 mM; EDTA at 5 mM.

and K_m for GTP in the presence of EDTA $\sim 2\times 10^{-6}$ M. No obvious Mg^{2+} optimum was observed between 0 and 10 mM in the absence of EDTA. The effect of various agents reactive to several protein functional groups is seen in Fig. 4*C*. The sulphydryl group reagent, *N*-ethylmaleimide (NEM), at 2.5 and 5 mM did not affect the reaction. At the GTP concentration used here, various chelating agents for metal ions at 2.5 mM or 5 mM also had little effect on the phosphorylation reaction, that is, 1,10-phenanthroline (PHE) which chelates Zn^{2+} and Fe^{2+}; EGTA which chelates Ca^{2+}; and EDTA which chelates Mg^{2+}, Mn^{2+} and Co^{2+}. If the enzyme requires these divalent cations at all, these metal ions must already be very tightly bound to the enzyme. These characteristics further distinguish the autocatalytic activity from most known protein kinases which require sulphydryl group and Mg^{2+} or Mn^{2+} for their activities, or in Ca^{2+}-dependent protein kinases, the Ca^{2+} for their activities[21]. Addition of $CaCl_2$ to the reaction mixture did not appreciably stimulate the p21 activity but is slightly inhibitory above 5 mM. The *p*H optimum has also been examined between *p*H 6.0 and *p*H 9.5. No sharp maximum was noted and phosphorylation decreased slightly above *p*H 8.5, perhaps due to alkaline lability of the phosphate linkage (see next section). The enzymatic activity was inactivated either by heating at 95 °C for 10 min or proteolytic degradation.

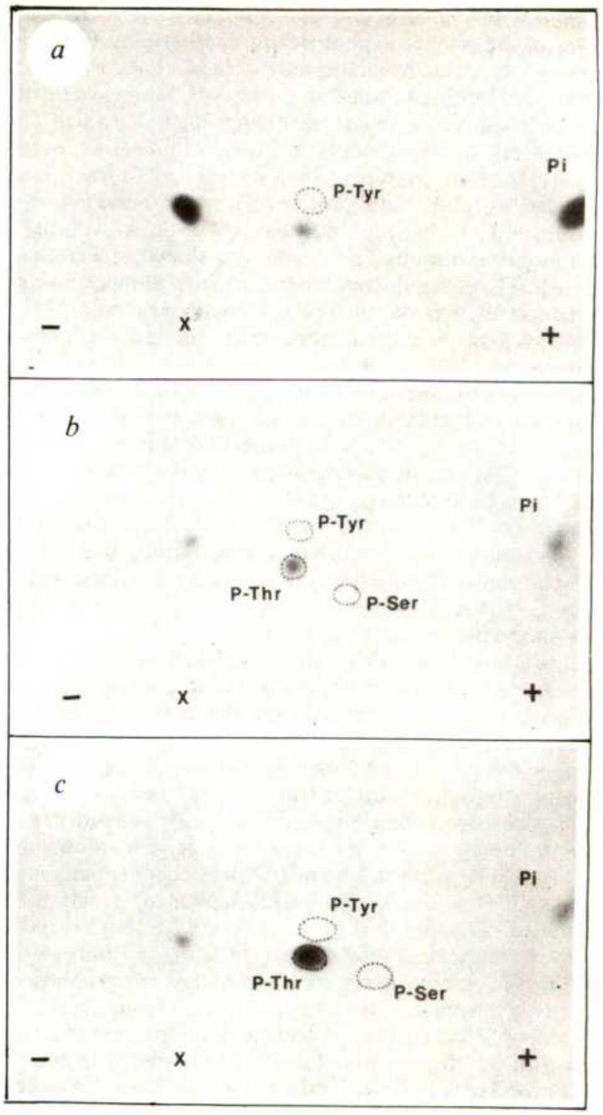

Fig. 5 Analysis of the phosphoamino acids of p21 phosphorylated *in vitro*. The purified p21 from phenyl-Sepharose column was autophosphorylated by incubation with [γ-^{32}P]GTP as described in Fig. 2*a* legend. The ^{32}P-labelled p21 was immunoprecipitated with anti-p21 serum and protein A-Sepharose (Pharmacia). The precipitated protein was solubilized with buffer containing SDS and β-mercaptoethanol. The solubilized protein was further precipitated with 20% cold TCA, washed with ethanol and hydrolysed with 6 M HCl at 100 °C at various time intervals. Approximately 4,000 c.p.m. of lyophilized sample was analysed by the two-dimensional method of Eckhart *et al.*[18] on the thin-layer cellulose plates. × marks the origin of samples. The first dimension at the horizontal direction was electrophoresis at 950 V for 90 min in *p*H buffer (glacial acetic acid : formic acid [88%] : H_2O, 78 : 25 : 897). The second dimension from bottom to top was chromatography in isobutyric acid : NH_4OH (0.5 M), 5 : 3. The phosphoamino acid markers, 5 μg each of phosphothreonine (Sigma), phosphoserine (Sigma) and phosphotyrosine (a gift of Dr Karen Beemon through Dr Gilbert Jay) were mixed with the ^{32}P-labelled samples and were spotted on the TLC plates. The radioactive spots were detected by autoradiography (6 days) with Dupont intensifying screen and the marker amino acids were visualized by ninhydrin spray. *a*, 4 h hydrolysis in 6 M HCl; *b*, 8 h hydrolysis; *c*, 15 h hydrolysis.

The phosphorylated amino acid residue

The p21 purified by phenyl-Sepharose was phosphorylated *in vitro* by [γ-^{32}P]GTP and the p21 was immunoprecipitated with the antiserum. The precipitated p21 was solubilized by SDS and β-mercaptoethanol and was precipitated with 20% trichloroacetic (TCA) acid at 4 °C. The precipitated protein was hydrolysed with 6 M HCl at 100 °C for various periods of time. The only ^{32}P-labelled amino acid was found to co-migrate with the *O*-phosphothreonine internal marker but not with *O*-phosphotyrosine or *O*-phosphoserine (Fig. 5). The spot moving more slowly towards the anode especially noticeable in the 4-h hydrolysate (Fig. 5*a*) seems to be an incomplete digestion product, as after longer hydrolysis of 8 h (Fig. 5*b*) and 15 h (Fig. 5*c*), the intensity of this spot decreases with concomitant increase in the phosphothreonine spot. Similar results were obtained by analysis of the p21 recovered from SDS-polyacrylamide gels or straight TCA precipitation of the reaction mixture. dGTP also appeared to phosphorylate the same amino acid residue as GTP. Consistent with the phosphorylated residue being phosphothreonine but not phosphotyrosine is the alkaline lability of the phosphate linkage. After treatment of the p21 phosphorylated *in vitro* with 0.1 M NaOH at 37 °C for 30 min, the phosphorylated p21 completely disappeared from gel electrophoresis.

In another experiment (data not shown), the p21 was labelled *in vivo* with ^{32}P-orthophosphate. After immunoprecipitation and SDS-gel electrophoresis, the p21 band was eluted and the amino acids analysed. The phosphorylated amino acid residue was threonine, similar to the *in vitro* product. Furthermore, a two-dimensional tryptic peptide map of the *in vitro* phosphorylated p21 was observed to be identical to a two-dimensional tryptic peptide map of the p21 labelled by ^{32}P-orthophosphate *in vivo* (unpublished observation). Several phosphopeptides were observed in each map and the maps were identical. However, as some of the phosphopeptide spots may represent incomplete trypsinization, the exact number of phosphorylation sites on each p21 molecule remains to be determined.

Discussion

The GTP-specific autophosphorylation of $p21^{src}$ observed here seems to be a unique enzymatic activity among those reported for many other transforming proteins. First, the nucleotide substrate specificity of the p21 reaction is more restrictive than the substrate specificity of either the $p60^{src}$ of RSV[12–15], the p120 of Abelson MuLV[19], or the T antigens of adenovirus[16], polyoma virus[17,18,22] or SV40 (refs 23–25). The protein phosphorylating activities associated with each of those transforming proteins use as phosphoryl donor ATP and in most cases also GTP, whereas p21 uses only GTP. Second, the protein kinase activity of the partially purified RSV $p60^{src}$ and the SV40 large T antigen has been demonstrated to phosphorylate exogenous protein acceptors such as casein, phosvitin or immunoglobulin heavy chain in soluble systems[23–27]. No such activity has been detected in reactions containing p21. Third, the phosphorylating enzymatic activities associated with $p60^{src}$, the Abelson MuLV p120 and the T antigens occur rapidly at 4 °C (refs 15, 19). Although binding of GDP or GTP to p21 can be observed at 4 °C, phosphorylation is markedly temperature-activated and proceeds linearly for up to 80 min at 37 °C. Finally, the amino acid residue phosphorylated with [γ-^{32}P]GTP in the p21 is a threonine residue, not a tyrosine residue as observed for the other proteins[18–20]. Thus at this point, it is not possible to assign a common denominator to the phosphorylating activities associated with transforming proteins. Comparing the results of p21 with other transforming proteins, note that p21 was purified by a GDP-binding assay that does not require the measurement of protein kinase activity. Thus it is possible that our binding assay and/or method of purification have allowed us to discern this novel GTP-specific autophosphorylating activity.

The question, then, is: what is the biochemical activity of p21 that is responsible for cell transformation? Two types of biochemical activities have now been associated with p21: (1) a binding activity in which either GDP or GTP will bind non-covalently to the p21; and (2) an autophosphorylating activity in which p21 is phosphorylated by the gamma phosphate of GTP. It is possible that the nucleotide-binding activity is the first step in the interaction of the p21 with GTP and that the subsequent phosphorylating activity is responsible for its transforming function. Within this model, autophosphorylation could be a phosphoenzyme intermediate which is a step in an enzymatic reaction which normally will go to completion *in vivo* and is trapped in the present *in vitro* condition due to the lack of suitable acceptors or cofactors for the catalytic turnover of the reaction. Alternatively, autophosphorylation of p21 may simply be an autoregulatory mechanism for some other activities of the p21 which may more closely reflect the transforming activity *per se*. The p21 may be activated or inactivated as a consequence of its phosphorylation and p21 activity may function in a way that does not *per se* require phosphorylating activity. Regulatory proteins which bind guanine nucleotides do exist and p21 could function as such a protein in a 'transforming reaction' which itself does not necessarily require phosphorylating activity. The regulatory G-protein of the adenylate cyclase system is an example[28,29]. Purified p21 and its phosphorylated product reported here may permit one to determine the missing components of its transforming activity. These may be protein substrates, other small or large metabolite molecules which simply bind to the p21–guanine nucleotide complex or actively participate in a unique phosphotransferase or even GTPase reaction. Recently, the Ha-MSV p21 and RSV p60 have been found to be located at the inner surface of the plasma membrane of transformed cells with the p60 being concentrated at gap junctions[10,30]; the Abelson MuLV p120 has a transmembrane subcellular location[31] and the polyoma middle T antigen is also membrane-associated[32]. The generally similar anatomical locations within cells of these transforming proteins suggest that the cell membrane may be a major site of action for transformation. Autophosphorylation of these proteins may have an important role in regulating normal membrane functions.

We thank Dr Harry Langbeheim for valuable discussion during this work.

Polyadenylated RNA from leaves of pea (Pisum sativum) *has been copied into DNA and cloned in the* Escherichia coli *plasmid pBR322. From these clones we have identified and sequenced DNA encoding the mRNA for the precursor of the small subunit of the chloroplast enzyme ribulose-1,5-bisphosphate carboxylase.*

CHLOROPLAST development requires the coordinated activities of both plastid and nuclear genetic systems. Some chloroplast polypeptides are encoded in the nucleus and synthesized in the cytosol, whereas others are encoded and synthesized in the chloroplast[1]. Recent data suggest that chloroplast polypeptides synthesized in the cytosol take the form of higher molecular weight (MW) precursors that are cleaved to the mature form on entry into the chloroplast[2]. One much studied chloroplast protein, which provides a model system for studying nucleus–chloroplast cooperation, is the stromal enzyme ribulose-1,5-biphosphate carboxylase (EC 4.1.1.39, also known as Fraction I protein, here abbreviated to RuBPCase). This enzyme is the most abundant chloroplast protein[3]. In higher plants it occurs as an oligomer of eight large subunits (MW 55,000) and eight small subunits (MW 14,000). The function of the small subunit is unknown, but the large subunit contains the catalytic sites for both the carboxylase and the oxygenase activities[4].

The large subunit is encoded in the chloroplast DNA[5,6] and synthesized inside the chloroplast[7]. The small subunit is encoded in nuclear DNA[8], and synthesized in the cytosol as a precursor of

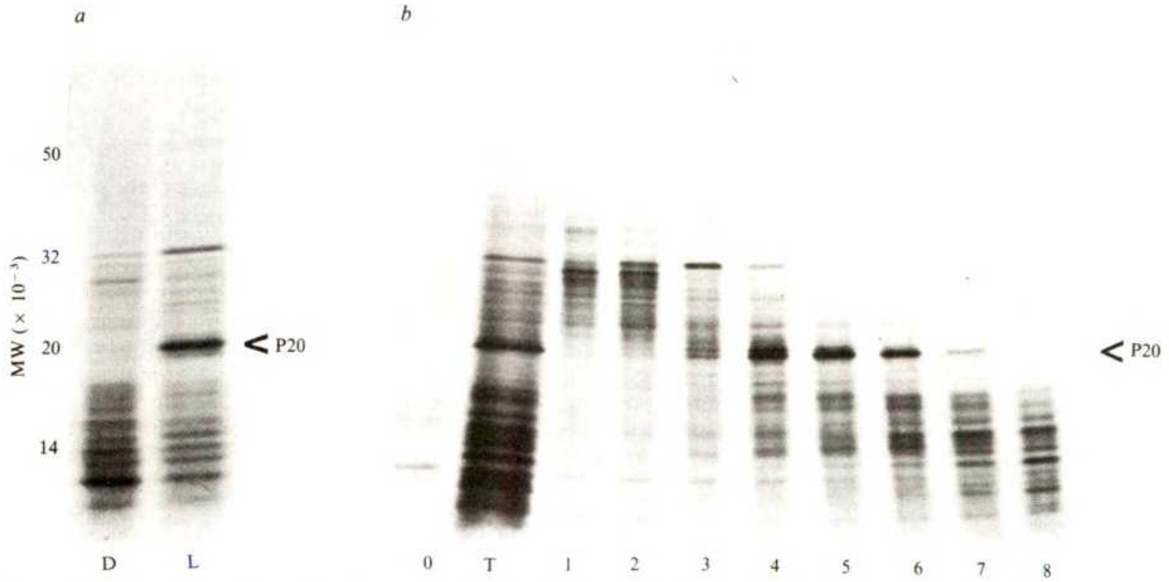

Fig. 1 Translation products of RNA preparations used in cloning and colony hybridizations. *a*, RNA from dark-grown and illuminated pea plants. Polysomal polyadenylated RNA was prepared from shoots of pea (*Pisum sativum*, var. Feltham First), translated in a wheat-germ protein-synthesizing system and the products analysed as described previously[10,12]. The photograph shows the autoradiograph of an SDS-polyacrylamide gel of the translation products. D, RNA prepared from pea plants grown for 9 days in darkness; L, RNA prepared from pea plants grown for 9 days in darkness followed by 48 h continuous illumination; P20, precursor to the small subunit of RuBPCase. Each sample contains an equal amount of trichloroacetic acid-precipitable radioactivity. *b*, Size-fractionated RNA from illuminated pea plants. Polyadenylated RNA from the leaves of illuminated pea plants (L, above) was fractionated by electrophoresis in a gel (17 × 17 × 0.3 cm) of 1.5% (w/v) agarose containing 0.1 × E buffer[26] (3 mM NaH_2PO_4, 3.6 mM Tris, 0.1 mM Na_2 EDTA) and 50% (v/v) deionized formamide. Electrophoresis was for 3 h at 30 mA after which the region of the gel containing RNA species between 0.1 and 0.7×10^6 MW was cut into eight equal fractions. Each gel fraction was cut further into 3-mm cubes and placed in a test tube. RNA was eluted from these gel sections (0.2 g each) by shaking at 4 °C with 0.25 ml 10 mM Tris-Cl *p*H 7.6, 0.4% (w/v) SDS, 1 mM EDTA and 400 mM LiCl. Elution was for a total of 20 h during which time the elution buffer was changed twice. Eluates for each fraction were pooled and the RNA precipitated with ethanol. The RNA was dissolved in 200 mM HEPES-KOH, *p*H 7.6, and centrifuged for 5 min in an Eppendorf 5412 microcentrifuge to remove any insoluble material. The RNA was ethanol-precipitated from the supernatant and finally reprecipitated once more from this buffer before being dissolved in sterile distilled water for translation and colony hybridizations (see Fig. 2). Translation and product analysis on a SDS-polyacrylamide gel were as described previously[10,12]. The photograph shows an autoradiograph of the translation products. O, No RNA added; T, unfractionated RNA; 1–8, RNA size fractions of decreasing MW; P20, precursor to the small subunit of RuBPCase.

0028–0836/80/430692—06$01.00

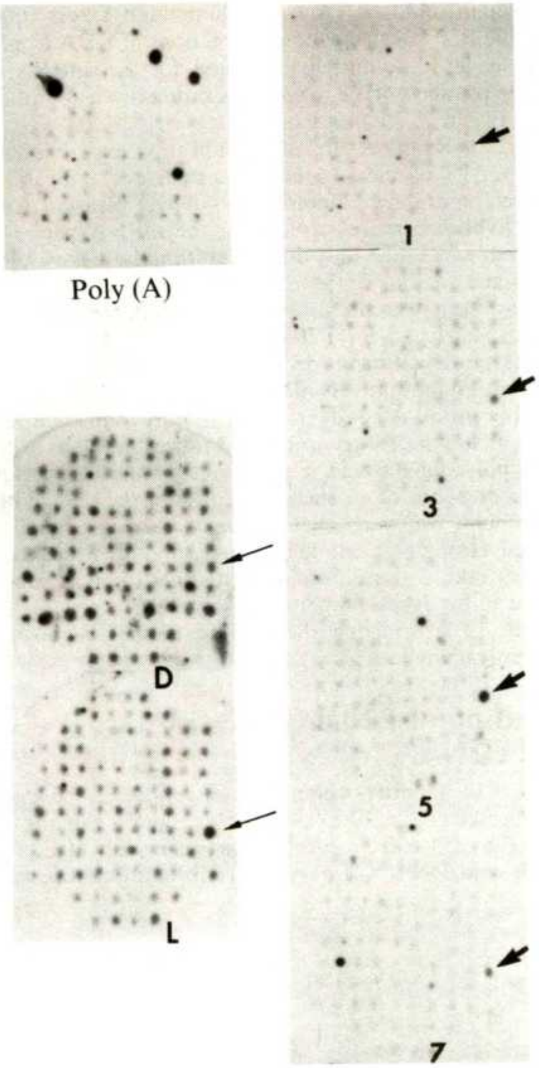

Fig. 2 Isolation and identification of cDNA clones. Polysomal polyadenylated RNA (10 μg) from illuminated pea leaves (see Fig. 1*a*) was used to direct the synthesis of cDNA using the method and buffers described by Myers and Spiegelman[27]. The reaction was carried out in 100 μl using 40 units of AMV reverse transcriptase. The cDNA was purified by phenol–chloroform extraction, and chromatography on Sephadex G-50 in a buffer containing 0.2 M sodium acetate and 1 mM EDTA. The cDNA fraction was concentrated by ethanol precipitation, dissolved in 70 μl H_2O, heated to 100 °C for 2 min and cooled in ice water. The denatured cDNA was converted to double-stranded DNA in a 100-μl reaction mixture containing 50 mM HEPES *p*H 6.9, 10 mM $MgCl_2$, 10 mM dithiothreitol (DTT), 0.5 mM deoxynucleotide triphosphates, 200 mM KCl and 10 units of fragment A polymerase I (Boehringer). The reaction mixture was incubated at 37 °C for 120 min, and the DNA purified by phenol–chloroform extraction and chromatography on Sephadex G-50, and concentrated by ethanol precipitation. The double-stranded DNA was treated with S_1 nuclease in a 100–μl reaction mixture containing 3 M NaCl, 0.3 M sodium acetate *p*H 4.5, and 1 mM $ZnSO_4$. The amount of S_1 nuclease required to remove the hairpin loop was determined empirically by titrating against double-stranded cDNA prepared from rabbit globin mRNA, and assaying the length of the product on denaturing polyacrylamide gels. The double-stranded cDNA was incorporated into the vector plasmid pBR322 (ref. 28) in two ways. (1) Using synthetic *Hin*dIII sequence linkers. Double-stranded cDNA obtained from 10 μg RNA was dissolved in 10 μl of a buffer containing 60 mM Tris-HCl *p*H 7.6, 8 mM $MgCl_2$, 10 mM 2-mercaptoethanol, 1 mM ATP and 0.2 mM deoxyribonucleotide triphosphates, and incubated with 1 unit of DNA polymerase I for 15 min at 15 C. 5′-Phosphorylated linkers (60 pmol) in 6 μl were added to the reaction together with 15 μl of 60 mM Tris-HCl *p*H 7.6, 8 mM $MgCl_2$, and an excess of DNA ligase. The mixture was incubated at 15 °C for an additional 4 h and the nucleic acid purified by phenol–chloroform extraction and chromatography on Sephadex G-200. The cDNA was recovered after ethanol precipitation and ligated to 1 μg of *Hin*dIII-linearized pBR322 DNA. The ligated DNA was used to transform the *E. coli* strain HB101 (ref. 29) to ampicillin resistance. (2) By homopolymer tailing of the double-stranded cDNA with dCTP, and *Pst*I-linearized pBR322 DNA with dGTP. The tailing reactions were as described previously[30]. Double-stranded cDNA from 5 μg RNA was reacted with 20 units of terminal transferase (PL Biochemicals) in a 100-μl reaction mixture containing 140 mM potassium cacodylate, 30 mM Tris-HCl *p*H 7.6, 1 mM DTT, 0.2 mM dGTP or 0.1 mM dCTP, 1 mM $CoCl_2$, and the plasmid DNA or the cDNA. The reaction was at 37 °C for 30 min. The tailed DNA was recovered by phenol–chloroform extraction and ethanol precipitation, and dissolved in 100 mM NaCl, 1 mM EDTA and 10 mM Tris-HCl, *p*H 8.0. The pBR322 and cDNA were mixed at approximately equal molar ratios, heated at 60 °C and annealed at 42 °C for 14 h. The annealed samples were used directly for transformation. Bacterial clones containing cDNA chimaeric plasmids produced by the linker method were detected by their sensitivity to tetracycline. Such clones were arrayed on Millipore filters, grown and prepared for nucleic acid hybridization. These filters were hybridized with RNA probes derived from RNA preparations described in Fig. 1 legend. Radioactive RNA probes were prepared using the 5′-phosphorylation procedure[31]. Samples of RNA (0.5 μg) were hydrolysed in 5 mM Tris-HCl *p*H 9.5, 10 mM EDTA and 0.1 mM spermidine at 95 °C for 5 min in a 17-μl reaction volume. The mixture was cooled, made to 50 mM Tris-HCl *p*H 9.5 and 10 mM $MgCl_2$, and added to a tube containing 30 μCi of dried [γ-^{32}P]ATP. After mixing, 4 units of T_4 polynucleotide kinase were added and the reaction mixture incubated for 30 min at 37 °C. RNA was purified from the reaction by phenol–chloroform extraction and ethanol precipitation. Before hybridization to probes, each filter was incubated for 6 h in 2 × SSC, 100 μg ml^{-1} *E. coli* tRNA, and 100 μg ml^{-1} polyadenylic acid at 60 °C. Hybridization to each 15-cm filter was carried out in 2 ml of 2 × SSC containing $\sim 4 \times 10^5$ c.p.m. of probe, 100 μg ml^{-1} tRNA, and 100 μg ml^{-1} polyadenylic acid at 60 °C for 16 h. After the incubation, the filters were washed in 2 × SSC, 0.1% (w/v) SDS at 60 °C, dried and exposed to X-Omat H X-ray film. The photographs show the results of hybridizing seven different RNA probes to the same 97 clones, the probes being: Poly(A), polyadenylic acid; D and L, polysomal poly(A)-containing RNA from dark-grown and illuminated leaves, respectively (see Fig. 1*a*); 1, 3, 5 and 7, size-fractionated poly(A)-containing RNA from light-grown leaves (see Fig. 1*b*). Clone 160 is indicated by an arrow.

MW 4,000–6,000 larger than the mature polypeptide[9–11]. This precursor (P20) enters isolated chloroplasts with cleavage to its final size by a mechanism which is independent of concomitant translation[10,11], and assembles in the stroma with the large subunit molecules into the holoenzyme[11,12]. The processing activity which cleaves P20 to small subunit is found in the soluble stromal fraction of the chloroplast[12]. These features establish a clear difference between the signal hypothesis advanced to explain the transport of secretory polypeptides across microsomal membranes[13] and the envelope carrier hypothesis proposed to explain the transport of polypeptides into chloroplasts[10].

The mechanism by which the expression of chloroplast and nuclear genomes is coordinated and the polypeptide transported into the chloroplast can be investigated using molecular cloning to elucidate the physical properties of the relevant genes. Specific hybridization probes can be used to obtain information on the structure and function of their RNA and polypeptide products. A cloned fragment of maize chloroplast DNA encoding the large subunit of RuBPCase has been used to show transcriptional control of the expression of this gene in maize leaf mesophyll cells[14]. Here we describe the isolation of cDNA clones of the mRNA for the small subunit of RuBPCase from pea (*Pisum sativum*). The cloned DNA has been sequenced to determine the amino acid sequence of most of the precursor polypeptide, and the sequence used to isolate and characterize P20 mRNA.

Light increases the amount of translatable P20 mRNA in polysomes

Light stimulates the accumulation of RuBPCase in pea leaves[10]. Polyadenylated RNA was prepared from polysomes isolated from leaves of pea plants grown in darkness for 9 days, and also from pea plants subsequently exposed to 48 h of continuous illumination. Translation of these RNA preparations in a cell-free protein-synthesizing system derived from wheat germ produced the polypeptides shown in Fig. 1*a*. A comparison of these translation products shows that the RNA from leaves of plants exposed to 48 h of light directs the synthesis of significantly more P20 than that from dark-grown pea plants. If plants are maintained in darkness for a further 48 h instead of being illuminated, this change does not occur (not shown). Thus, one result of illuminating etiolated pea plants is to cause an increase in the amount of translatable P20 mRNA in polysomes. The identity of P20 as the precursor to the small subunit of RuBPCase has been established previously[10].

Electrophoresis of these two RNA preparations in a polyacrylamide gel containing 7 M urea shows that the RNA from illuminated pea plants contains a ~900-nucleotide species which is not apparent in that from peas grown in the dark. A densitometer scan of a photograph of this gel indicates that this RNA species represents no more than 2% by weight of the total polyadenylated RNA. This RNA species was tentatively identified as the mRNA for P20 due to its co-electrophoresis (not shown) with a size class of polyadenylated RNA enriched with respect to translatable P20 mRNA (Fig. 1*b*, track 5). Figure 1*b* shows that RNA, fractionated by size on electrophoresis in an agarose gel containing formamide, is considerably enriched for P20 mRNA. Such enriched RNA fractions proved important in the identification of cDNA clones of P20 mRNA.

Identification of P20 cDNA clones using RNA probes containing different amounts of P20 mRNA

Clones were prepared from polysomal polyadenylated RNA derived from illuminated pea leaves as described in Fig. 2 legend. P20 cDNA clones were identified from the collection of clones by hybridization to RNA probes differentially enriched for P20 mRNA. Clones were arrayed on nitrocellulose filters and hybridized with ^{32}P-phosphate-labelled RNA probes using the method described by Grunstein and Hogness[15]. The probes included RNA from dark-grown leaves (low or devoid of translatable P20 mRNA), RNA from illuminated leaves (high in translatable P20 mRNA), and size fractions of RNA from illuminated leaves differentially enriched for P20 mRNA. The translation products of the RNA preparations used as probes are shown in Fig. 1.

Figure 2 shows the results of hybridization experiments carried out on 97 of the 278 clones tested, and indicates that different colonies show different levels of hybridization. Certain colonies hybridize more strongly to the mRNA probe from illuminated leaves than they do to that from dark-grown leaves (Fig. 2, D and L). One of these colonies (arrowed in Fig. 2) also hybridizes strongly to the probe derived from the size class of RNA most enriched for P20 mRNA (Fig. 2, 1–7). Colonies having the hybridization properties of the colony arrowed in Fig. 2 were therefore tentatively identified as P20 cDNA clones. To observe the probe-dependent differential hybridization shown in Fig. 2, it was necessary to pre-hybridize the filters with an excess of polyadenylic acid. The hybridization was also carried out in the presence of an excess of polyadenylic acid. Without this treatment, we found that clones containing poly(dT-dA) hybridized strongly to all the probes, and this masked the differences due to the differential amounts of coding mRNA sequences in the RNA preparations. Figure 2 [Poly(A)] shows the results of hybridizing the colonies with ^{32}P-phosphate-labelled polyadenylic acid.

Purification of P20 mRNA with cloned cDNA

To establish the identity of clones tentatively described above as containing P20 cDNA, the translation properties of the RNA hybridized by DNA from such clones was investigated. Supercoiled plasmid DNA was purified from liquid cultures of the

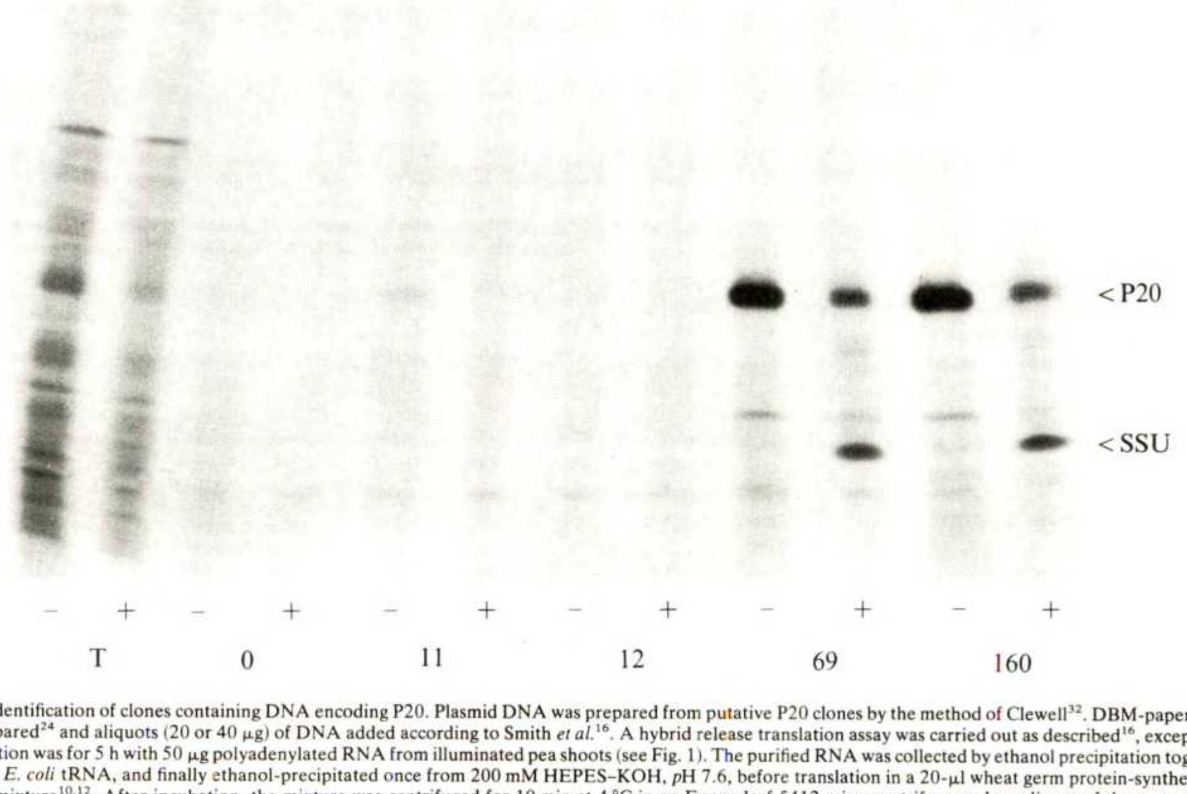

Fig. 3 Identification of clones containing DNA encoding P20. Plasmid DNA was prepared from putative P20 clones by the method of Clewell[32]. DBM-paper discs were prepared[24] and aliquots (20 or 40 μg) of DNA added according to Smith *et al.*[16]. A hybrid release translation assay was carried out as described[16], except that hybridization was for 5 h with 50 μg polyadenylated RNA from illuminated pea shoots (see Fig. 1). The purified RNA was collected by ethanol precipitation together with 6 μg *E. coli* tRNA, and finally ethanol-precipitated once from 200 mM HEPES–KOH, *p*H 7.6, before translation in a 20-μl wheat germ protein-synthesizing reaction mixture[10,12]. After incubation, the mixture was centrifuged for 10 min at 4 °C in an Eppendorf 5412 microcentrifuge and an aliquot of the supernatant solution removed for processing with isolated chloroplasts as described previously[12]. Translation products (9 μl) were incubated with 30 μl intact plastid buffer containing washed chloroplasts (6 μg chlorophyll), isolated from 10-day-old pea seedlings[12]. The non-processed control consisted of adding 9 μl translation products to an equivalent chloroplast preparation that had been denatured by boiling for 1 min in 1% (w/v) SDS. Products were analysed by SDS-polyacrylamide gel electrophoresis and autoradiography as described previously[10,12]. The photograph shows an autoradiograph of the products. T, Translation of total polyadenylated RNA; 0, no RNA; 11, 12, 69, 160, RNA complementary to the respective cloned DNA; −, non-processed control; +, post-translational processing with chloroplasts; P20, precursor to the small subunit of RuBPCase; SSU, small subunit of RuBPCase. The DBM-paper disc bearing DNA from clone 11 had only 20 μg DNA added to it, and had been used in two previous experiments. Other DBM-paper discs had 40 μg DNA added and were previously unused.

colonies and covalently linked to diazobenzyloxymethyl (DBM)-paper[16]. Polyadenylated RNA from leaves of light-grown plants was then hybridized to these DNA filters, and after removal of non-hybridized RNA by washing, the hybridized RNA was recovered for translation[16]. The translation of an RNA species purified by hybridization to cloned DNA encoding P20 would be expected to produce a single polypeptide of MW 20,000. To identify such a polypeptide as P20, a post-translational processing reaction with isolated chloroplasts[10,12] was carried out using an aliquot of the translation products. This treatment should process P20 to the mature small subunit of RuBPCase. Figure 3 shows the results of such experiments. DNA from clone 160 (arrowed in Fig. 2) hybridizes to a mRNA whose translation in the wheat-germ system produced a polypeptide of MW 20,000. We deduce that this polypeptide is P20 from the observation that on incubation with isolated chloroplalsts it is cleaved to a polypeptide which co-migrates with the mature small subunit of RuBPCase. Clone 12 provides a control for this experiment because it is shown to encode a minor polypeptide of MW ~29,000. We conclude from this experiment that clone 160 contains DNA encoding P20; this is confirmed by DNA sequence analysis (see below).

The translation products of the RNA purified by hybridization to the DNA of clone 160 includes other low molecular weight polypeptides in addition to P20. These other minor products have not been characterized because the identity of the cloned DNA was confirmed by nucleotide sequence analysis. However, we believe that they probably represent partial P20 polypeptide sequences generated as a result of RNA degradation during hybridization, or due to the infidelity of the wheat-germ protein-synthesizing system. The amount of polypeptide of about 15,500 MW decreases on incubation with isolated chloroplasts. After processing with isolated chloroplasts, an additional polypeptide of MW 18,000 is observed (Fig. 3). This product may represent either an intermediate in the processing of P20 to the mature small subunit or may arise from incorrect processing.

Several clones with properties identical to those of clone 160 were identified among the collection of clones prepared by the synthetic *Hin*dIII-linker procedure. Two clones (numbers 11 and 69) are included in the experiment shown in Fig. 3. The inserted sequence was purified from the plasmid of clone 160 (designated pSSU160) and used to screen for plasmids containing P20 cDNA in clone banks prepared by the homopolymer tailing method (see Fig. 2). The clones were used for sequence studies on the inserted cDNA.

DNA and polypeptide sequence determination

cDNA clones identified as P20 clones by the methods described above were used to determine the nucleotide sequence of P20 mRNA by the method of Maxam and Gilbert[17]. Both the physical map for P20 cDNA and the sequencing scheme are shown in Fig. 4*a*. The map was determined by a combination of hybridization methods[18], multiple digests with various restriction enzymes and the end-labelling procedure of Smith and Birnstiel[19]. Figure 4*a* illustrates the map position of some of the cDNA clones used in the sequencing. Figure 4*b* gives the determined nucleic acid sequence and the deduced amino acid sequence. The deduced amino acid sequence of the mature small subunit has been confirmed by sequence analysis, carried out directly on purified pea small subunit (I. A. H. Takruri, D. Boulter and R. J. Ellis, unpublished results). The molecule consists of 123 amino acids with a calculated MW of 14,480. The sequence shows considerable homology with that of the spinach molecule[20]; 89 residues are the same in both species. As the C-terminal amino acid codon is followed immediately by a termination codon (TAA), we conclude that the entire additional amino acid sequence of P20 is located at the N-terminus of the mature small subunit polypeptide. Schmidt *et al.*[21] have determined that the small subunit precursor in *Chlamydomonas*

Fig. 4 Physical map and nucleotide sequence of P20 cDNA. *a*, The upper line gives the location of restriction enzyme targets used in sequencing experiments. The numbers refer to nucleotide base pairs. The blocked region between nucleotides 40 and 408 represents the coding sequence for the mature small subunit. The lower lines indicate the region of the map covered by specific clones. The homopolymer tailing procedure was used to obtain pSSU1 whereas pSSU11, 60, 69 and 160 were prepared using the *Hin*dIII-linker sequence procedure. The arrows under each of the clone maps indicate the start points and directions of sequence reading. The sequencing was carried out by the Maxam and Gilbert technique[17]. For pSSU1 the labelled 5′ ends of the various fragments were separated by cleavage with a second restriction endonuclease. For pSSU11, 60, 69 and 160 the labelled 5′ ends were separated either by strand separation or by cleavage with a second restriction endonuclease. *b*, The nucleotide sequence is that determined for the coding strand of the cloned DNA. The deduced amino acid sequence is indicated above the nucleotide sequence, in single-letter notation. The N-terminus of the mature small subunit is indicated by an arrow.

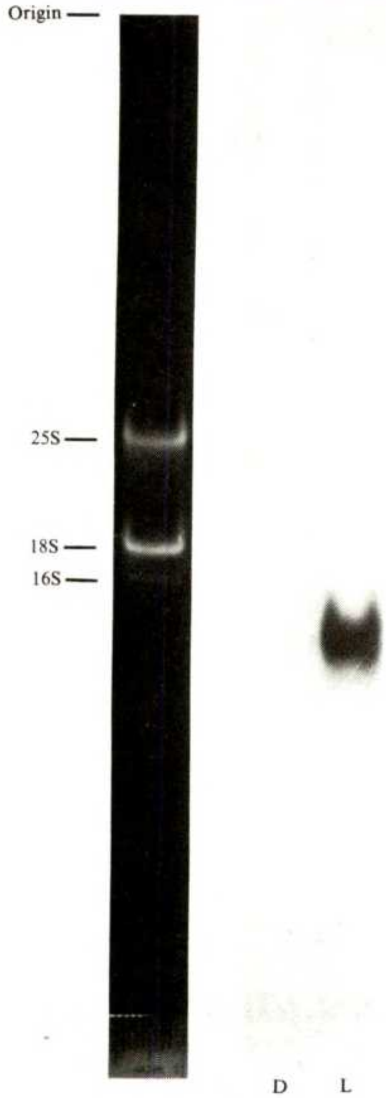

Fig. 5 Identification of P20 mRNA by hybridization with the cloned DNA probe. Samples (2.5 μg) of each of the two RNA preparations whose translation products are shown in Fig. 1*a* were glyoxalated according to McMaster and Carmichael[23]. This RNA was fractionated by agarose-gel electrophoresis, then transferred by blotting to DBM-paper[24] for subsequent hybridization to the cloned P20 DNA probe. Plasmid DNA was prepared from clones 60 and 160 (Fig. 4*a*) as described by Clewell[32]. DNA was digested with *Hin*dIII and fractionated by polyacrylamide-gel electrophoresis[33]. Gel pieces containing P20 DNA were excised and the DNA eluted at 37 °C for 10 h with 0.5 M $(NH_4)_2CH_3COOH$, 0.1 mM Na_2EDTA, 5 mM Tris-HCl *p*H 8.0. The purified DNA was collected by ethanol precipitation, and the different P20 DNA sequences were mixed in equimolar amounts. DNA was radioactively labelled by nick-translation[34] using [α-^{32}P]dCTP (Amersham) to a specific activity of 5×10^7 c.p.m. per μg DNA. Hybridization of this DNA to the RNA immobilized on DBM-paper was as described by Alwine *et al.*[24], using 10^6 c.p.m. per 100 cm^2 paper. After hybridization for 16 h at 42 °C, the paper was washed 3×30 min at 60 °C in $2\times$SSC, dried and exposed to X-omat H film (Kodak) with intensifying screens for 2 days. Shown here is a photograph of the autoradiograph. D, RNA from leaves of peas grown in darkness for 9 days; L, RNA from leaves of peas grown in darkness for 9 days followed by 48 h continuous illumination (see Fig. 1*a*). The electrophoretic mobilities of cytoplasmic ribosomal RNAs (25S and 18S) and 16S chloroplast ribosomal RNA are shown by the UV fluorescence photograph of a track of the same gel in which 2.5 μg total pea leaf RNA was fractionated and stained with ethidium bromide. Low molecular weight ribosomal RNAs are not seen in this RNA because its preparation involved precipitation from 2.5 M NaCl.

contains 44 additional amino acid residues at the N-terminus, but did not investigate the C-terminus. The available DNA sequence to the 5′ side of the ATG codon which specifies the N-terminal methionine residue of the mature small subunit encodes 13 amino acid residues. We deduce that these amino acid residues comprise part of a longer N-terminal extension. The elucidation of the complete sequence of this N-terminal extension awaits further molecular cloning.

Polyadenylated mRNAs from eukaryotes commonly contain the hexanucleotide 5′ AAUAAA 3′, about 20 nucleotides from the poly(A) tail[22]. Figure 4*b* shows that no such sequence occurs in the 3′ non-coding sequence of P20 mRNA. The 3′ non-coding sequence, including the translation termination codon, represents 260 nucleotides. The 3′ terminus of pSSU1 contains 98 A residues. Together with the deduced coding sequence of 408 nucleotides, our clones account for 766 residues of P20 mRNA.

Use of cloned DNA as a hybridization probe for P20 mRNA

The strategy for identifying cDNA clones encoding P20 depended on the assumption that the amounts of P20 mRNA in polyadenylated RNA preparations from dark-grown and illuminated pea leaves were reflected in the *in vitro* translation products of those RNAs. The success of this approach implies that our assumption is correct. The availability of cloned cDNA sequences enabled us to check this assumption. Further, we were able to determine the extent to which the size of the P20 mRNA molecule correlates with the cloned sequences which total 766 nucleotides (Fig. 4*a*). Equal amounts of the polyadenylated RNAs whose translation products are shown in Fig. 1*a* were denatured by glyoxalation and fractionated by agarose gel electrophoresis[23]. The fractionated RNA was transferred to DBM-paper and hybridized with the cloned P20 cDNA probe labelled by nick-translation[24]. The results of this analysis are shown in Fig. 5. The probe hybridizes to an RNA species of 900–1,000 nucleotide residues which is observed only in the RNA from illuminated leaf tissue. We conclude that this RNA species is P20 mRNA and that our cloned sequences encode most of this molecule.

The results presented here thus suggest various approaches for increasing our understanding of chloroplast development. We have predicted part of the amino acid sequence of the P20 polypeptide that is removed on entry into the chloroplast[10–12]. There is no apparent homology between this sequence and that of signal peptide sequences occurring in secreted animal proteins[25]. This is not surprising in view of the fact that a different mechanism is used to transport proteins into chloroplasts[2,10]. Furthermore, no significant homology is observed when comparing the pea P20 sequence with that from *Chlamydomonas*[21]. Again, this is not surprising because the *Chlamydomonas* polypeptide is not processed by pea chloroplasts[11]. Further sequence analysis with other cytoplasmically synthesized chloroplast polypeptides is necessary to determine whether any sequence rules are operating, and how they vary between species. The availability of cloned probes for the small subunit of RuBPCase will allow P20 to be prepared free from other labelled polypeptides, thereby facilitating investigation of its postulated interaction with proteins in the chloroplast envelope[10]. The nature of the control of P20 synthesis by light and the structure of the nuclear gene for this chloroplast polypeptide can also now be studied.

This work was supported by an EMBO long-term fellowship to J.R.B. and an SRC studentship to S.M.S. We thank Dr R. B. Flavell for laboratory facilities at the Plant Breeding Institute. Genetic manipulations were carried out under category II containment conditions as defined by GMAG (UK).

Cell cycle and experimental pattern duplication in the chick wing during embryonic development

J. Cooke & D. Summerbell

Division of Developmental Biology, National Institute for Medical Research, The Ridgeway, Mill Hill, London NW7 1AA, UK

Transient stimulation of cell division within chick wingbud mesenchyme is associated with the reorganization of limb pattern that follows insertion of a small graft from the posterior zone of limb polarizing activity into the anterior border of a host bud. This increase is initiated as an enhanced rate of entry to S phase, correlated with a decrease in packing density among mesenchyme cells, through much of the limb rudiment a few hours after the operations.

GROWTH CONTROL and pattern formation during embryonic development have been largely considered separately in recent years (but see refs 1, 2), because the spatial pattern for differentiation must be determined by direct cellular interactions during early stages, whereas growth has mainly been studied at much later (fetal) stages, where control through circulating hormones of varying degrees of target specificity has been documented[3,4]. There is, nevertheless, indirect evidence from stages of pattern formation for very local intercellular mechanisms, influencing the rate or amount of cell division in relation to the positional information or position value[5] that is determining which parts of patterns the cells concerned are to construct[6–10].

Relationships between intercellular signal systems controlling the cell cycle and those controlling pattern vary with stage of development. Determination of pattern up to gastrula stages in vertebrates and echinoderms is quite independent of the schedule of cell division which reflects the determination of the pattern rather than determining it[11–13]. By contrast, in regeneration of insect epidermal patterns after deletion of tissue, replacement and regulation of pattern occur very largely within new tissue specially grown as a response to the disturbance[6,7]. If generally circulating hormones and their cell-bound receptors mediate growth control in the differentiated and functioning body, while strictly local growth control via cell-bound positional codes is involved in pattern regeneration and the initial building of certain 'second-order' patterns[14] during post-gastrular development, we might expect at certain phases of embryonic life to observe signalling systems for growth which are intermediate between these extremes. We have studied the early wing rudiment in the chick as such a second-order embryonic field[14,15], in which pattern is actually being determined during extensive growth.

Within the chick wingbud, grafting a small piece of mesenchyme from a posterior limb-field region (the zone of polarizing activity, ZPA) into an anterior position leads to duplication of the wing pattern about its normal anterior border (Fig. 1)[16]. It has been suggested that an increase in the antero-posterior dimension, or width of the outgrowing bud, is a necessary accompaniment of successful duplication[17].

We have examined changes in the cell cycle within the host bud during the very early period after ZPA grafting, and compared this with the effect of a graft from an anterior donor position similar to the implantation site, an operation causing at most a small pattern disturbance (see later discussion) but usually resulting in quite normal development. The system is a sensitive one for cell cycle studies, as right and left buds are normally closely coordinated in their development[18], and equivalent populations of many thousands of cells can be scanned for uptake after labelling with ^{3}H-thymidine *in ovo*, and scored for mitotic incidence.

Hen's eggs after 3.5 days of incubation (a mixed local strain, Needle Farm, Hamburger & Hamilton, stage 19–20) were windowed and the right limb area of embryos exposed by removal of membranes. Operations grafting a piece of donor right wingbud mesenchyme with overlying ectoderm into a prepared anterior site were performed as described elsewhere[19]. In experimental cases the piece came from a posterior region known to possess polarizing activity (opposite somites 19/20, at stage 19), whereas in control operations it was from a donor position similar to the host site, opposite somite 16 at the same stage. Eggs were re-sealed with Sellotape and incubated for 4, 8 or 16 h before onset of ^{3}H-thymidine labelling. Figure 1*a* shows these operations in diagrammatic form, and Fig. 1*b* shows the morphogenesis that is finally seen after successful ZPA operations (about 90%) at 10 days of incubation.

The embryos were allowed to incorporate label for 1 h, then fixed. Figure 2 shows the appearances of typical fields within autoradiographs of sections through limb-bud mesenchyme (see legend for details of labelling, fixation, sectioning and staining). Whole buds were dissected free as right–left pairs during dehydration, embedded in Araldite and sectioned transverse to their own proximo-distal axes at 2 μm. All cells visible at each sectional level, distalwards from that where the graft–host junction was visible in the right limb, were scanned as sample populations for labelling index (proportion of nuclei in S phase at some time during the hour before fixation). This was done by dividing the mesenchyme outline concerned into four (or, at the tip, two) parts of equal antero-posterior extent (not equal area) to form boxes. The nuclear population within such boxes was usually between 500 and 1,100, and where fewer cells were transected near the bud tip, pairs of adjacent boxes in the proximo-distal sense were pooled. Data were collected directly with an electronic colony-counter (labelled + total nuclei) and by planimetry, from photographs of standard magnification. The

0028–0836/80/430697—05$01.00

data boxes are represented in grid plan form for each limb of the pairs shown in Fig. 2. Counts from replica photographs lie within 2% for both cell totals and labelling index, with the latter distributed around 35%. A typical cell packing density is 10,000 cells mm^{-2} of mesenchyme in these transverse sections.

Mitotic index (metaphases per 100 cells) as seen in the toluidine blue images was estimated for the whole population at each sectional level in some limb pairs, from the total cells visible per section (a large number with small relative variation among sections from a level) and the mitoses scored in four to six sections (a small number, of much greater relative variation as it records infrequent events). Estimates of mitotic index lie between 3 and 6% by this method, and are expressed here as % relative difference on the operated in relation to the left side (that is, a mitotic index of 6% is 100% enhancement over 3%). Even with effective samples at each level of 6–10,000 cells, only enhancements of around 25% or more on the right as compared with the left will reach statistical significance ($P < 0.01$), whereas much smaller relative differences in labelling incidence are significant with comparable sample sizes because the absolute incidence is so much higher.

Cell cycle stimulation spreads through host mesenchyme after ZPA grafts

We have analysed in detail two limb pairs labelled between 4 and 5 h after ZPA grafts (5-h limbs), two labelled between 8 and 9 h (9-h limbs) and one labelled between 16 and 17 h (by this stage, selection of visibly successful operations is possible because of the onset of width and shape changes that predict pattern duplication). A further visibly successful 17-h pair has been analysed for mitotic incidence only.

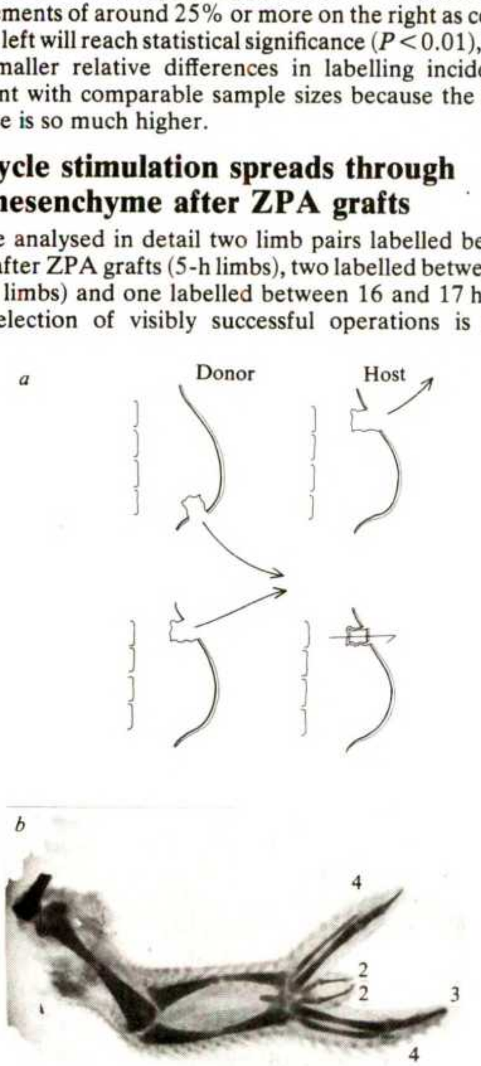

Fig. 1 The grafting operation. *a*, The diagram shows the graft site on the host, and the origin of the graft for ZPA and for sham operations. *b*, Typical result of a ZPA graft at 10 days of development, showing antero-posterior reduplication, together with contralateral control limb. The normal conventions of 2, 3, 4 (relative to a primitive pendadactyl limb pattern of 1–5) are observed for characterizing the digits. Scale bar, 1 mm.

Three anterior → anterior grafted (control) limbs and their left counterparts were examined for S-phase incidence and cell packing density after 8–9 h labelling, and two further 17-h pairs, one control-operated and one after an apparently unsuccessful ZPA graft (in view of lack of shape changes) were analysed for mitotic incidence only. Only host mesenchyme tissue is analysed, the boundary between host and small, discrete graft mesenchymal mass being still evident at these times. The large body of data collected per limb, and the magnitude in biological terms of the effects seen, assures us that our results document real events associated with ZPA implantation.

Figure 3 displays the spatial distribution of labelling index as determined within three of the experimental limb pairs and two of the control-operated pairs. It can be seen that a spatial pattern tends to exist in normal limb buds at these stages (around 21) whereby this index falls off from distal to proximal and from posterior to anterior borders within the mesenchyme. Variation in overall labelling incidence between embryos is unavoidable, probably because of biological variation and variation in precise conditions for ^{3}H-thymidine uptake during the experimental processing of groups of eggs. There is an enhancement of labelling index in ZPA grafted limbs, relatively local at 5 h, and widespread but concentrated on the anterior side at 9 and 17 h. The effect is not confined to the proximal level of the graft–host junction. A highly comparable sampling of the anatomy is made and 5–10,000 cells are involved in the grand total indices for each limb of each pair, so that the overall enhancements are highly significant ($P < 0.005$), even that within the 5-h pairs. Within individual data boxes, increases in labelling index of 8–10% over the left-hand equivalent (that is, 25–40% relative increase in S-phase entry over the hour, significant at $P < 0.01$) are typical within affected limb regions at each stage. The 9-h pair not illustrated showed an S-phase effect extremely similar on a quantitative and spatial basis to that in Fig. 3, whereas the other 5-h pair showed enhancement near the graft site comparable to that displayed, but could not be analysed spatially due to non-comparable planes of section in right and left buds.

None of the three control-operated 9-h pairs showed an S-phase effect on the right comparable with that seen after ZPA grafting to the anterior site. No overall enhancement was detectable even within the anterior half-mesenchyme total of right as compared with left side (28.4%, 31.6% and 33.9% right anterior half grand total labelling index, compared with 30.2%, 30.3% and 32.0% on left sides, respectively), whereas analysis of each 9-h ZPA pair reveals even posterior half-mesenchymal labelling index to be significantly enhanced within right limbs ($P < 0.01$). We deduce from this that the left is indeed an appropriate control for the right limb within individuals in terms of access of label, which would be essentially via the embryo's circulation. We consistently observe that mean grain density over labelled nuclei appears qualitatively greater in regions (especially in ZPA limbs) of highest labelling incidence among nuclei (see Fig. 2). The rate of DNA synthesis within S phase is probably correlated with the rate of cycle in cells that are susceptible to growth control (see below). The spread of stimulation of entry to S phase, through mesenchymal tissue, is therefore strongly associated with positional disparity between graft origin and implantation site within the rudiment, this disparity being itself generally necessary for the occurrence of new pattern formation as well as the morphological signs of early widening.

Full analysis reveals, however, in one out of the three control-operated cases (Fig. 3), a strong labelling enhancement in certain data boxes adjacent to the graft. This could reflect an effect on the cell cycle of local disturbance to the tissue integrity by the grafting operation, but it may occur because even an 'anterior-to-anterior' graft will induce some cell positional disparity, and any degree of such disparity triggers morphogenetic interactions to some extent (see below).

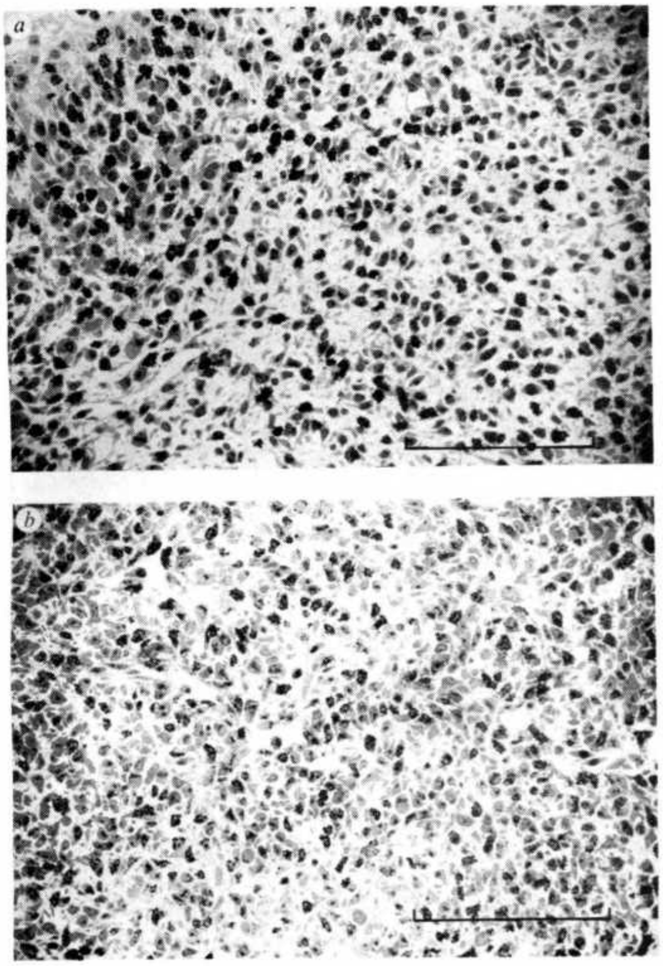

Fig. 2 Typical fields in autoradiographs of a 9-h limb pair. 500 KBq of ^{3}H-thymidine (TRK 120 [*Me*-^{3}H]thymidine, 720 GBq mmol^{-1}) in 100 µl of warm BSS were dropped into the opened amniotic cavity of each embryo. Eggs were resealed and incubated for 1 h at 38.5 °C. Embryos were then dissected off their chorio-allantoic membranes, removed from the egg and placed in warm BSS for 5 min, during which perfusion of the vascular system with BSS due to continued heart beat and the open circulation acted to lower background radioactivity. They were then fixed in half-strength Karnovsky fluid at *p*H 7.3, dehydrated in graded alcohols and propylene dioxide and embedded in Araldite. A small set of 2-µm sections from each limb of each pair, parallel to the embryo's long axis, was collected at each 50- or 100-µm interval along the proximo-distal axis, mounted on a subbed slide, dipped in Ilford K2 emulsion, exposed for 14 days, developed in Ilford D19 for 5 min at 20 °C, air dried and stained for 1 min in toluidine blue in 0.1% borax solution at 80 °C. This procedure strongly labels 25–50% of mesenchyme nuclei in various regions of control and experimental limbs, with very low background and no labelled mitoses. *a*, Anterior (pre-axial) region, labelled 8–9 h after ZPA grafting. Labelling index within the field is 32% and mean cell density 8,500 per mm^2. *b*, Anterior (pre-axial) region in the left, control limb for *a*. Labelling index is 23% and mean cell density 11,100 per mm^2. Scale bars, 100 µm.

Table 1 gives the relative mitotic incidence for the operated as opposed to the left side, in four ZPA grafted pairs and the two 17-h pairs acting as controls. Mitotic enhancement does not become significant before our 17-h time point, but is then dramatic, lying between 50 and 100% at various proximo-distal levels in the two ZPA grafted limbs examined. S-phase entry is responding at least as vigorously in both 9-h limbs (some 25% relative enhancement overall) as at 17 h, and has responded strikingly on a local level by 5 h. These data indicate that the signal caused by newly introduced positional disparity exerts a primary effect on the mesenchymal cell 'cycle' at a point near the passage from a G_1/G_0 condition into the determinate sequence that includes DNA synthesis and culminates in mitosis[20]. This resembles the situation found for conditions that control growth of cultured cells, and means that significant extra production of tissue would set in over the period (9–17 h post-operatively) when indeed width change is first observed. None of the control pairs (three 9-h, two 17-h) showed a trace of the massive mitotic effect seen in successful experimental limbs at 17 h.

The greater proportional enhancement of mitotic, as opposed to labelling, incidence seen at the peak of response can be understood by supposing that the actual time spent in mitosis is little changed during faster growth, whereas time taken by S may decrease in partial adaptation to a faster cell cycle[21,22]. Mitotic incidence might therefore be the more sensitive index of relative cycle time even though ^{3}H uptake reveals changes closer to the control point in the cycle.

Previous work has documented a general inverse, though complex relationship between mitotic index and cell packing density in normal early wingbuds. Our records of cell packing, in our control and experimental mesenchymes, both confirm this for S-phase and show that where the latter has been stimulated by the morphogenetic interactions we are studying, a correlated decrease of cell packing immediately occurs as exemplified in Fig. 2 (D.S. and J.C., in preparation).

Pattern formation and the control of size in wingbud mesenchyme

Our experiments suggest that, by contrast with a previously studied gastrular embryonic organiser[11], the ZPA region may control not only the spatial pattern of fates in limb tissue, but also the production of sufficient tissue to allow establishment of a normal version of pattern.

The postero-anterior decline in mesenchymal S-phase incidence, and the nonlinear aspect of the normal fate-map, whereby tissue whose fate is to form various parts of the structure is 'crowded' towards the posterior in the early bud (see Fig. 4 and refs 23, 24), are both consistent with the idea of a continuous, graded growth signal emanating from the posterior in normal development. However, the growth-stimulating effect of an anterior ZPA graft cannot simply be interpreted as an induction of 'posteriorness' in an anterior strip of tissue by

Table 1 Mitotic incidence at each proximo-distal level of right (operated) limb buds, expressed as % relative difference from the homologous left bud level, for five limb pairs

Limb pair	Level	Relative difference
Pair 623	1−	− 17%
Op. + 5 h	1+	+ 12%
	2	+ 14%
Pair 619	1	+ 26%
Op. + 9 h	2	+ 18%
	3	− 12%
	4	+ 12%
	5	+ 15%
Pair 634	2	+ 88%*
Op. + 17 h	3	+124%*
	4	+ 62%*
	5	+ 72%*
Pair 240	2	+ 56%*
Op. + 17 h	3	+ 52%*
	4	+ 49%*
	5	+ 65%*
Pair 632	2	+ 11%
Op. + 17 h	3	− 17%
failing to show width	4	− 8%
and shape change	5	+ 12%
Pair 633	2	− 13%
Sham op. + 17 h	3	+ 21%
	4	− 9%
	5	− 15%

Mitoses were pooled from four or six replica sections (toluidine blue, scanned at ×250) and related to the mean number of cells visible at each sectional level. Absolute mitotic index was ~3–6% in this work.

* Only differences between buds in pairs 634 and 240 were significant ($P < 0.01$).

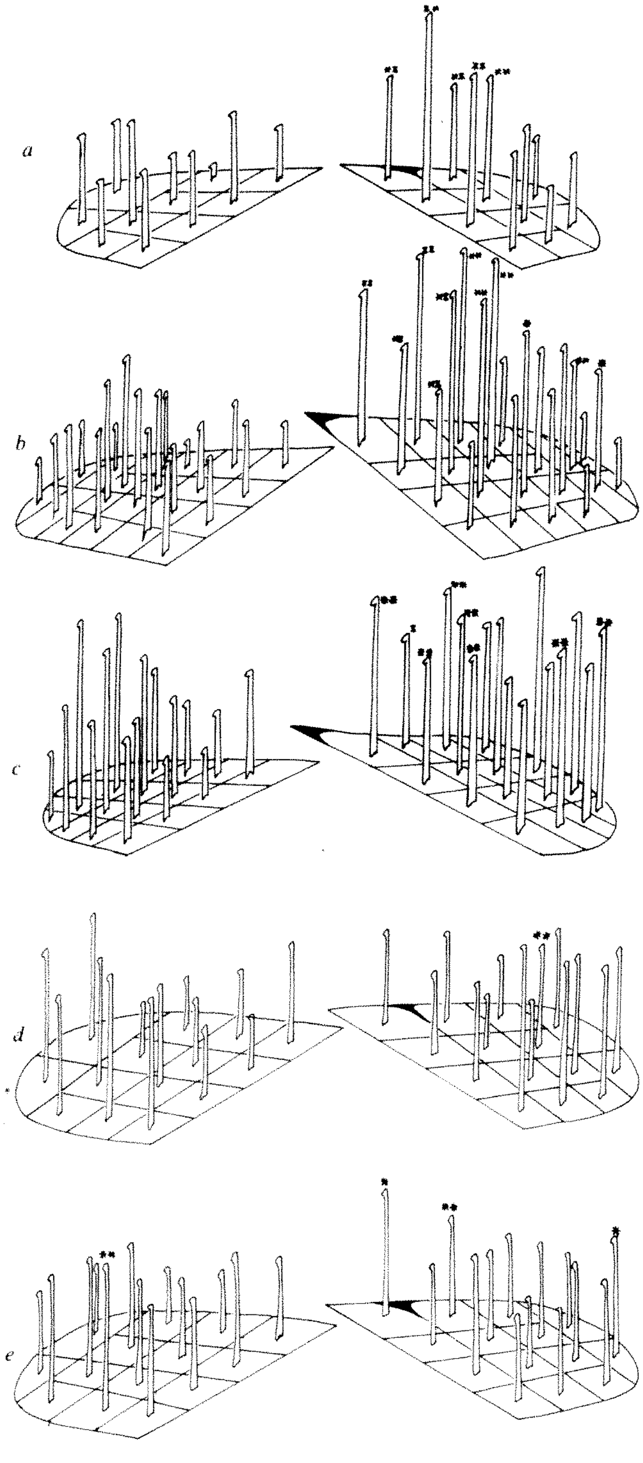

Fig. 3 Spatial variation in labelling index within limb pairs. Each outline represents a single limb-bud with dorsal surface viewed obliquely from the posterior, the (proximal) junction with the body towards the centre. They are arranged in pairs from single embryos, operated ones being on the right-hand side. Each box represents the cell population sampled in an area of mesenchyme derived by dividing the total cross-section visible at that proximo-distal level into four (or sometimes, distally, two) areas of equal antero-posterior width, and thus includes some 500–1,100 (usually around 800) nuclei. Solid corners anteriorly indicate those boxes where graft–host junction was visible. The column height in each box represents the labelling index there, in excess of an arbitrary baseline of 20% (the highest index shown being of 57%, in the 17-h experimental limb). Single and double asterisks above columns signify, respectively, an enhancement over the index of the homologous box in the control limb significant at $P < 0.05$ and $P < 0.01$. Lengths of the proximal baselines of each limb pair are drawn proportional to the total anterior-posterior widths of proximal cross-sections, but no attempt is made to depict the detailed shapes of bud outlines. *a*, Limb pair labelled from 4 to 5 h after a ZPA graft; *b*, limb pair labelled from 8 to 9 h after a ZPA graft; *c*, limb pair labelled from 16 to 17 h after a ZPA graft, where preliminary shape changes (indicating width increase) were visible externally in the right bud. *d,e*, Two limb pairs labelled from 8 to 9 h after an anterior → anterior (control) graft.

Fig. 4 Outline model for relationship of limb pattern specification to early growth control. Pattern-controlling and growth-promoting signals in the system are seen as distinct entities, and perhaps only loosely correlated in profile at any time, although both organized from the ZPA and of a general gradient form. Cells may respond to the growth signal according to its 'rate of flux' as well as its absolute level, so that cycle stimulation is most pronounced locally soon after ZPA grafts, before the system reaches equilibrium (see, for example, Fig. 3*a*). The process of assigning a complete set of developmental programmes (that is, a whole pattern) to tissue is one that intrinsically occupies a particular space. There may be a stable gradient system of characteristic extent, and also perhaps a pre-pattern of spatial variables[28,29], requiring a standard size, for the detailed form. On this view, an anterior ZPA graft might be expected to lead initially to loss of anterior parts, centrally, in a mirror-image duplication. If complete duplication of distal—that is, later-determined[30]—pattern parts is ultimately found (see Fig. 1*b*), then the antero-posterior extent of territory across which pattern-forming events are occurring must have been appropriately increased by widespread, early response to the extra growth signal. Highly controlled size of the final limb is seen as a result of the constancy of the size at which patterns, for highly programmed growth as well as differentation, are initially laid down. The first three levels of the diagram represent the normal situation and then two time points within the first, say, 24 h after an anterior ZPA graft. The ordinate is the signal value at each location, the abscissa is the anterior (left) to posterior (right) tissue extent of the limb rudiment at each stage. – – – –, Profile of a signal influencing the cell cycle. ——, Profile of a signal assigning position value. 2, 3 or 4, levels of positional signal associated with formation of particular digits, but cell fate still labile (undetermined). ②, ③ or ④, local tissue determined as, or actually forming, particular digits. The bottom line in the diagram gives the proportions in the later (much larger) developing limb cross-section. Note that growth has been greatest for more posterior elements in the pattern.

pattern re-specification, with an early expression of that altered pattern in terms of intrinsic growth rate. Higher S-phase entry is seen, in regions where we would expect the most rapid changes of position value due to cell interactions at early times, than is found anywhere in the normal limb (for example, 53% labelling index, a 60% relative increase over the left bud as a whole, near a ZPA graft at 5 h after operation). This growth control effect, exaggerated by the unusual positional disparity initially involved in duplication after grafting, largely underlies the early antero-posterior widening whereby both the original and the newly induced limb pattern are able to be complete and to occupy normal amounts of tissue by the time of their specification.

Knowledge of the rate of spread of the growth signal and the kinetics of new tissue production is highly relevant to our understanding of normal and experimental pattern specification in this system. Recent modelling of the antero-posterior pattern control has conceived of the ZPA as source, and limb mesenchyme elsewhere as sink, for a morphogen substance giving a signal gradient of particular profile and spatial extent and hence, by cellular interpretation of local value, a specified differentiation pattern of particular size and proportions[17,19,24]. Despite recent suggestions that the cell interaction system may also have a component whereby any induced disparity of cell position value (that is, heterotopic grafting) produces some new pattern formation by local interaction[25], there is little doubt about the dominance and primary role of the ZPA in organizing large and potentially complete new patterns when grafted. Although the most pronounced local stimulation occurs very soon after operation (Fig. 3*a*), the widespread nature of the response thereafter effectively rules out the idea that the new pattern is produced solely in a local zone of special growth, and even makes it unlikely that the entire second pattern is formed within tissue derived from a very small ($\simeq$100-μm wide) region taken over by the new organizer. The present results support models of the general gradient form for pattern specification (regardless of molecular nature of the signal) and will help in improving their fit to some of the data.

Figure 4 gives the outline of a model for size control and pattern formation across the limb mesenchyme, which could be tested by future work and which seems most compatible with the data. The ZPA or organizing region is seen as emitting signals, both of essentially graded form but of separate molecular identities, one controlling the fates of cells in the pattern of differentiation, the other the rate and pattern of early growth which may ensure adequate tissue space for the complete specification of pattern by the first signal. The specified, normally sized and proportioned rudiment is then thought to grow according to its own endogenous programme to give the normal anatomy (see above and ref. 9). The ideas are treated further in Fig. 4 legend. Separate, correlated growth and position signals, although not the only tenable hypothesis (D.S., in preparation), would explain (1) the fact that we see widespread, considerable cellular response in growth within 9 h of grafting, whereas the grafted ZPA must be present for more than 10 h to produce any effect on pattern if excised again, and (2) the avoidance by the system of the loss of anterior pattern values (digit 2), between host and grafted ZPAs, expected on the simplest diffusion gradient models for specification.

Essentially all cells are cycling in the early wingbud[26], and the cycle time may be 6–10 h (refs 23, 27). Our data do not allow us to quantify the cycle shortening involved in our experiments but suggest that it is very considerable, and widespread (Fig. 3, Table 1). As total tissue mass only approaches a doubling in the most completely duplicated wings, and each limb pattern is believed to grow to a fixed schedule in late development, the growth stimulation must be very short-lived and followed by a return to equilibrium, perhaps within 24 or 36 h (two or three normal cycle times) of grafting.

We believe this to be the first report of an intercellular growth control system linked to morphogenetic processes in an early vertebrate embryo. Future work should be directed particularly at the question of whether the roles of the ZPA in pattern and in growth control utilize separate, correlated molecular signals, or reflect separate cellular responses to one positional signal system. We are now studying this by more complex experiments in which we attempt to separate the effects of possibly distinct growth signals from those of positional signals.

We thank Jasmail Jhite and June Colville for histology, and Beverley Block for assistance with computation. The work is supported by the MRC.

Ultraviolet spectra of asteroids

P. S. Butterworth*, A. J. Meadows*, G. E. Hunt†, V. Moore† & D. M. Willis‡

Spectra over the range 2,100–3,200 Å have been obtained for the three largest asteroids—Ceres, Pallas and Vesta—using the International Ultraviolet Explorer (IUE) satellite[1]. These represent the first detailed UV reflectivity data for asteroids. They extend the numerous measurements already carried out in the visible and IR[2,3] to shorter wavelengths, and so enlarge on previous studies of both the classification and the mineralogy of asteroids[4].

Table 1 lists basic information concerning the spectra we have analysed. Spectra labelled 'Arizona' were obtained by the University of Arizona: we have acquired them from the World Data Centre {Cl} at the Rutherford and Appleton Laboratories. Those labelled 'UK' were obtained by us at VILSPA, the European ground observatory located near Madrid.

The reduction and calibration of asteroidal spectra has presented a number of problems. In order to obtain the asteroidal contribution, it is first necessary to divide by the solar spectrum. Slight errors in the juxtaposition of wavelength scales in this process can lead to major errors in the residual asteroidal spectrum, and it has proved difficult to achieve exact coincidence. Partly to obviate this, the resolution of the original observations (6–8 Å) has been smoothed in our reduction program to an average resolution of 50 Å. This does not significantly affect our investigation, as solid-body absorption features are much wider than this.

The solar spectrum we have used in our reductions[5] was obtained in mid-1970, just after a solar maximum. Our spectra were obtained just before maximum. It is possible that this has introduced a systematic error in our results. However, from the data available on variations in the solar UV spectrum as a function of the solar cycle,[6] we estimate that the colour ratio λ 2,590/λ 3,075 should not differ by more than 5–10% between mid-1970 and the dates of our observations. Variations between spectra of the same asteroid (see Figs 1 and 2) taken at different times can be adequately explained by errors in the observational and reduction processes. There is no evidence that the results are affected by short-term changes in the solar UV flux.

0028–0836/80/430701—03$01.00

Table 1 Asteroidal spectra analysed

Object	Date observation	Image no.	Exposure time (min)	Aperture	Source
Ceres	28 July 1978	LWR 1890	10	Small	Arizona
Ceres	28 July 1978	LWR 1890	20	Large	Arizona
Ceres	12 November 1979	LWR 6107	10	Large	UK
Pallas	2 June 1978	LWR 1539	16	Small	Arizona
Vesta	21 May 1978	LWR 1532	5	Small	Arizona
Vesta	2 July 1978	LWR 1772	20	Large	UK
Vesta	12 November 1979	LWR 6106	120	Small	UK

The data obtained from IUE were next calibrated to transform them into geometric albedos. This involved four steps. First the radiometric visual albedos from the TRIAD database[7] were corrected to allow for new estimates of the diameters of Ceres, Pallas and Vesta[8]. Then the visual spectral reflectances of these asteroids (also from the TRIAD database)[9] were normalized to the absolute visual albedos. After this, the albedos obtained for the three asteroids with the OAO 2 satellite[10], which covered bands in both the visual and the UV, were normalized, over the appropriate wavelength region, to the visual spectral reflectance curves. Finally, our IUE spectra were normalized to the corresponding OAO 2 albedos at 3,075 Å. (One Vesta spectrum {LWR 6106S} was saturated at 3,075 Å and was therefore normalized to the average of the other two Vesta spectra.) These successive steps necessarily introduce uncertainties into the calibration process; as do uncertainties in the IUE calibration, itself[11]. We estimate that the cumulative random errors from all these sources are ±15%. Systematic errors, due especially to uncertainties in the original calibration of the OAO 2 observations, also almost certainly occur, and may be larger than the random errors.

Figure 1 shows our calculated geometric albedo values for Ceres and Pallas over 50-Å intervals. The corresponding values for Vesta are shown in Fig. 2. The estimated error bars are given for one set of measurements only for Ceres and Vesta to avoid confusion in the diagram. The set chosen is in each case the one for which the error estimates are largest. These errors have been derived from measurement of background noise along two strips parallel to, and on either side of, the UV spectrum strip as it appears on the image field recorded by the spectrograph camera. Some data points are missing from the Pallas spectrum, one Vesta spectrum and two Ceres spectra. These correspond to wavelength regions where the original UV spectra are saturated.

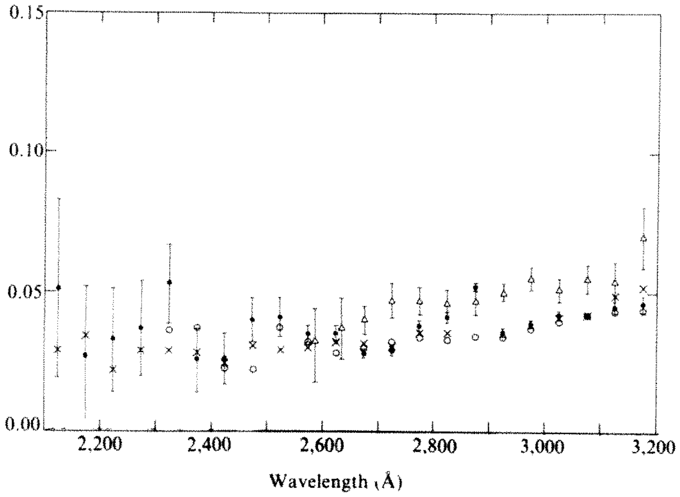

Fig. 1 Values for the geometric albedos of Ceres (●, ○, ×) and Pallas (△) over the range 2,100–3,200 Å. ●, LWR 6107 (large slot); ○, LWR 1890 (small slot); ×, LWR 1890 (large slot); △, LWR 1539 (small slot).

The results for Ceres presented in Fig. 1 suggest that its reflectivity near 3,200 Å is approximately 0.047. This is some 30% higher than the value obtained from ground-based measurements at 3,300 Å, which not only represents a large and sudden increase, but also goes against the trend of reflectivity in this wavelength region. It seems possible that the OAO 2 albedo at 3,075 Å, which we have used in our calibration, may be in error. D. L. Matson (personal communication) has unpublished data which suggest that the albedo of Ceres at 3,000 Å could be as low as 0.025. Use of this latter value—which corresponds to a lowering of the entire albedo for Ceres in Fig. 1 by a factor of 40%—would resolve the apparent discrepancy in values for the 3,200–3,300 Å region. The shape of the spectral curve for Ceres is not, of course, affected by such a shift: there is some indication of genuine dips centred on 2,425 Å and 2,650 Å.

The OAO 2 calibration for Pallas and Vesta gives results which agree better with ground-based observations. The Pallas spectrum shows no certain features, but there is some indication of a significant change in slope of the Vesta spectrum at about 3,000 Å. Unfortunately, coverage of this region of the Vesta spectrum is poor: further ground-based photometry is needed to define the slope longward of 3,000 Å more accurately.

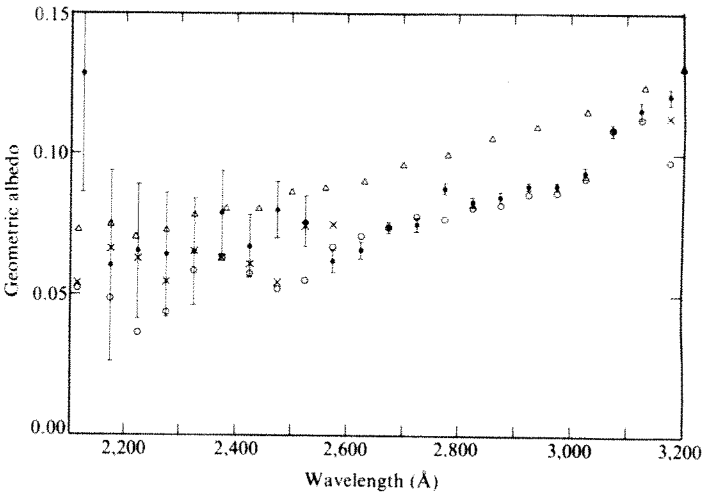

Fig. 2 Values for the geometric albedo of Vesta (●, ○, ×) over the range 2,100–3,200 Å. The spectral reflectance of the meteorite Kapoeta (△) over the same range is shown for comparison. ●, LWR 1532 (small slot); ○, LWR 1772 (large slot); ×, LWR 6106 (large slot).

Particular interest attaches to the UV spectrum of Vesta. At visible and IR wavelengths Vesta's spectrum shows considerable similarity to the spectra of the basaltic achondrite group of meteorites[4]. Laboratory measurements of UV reflectivity are available for the meteorite Kapoeta[12], a member of this group, and are plotted in Fig. 2 along with our results for Vesta. The values for Vesta are mainly smaller than those for Kapoeta, though the results for the two bodies suggest a generally similar trend with wavelength.

Systematic differences between the Vesta and Kapoeta spectra may well be attributable either to errors in our calibration procedure, or to differences between the surface texture of the meteorite samples and the asteroid. However, the Kapoeta measurements do not show a change in slope at 3,000 Å, as may occur in the Vesta observations. Confirmation of the existence of this feature might therefore be of importance for the study of the mineral assemblages present on Vesta.

We are currently examining the UV spectra of a number of other asteroids. The main limitation on reduction of this material is that albedo normalization data are only available for the three asteroids discussed above. However, our preliminary work suggests that the UV spectra of asteroids may be as distinctive as their spectra in the visible and near IR. To the extent that differences in spectral reflectance are due to differences in surface mineralogy, UV observations can therefore be used to extend the knowledge of asteroidal mineralogy already obtained from observations at longer wavelengths.

This work was supported by the SRC. We thank the resident astronomers at VILSPA for their unfailing assistance, and Drs D. L. Matson and M. J. Gaffey for their comments on the manuscript.

Discovery of intrinsic linear polarization in SS433

I. S. McLean*† & S. Tapia

* Royal Observatory, Edinburgh EH9 3HJ, UK
† Steward Observatory, University of Arizona, Tucson, Arizona 85721

The remarkable object[1] SS433 is the optical counterpart of a discrete variable radio and X-ray source[2–7] located in an extended radio-emitting region (W50) which may be a supernova remnant[8–11]. The best known attribute of SS433 is the 'moving' emission lines in the visible and near IR spectrum[12]. The displacements of the emission features have been shown to be due to Doppler shifts[12,13] arising from velocity variations with a period of $P \sim 164$ days; velocities up to +50,000 (0.17*c*) and −35,000 km s^{-1} are attained by the redshifted and blueshifted components respectively. A favourable configuration seems to involve two highly collimated, oppositely directed near-relativistic streams emerging from the central object. We report here new observations which reveal that the linear polarization of the optical radiation from SS433 exhibits a long-term variation as well as large night-to-night changes. This establishes that a substantial fraction of the observed polarization is intrinsic to SS433 whereas the remainder may be produced in the interstellar medium. As polarization is an indicator of physical and/or geometrical asymmetries in nature, this phenomenon can have a useful role in discriminating between contending configurations for SS433.

Early attempts to search for polarization of radiation from SS433, mainly as an indicator of magnetic fields and non-thermal processes in general, proved negative. Liebert *et al.*[13] found no circular polarization in red light, and Thompson *et al.*[14] found no significant linear polarization at 2.2 μm. Kemp[15] reported (3.1 ± 0.6)% linear polarization at $\theta = 3.1° \pm 3.0°$ in the blue-green region of the visible, and Shawl (personal communication) found (3.96 ± 0.41)% at $\theta = 4.1° \pm 3.0°$; these values were largely attributed to interstellar polarization. The linear polarization data presented here were obtained with the 2.3-m and 1.55-m telescopes of the University of Arizona Observatories. These measurements are an order of magnitude more accurate than the above and provide the first clear evidence of variations.

To maximize the signal-to-noise ratio, our observations were made with an unfiltered Ga–As photocathode covering the spectral region between 3,000 and 9,000 Å. As the bulk of the observed optical radiation from SS433 is concentrated at the red end of the spectrum, the characteristic wavelength of our unfiltered passband is near 7,000 Å and thus much redder than those of Kemp and Shawl. This is corroborated by a concordant measurement obtained with a filter having transmission only between 6,500 and 7,500 Å. The exceptional strength of the emission lines may have a small influence on the degree of polarization measured with our unfiltered passband but the effects of varying Doppler shift should be minimal. Also, the polarization at the rest wavelength of Hα (6,563 Å) was measured with a narrow passband (32 Å) in two consecutive cycles at times which were coincidentally near phase zero, that is when the emission lines cross the redshift of $z \simeq 0.04$.

Table 1 Optical linear polarization of SS433

Julian Day (2440000+)	(Phase (ϕ)	p(%)	θ(deg)
a, Unfiltered Ga–As, $\Delta\lambda \simeq 5{,}000$ Å			
3,964.99	2.496	2.64 ± 0.20	10.6 ± 2.2
3,966.98	2.508	1.97 ± 0.04	10.6 ± 0.6
4,114.70	3.409	2.18 ± 0.06	11.0 ± 0.7
4,126.64	3.482	1.87 ± 0.04	11.4 ± 0.6
4,127.75	3.489	2.13 ± 0.03	8.5 ± 0.5
4,146.625	3.604	2.03 ± 0.03	7.6 ± 0.5
4,194.585	3.896	2.33 ± 0.04	3.0 ± 0.5
4,217.579	4.036	1.92 ± 0.04	172.3 ± 0.7
4,218.579	4.043	2.15 ± 0.04	174.8 ± 0.5

4,349.972	4.844	2.48 ± 0.07	0.7 ± 0.8
4,369.949	4.965	2.41 ± 0.03	178.4 ± 0.4
4,383.944	5.051	2.24 ± 0.02	1.7 ± 0.3
4,384.944	5.057	1.80 ± 0.05	177.5 ± 0.8
4,385.944	5.063	1.47 ± 0.05	174.6 ± 1.0
b, $\lambda = 7{,}000$ Å, $\Delta\lambda = 1{,}000$ Å			
4,218.60	4.044	2.22 ± 0.09	176.1 ± 1.2
c, $\lambda = 6{,}563$ Å, $\Delta\lambda = 32$ Å			
4,217.60	4,037	2.65 ± 0.13	1.6 ± 1.4
4,218.599	4.043	2.61 ± 0.11	1.3 ± 1.2
4,383.944	5.051	2.69 ± 0.11	5.7 ± 1.2
4,384.944	5.057	2.47 ± 0.09	5.7 ± 1.0

The data are presented chronologically in Table 1 where p is the observed percentage of linear polarization and θ is the equatorial position angle. For comparison, ϕ is the 164-day phase[12]; the integer part of the phase is given to show the number of cycles observed. In these data the effects of instrumental polarization are negligible.

Because the observed continuum polarization is the vector sum of at least the intrinsic and the interstellar polarization, it is most instructive to plot the Stokes parameters defined by $Q = p\cos 2\theta$ and $U = p\sin 2\theta$, against time. Any constant interstellar polarization (Q_i, U_i) merely introduces an offset which still allows the intrinsic variations ($Q_*(t)$, $U_*(t)$) to be viewed directly because $Q_0(t) = Q_*(t) + Q_i$ and $U_0(t) = U_*(t) + U_i$. Thus Fig. 1 presents the phase dependence of the observed (continuum) Stokes parameters and shows that large variations in both Stokes parameters do indeed take place over the time scale spanned by the 164-day period but, as yet, the data are still too few to establish periodicity conclusively. The accuracy of our measurements is sufficient to reveal that very short time scale variations of the polarization are also present. In terms of our current knowledge of SS433 these short-term changes could originate in (1) the underlying binary period (13 days) or (2) stochastic (outburst-like) variations similar to the irregular departures of the radial velocity and light curve[16]. Obviously, such short-term variability will have to be averaged-out to enable variations following the 164-day cycle to be observed.

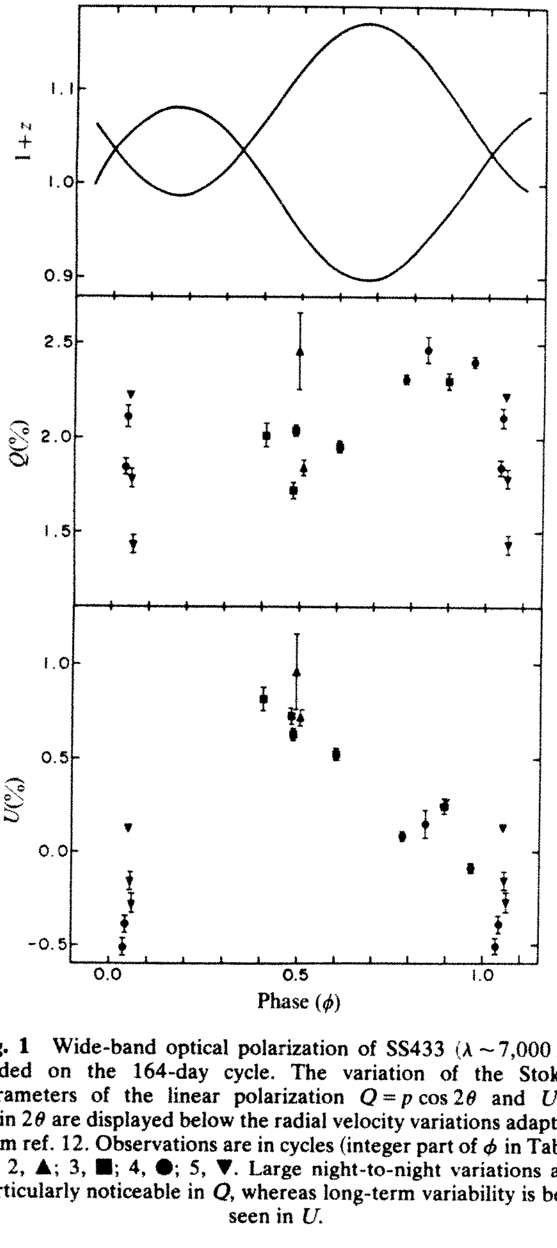

Fig. 1 Wide-band optical polarization of SS433 ($\lambda \sim 7{,}000$ Å) folded on the 164-day cycle. The variation of the Stokes parameters of the linear polarization $Q = p \cos 2\theta$ and $U = p \sin 2\theta$ are displayed below the radial velocity variations adapted from ref. 12. Observations are in cycles (integer part of ϕ in Table 1): 2, ▲; 3, ■; 4, ●; 5, ▼. Large night-to-night variations are particularly noticeable in Q, whereas long-term variability is best seen in U.

In Table 1 the observed degree of polarization at the wavelength of *Hα* is little different from that in the continuum. However, the difference between the position angles of the line and the continuum polarization exceeds the 3σ level. This rotation of the observed polarization at $\lambda 6{,}563$ can be thought of as an additional term in the expressions for the observed Stokes parameters: $Q_0 = Q_* + Q_{H\alpha} + Q_i$ and $U_0 = U_* + U_{H\alpha} + U_i$. However, without accurate values for the interstellar contributions it is not possible to assess whether the terms $Q_{H\alpha}$, $U_{H\alpha}$ are associated with an enhancement or a dilution of the polarization at $\lambda 6{,}563$.

From its reddening[2,17] ($0.75 < E(B-V) < 2.4$), albeit poorly determined, and location near the galactic plane, the allowed range of interstellar polarization (in the mid-visible) for SS433 is $2.25 > p_i(\%) < 7.20$. An upper limit (3σ) can be estimated using the 2.2-μm IR polarization of $(0.1 \pm 0.1)\%$ observed by Thompson *et al.*[14] at phase $\phi = 0.60$ if one assumes, *a priori*, no source of 2.2-μm polarization in SS433 and that the wavelength of maximum interstellar polarization is close to the normal value, $\lambda_{max} \simeq 0.55$ μm; the result is $p \lesssim 2.7\%$. (As the optical polarization mechanism is uncertain, a 2.2-μm polarization source in SS433 cannot be dismissed; however, the assumption is consistent with our discussion below.) An examination of polarization survey catalogues[18-20] suggests that, in the region of sky containing SS433, the mean position angle of interstellar polarization is $\theta_i \simeq 30° \pm 15°$. We have observed the broad band polarization of the uncatalogued stars in the 'diamond' pattern lying only ~2 arc min north-west of SS433. These data show that the northernmost component has no polarization, whereas the southernmost and westernmost components are polarized with $p = (1.54 \pm 0.09)\%$ at $35° \pm 2°$ and $p = (1.2 \pm 0.2)\%$ at $16° \pm 5°$ respectively. Thus a lower limit to p_i is ~1.5%. Until the interstellar polarization towards SS433 is known with accuracy comparable with the data in Table 1, it will be difficult to solve for the intrinsic polarization in the continuum and at Hα. However, for values of p_i in the range 1.5–2.7% at $\theta_i \simeq 30°$, the intrinsic polarization at $\lambda 6{,}563$ (continuum plus Hα) seems weaker than the continuum and at a position angle at least 15° larger. Because of the same difficulty one cannot yet derive the orientation of the intrinsic plane of polarization for comparison with that of the radio lobes in W50.

Several sources of intrinsic polarization in SS433 have been ruled unlikely. The lack of evidence for strong optical circular polarization (<0.1% in broad bands, <1% in emission lines) eliminates magnetic fields of $\sim 10^8$ G detected in degenerate dwarf stars[13]. Fields of $\lesssim 10^4$ G, found in Ap-type stars, may still be present[21] and could be detected with high resolution Zeeman spectropolarimetry. However, polarization in the continuum should be nil. Low degrees of linear polarization due to gyro radiation at radio frequencies are possible[21] but again with no detectable effects in the optical continuum.

Scattering processes commonly polarize optical radiation in many astrophysical scenarios. Milgrom[22] has suggested that light emitted by the regions producing the moving emission and rest-emission lines respectively can scatter from free electrons (Thomson scattering) in any of the other emitting regions and hence become polarized. Margon *et al.*[12], however, have searched for the predicted extra lines and find no conclusive evidence for them.

In the absence of any evidence for dust[14] and in view of the ionization levels expected in the line-emitting regions the most probable source of polarization in the optical continuum of SS433 seems to be electron scattering. Optically thick electron scattering could occur in a dense accretion disk. On the other hand, if the system includes a close binary undergoing mass transfer plus collimated, near-relativistic beams emerging in opposite directions, then optically thin electron scattering may occur in both regions[23], as in Be stars and some X-ray binaries. The continuum polarization would thus display two time scales of variation; one due to the binary period and a longer one due to the precession of the system. Differential changes in Q and U then provide information on the scattering geometry.

In terms of the models currently proposed[24-26] for SS433, the electron density (N_e) is sufficient to produce significant Thomson scattering. The corresponding optical depth τ needs to be equal to or larger than the fraction of polarized flux, that is $\tau \gtrsim 0.01$ according to the data in Table 1. Now, $\tau \simeq \sigma_T N_e L$, where L is the characteristic size of the scattering region. Then $N_e \gtrsim 1.5 \times 10^{22} L^{-1}$ cm^{-3}. If the scattering region and the source of radiation are close, L is approximately equal to the size of a typical circumstellar shell ($L \sim 10^{12}$ cm), as is known for Be-shell stars. In this case $N_e \gtrsim 1.5 \times 10^{10}$ cm^{-3}. However, for scattering blobs relatively distant from the star dilution effects are important and the characteristic length becomes $L \sim l^3/R^2$, where R is the distance to a scattering region of volume l^3. If such scattering regions can be identified with the emitting regions of the jets, then the estimated sizes[24,25] fall in the range $10^{12} \leq l \leq 10^{15}$ cm, with $R \gtrsim 20l$ for good collimation. Therefore, in this second case $10^9 \leq N_e \leq 10^{13}$. Optically thin electron scattering near the emitting regions is also consistent with the energy flow in the jets if this is less than 10^{40} erg s^{-1}.

These results emphasize the fact that polarization plays an important part in the search for a consistent model of SS433.

We thank J. C. Kemp, A. C. Fabian, M. J. Rees, G. V. Coyne, R. Williams and J. Liebert for helpful discussions, and H. S. Stockman for the polarization result on JD2444114.7. I. Can galaxy warps be used to provide constraints on halo properties?

George Lake

University of California, Berkeley, California 94720

James W.-K. Mark

Lawrence Livermore Laboratory, Livermore and Astronomy
Department, University of California, Berkeley, California 94720

The prevalence of flat rotation curves in external galaxies[1] strongly suggests an extensive but as yet unseen halo component. However, as direct observations of the implied matter distribution have proved very elusive, more indirect methods are needed to constrain its properties. At the same time, the explanation of observed warps in galaxies[3-7] has been intensively studied by dynamicists, resulting in the appearance of many rival mechanisms (see ref. 8 for a review). For galaxies with companions, the tidal interaction theory is the most attractive, but fails to account for the observed bending of our Galaxy "by a factor approaching 3" (ref. 9). The problem of the rapid kinematical disruption which results if one follows particle orbits in a self-consistent disk is avoided if one accepts the existence of a dominant spherical (halo) component in the region of the warps[8,10]. Here, we explore the consequence of separating disk and halo mass distributions using a recently developed theory of bending waves[2]. In this theory, the height of bending allows the functional form of the disk density distribution to be determined. With proper normalization this determination allows the halo density to be inferred from the rotation curve. We will discuss the warps in our Galaxy and in galaxies NGC2841 and M33, for which a relatively complete set of reduced data is available.

For many galaxies, the phenomena of warps start at moderate radii where the halo need not be the dominant contribution to the rotation curve. For these instances, Bertin and Mark[2] have developed an improved version of the earlier Kulsrud, Mark and Caruso[11] bending wave analysis and included disk–halo interactions in the manner of Mark[12]. This extended analysis is applicable to a wide range of disk-to-halo ratios. In this way, rather than instilling an initial bias towards dominant haloes, the theory may be used to constrain halo properties.

In the Bertin and Mark analysis, the transfer of angular momentum from disk to halo results in a destabilization of bending modes, much like a flag waving in the wind or the two-stream instability in a plasma. The resulting amplification can be large[2] and may explain the magnitude of the warp in our Galaxy, as well as the existence of warps in isolated spirals[5,7]. In this theory, the functional form of the warp is mainly dependent on the inertia (total surface density) of the disk $\Sigma(r)$,

$$H \sim \frac{1}{\Sigma(r) r^{1/2}} g(r) \qquad (1)$$

where r is the radial coordinate in the disk, H is the maximum vertical displacement at that radius and $g(r)$ is a smooth, weakly varying part of the amplitude. (For the following comparisons with observation, $g(r)$ may be assumed to be constant[2].)

The warp should be mostly observed in the outer parts of disks where the inertia is low. Frequently, in this region only the gaseous component is observed. Stellar disks are also observed to be warped[13,14], which is quite natural in the context of the theory of Bertin and Mark.

The theory as constructed by Bertin and Mark[2] has strong analogies with the theory of spiral structure[15]. As in any linear theory it is simple to calculate a relative amplitude as a function of radius, but the absolute normalization must be obtained directly from observations. However, equation (1) for the functional form of the amplitude provides a simple observational test which is independent of model parameters.

Figure 1*a* plots surface density against radius in our Galaxy as derived from equation (1) using the data of Henderson[4]. If we temporarily adopt a flat rotation curve with the circular velocity beyond the solar radius (R_0) equal to 250 km s^{-1}, we find the resulting points are well fitted by an exponential with a scale length of 3.4 ± 0.2 (R_0/10 kpc) kpc. This procedure is superior to determinations of the disk profile from fitting *HI* velocity profiles, because nothing is initially assumed about the mass distribution as a function of radius. (Of course, in both cases a rotation curve must be assumed or measured so as to derive distances from the observed line-of-sight velocities.) Assuming the same flat rotation curve, Knapp, Gunn and Tremaine[16] derive a scale length of 3.2 (R_0/10 kpc) kpc from such fitting of *HI* profiles with an assumed exponential mass distribution. Using the Oort limit[17] to normalize the density at R_0, we obtain a mass model close to that of Caldwell and Ostriker (in preparation). If we use the most recent rotation curve of Blitz, Fich and Stark[18], the scale length is 4.0 ± 0.2 (R_0/10 kpc) kpc, the disk mass integrated to 20 kpc is approximately 7.6×10^{10} $M_\odot$ (changing by ~10% depending on whether or not a central gap

0028–0836/80/430705—02$01.00

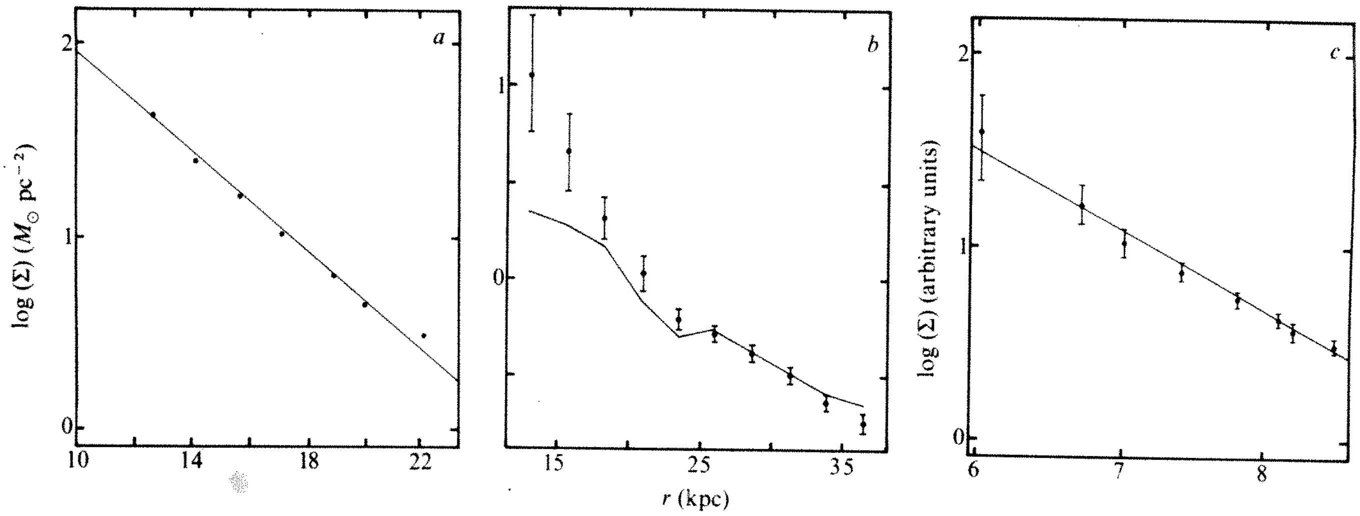

Fig. 1 *a*, The surface density $\Sigma(r)$ against radius in our Galaxy as derived from equation (1) using Henderson's[4] data for the warp. Distances are determined using a flat rotation curve with the circular velocity at the Sun equal to 250 km s^{-1}. The straight line is an exponential with a scale length of 3.4 kpc, normalized to the Oort limit[17] at the solar radius (10 kpc). Use of the rotation curve of Blitz, Fich and Stark[18] results in a computed scale length of 4.0 kpc. *b*, The surface density against radius for NGC2841 as derived from equation (1) using the data of Bosma[5] (H_0 is assumed to be 75 km s^{-1} Mpc^{-1}). The solid line is the observed neutral hydrogen surface density. The deviations at distances less than 20 kpc may be due to the contribution of the optical disk and (with more accurate data) may provide a method of measuring the mass-to-light ratio of the optical disk. *c*, The surface density against radius for M33 as derived from equation (1) using the data of Rogstad *et al.*[6]. The straight line is an exponential with a scale length of 1.1 kpc.

is included), and the combined mass of the halo and bulge out to 20 kpc is 3.1×10^{11} $M_\odot$. If this new rotation curve is used to recompute the halo component in the Caldwell–Ostriker model (leaving their bulge and disk parameters fixed), we find that the fraction of the gravitational force due to the halo at R_0, 1.5 R_0 and 2 R_0 is 17, 42 and 64%, respectively.

Next, we examine the galaxy NGC2841, which has been observed by Bosma[5]. Figure 1*b* compares the surface density of neutral hydrogen with the surface density derived from the observations of the amplitude of the warp, normalized to the *HI* surface density in the outer parts. (All distances in NGC2841 assume $H_0 = 75$ km s^{-1} Mpc^{-1}.) If there is no systematic variation of the mass-to-light ratio with radius in the observed optical disk and the mass-to-light ratio is less than 6 (twice the values obtained from stellar population models[19]), the surface photometry[20] suggests that the density of the optical disk is negligible in the region from ~20 to 30 kpc; this allows the normalization of the derived density from the warp to the *HI* surface density in the outer parts. However, the optical disk may be the source of the extra mass at radii less than 20 kpc. In any case, the agreement in the range ~20–35 kpc indicates that the *HI* surface density dominates the total surface density in this region. This is only ~1% of the local surface density needed to maintain the observed flat rotation curve[5], which implies that the mass density of the halo is inversely proportional to the square of the distance, as may be derived from the rotation curve in this region.

Although the bending wave results were derived with the assumption of small inclinations in the warp, it is encouraging that the theory gives a fairly reasonable description of the large inclinations in galaxy M33 (ref. 6). The derived density profile for M33 is shown in Fig. 1*c*. We calculate a scale length of 1.1±0.1 kpc, whereas the photometry yields a value of 1.6 kpc (ref. 21). This discrepancy might be attributed to the high degree of nonlinearity in the bend (the inclination angle of disk changes by 40° in the region from 5 to 9 kpc), but we feel that it is just as likely to be a problem in the photometry. The value of 1.6 kpc quoted by Freeman assumes an angle of inclination with respect to the sky of $i = 55°$, whereas Rogstad *et al.*[6] found $i = 50°$ and Sandage and Humphreys[14] found $i = 40°$, resulting in scale lengths of 1.4 kpc and 1.2 kpc, respectively. Furthermore, our length scale is derived from the radio data where the warp of the disk has been taken into account[6] in deriving the disk inclination as a function of radius. There, effects have not been included in the photometric determination of the length scale optical disk, which is observed to be warped in a manner consistent with the radio data[14]. Given these effects, our derived length scale of 1.1±0.1 kpc is quite reasonable.

For galaxies such as NGC2841, it may be possible with better data to measure a mass-to-light ratio in the disks of external galaxies using the bending wave theory. This measurement makes possible a computation of the core radius of the halo component, an important parameter for constraining theories of its origin and composition[22]. This is possible if the warp is measured over a range where it samples the mass distribution of the optical disk, and extends out to the region where the *HI* surface density dominates and provides the normalization. This project is ideally and uniquely suited for study with the VLA telescope, when accurate 21-cm line observations become possible.

Identification of the anomalous 26.131-MHz nitrogen line observed towards Cas A

David H. Blake*, Richard M. Crutcher† & William D. Watson‡

* Electrical Engineering Department, University of Illinois
† Astronomy Department, University of Illinois
‡ Physics Department and Astronomy Department, University of Illinois, Urbana, Illinois 61801

Konovalenko and Sodin[1] recently reported the detection of an absorption line at a frequency of 26.131 MHz towards Cassiopeia A and attributed the line to the 26.127 MHz $F = 5/2 \rightarrow 3/2$ hyperfine transition of ^{14}N. The difference in frequency corresponds to a radial velocity of -40 km s^{-1}, which is compatible with the mean velocity of the Perseus arm H I absorption lines seen towards Cas A. However, to explain the strength of the line, Konovalenko and Sodin require $(N/H) = 8\times10^{-3}$ compared with the cosmic ratio of 1.2×10^{-4}. An anomalous abundance of this magnitude would have substantial impact on ideas about galactic nucleosynthesis. We suggest here that the line is a 631α recombination line due to neutral atoms of heavy elements—either carbon atoms in the H I clouds or possibly heavier atoms (Mg, Ca, Fe) in hot ($\sim10^4$ K) ionized gas along the line of sight to Cas A.

The C631α line lies at 26.126 MHz and the analogous lines of the heavier elements lie at 26.127 MHz. Because of the broadness of the observed line ($\sim$2 kHz), a unique line identification cannot be made on the basis of frequency alone. Radio recombination lines are normally seen in emission and not absorption. We discuss below how absorption can occur for transitions of very large principal quantum number n.

First consider carbon atoms in diffuse clouds. The strength of a recombination line will be:

$$T_L = \tau T_c(T_{ex}/T_c - 1)$$

where τ is the optical depth, T_{ex} is the excitation temperature, and T_c is the brightness temperature of the background continuum source. The optical depth is given by:

$$\tau = 1\times10^7 (f/n) b T_{ex}^{-1} T_k^{-3/2} \exp(157{,}800/n^2 T_k) E/\Delta\nu$$

where f is the oscillator strength ($f = 120$ for $631\alpha^2$), E (cm^{-6}pc) is the emission measure, $\Delta\nu$ (s^{-1}) is the linewidth, T_k is the electron kinetic temperature and b is the departure coefficient from local thermodynamic equilibrium (LTE). For the levels of interest, b is close to unity.

As carbon is primarily singly ionized in H I clouds, we use

$$E = \int n_e n_{C^+}\, dl = \overline{n_e} N_H(C/H),$$

where we will assume the cosmic abundance value $(C/H) = 3.7\times10^{-4}$. Neutral atomic hydrogen in the direction of Cas A has been studied by Griesen[3]. Using data of high spatial and velocity resolution he found H I column densities between 3 and 6×10^{21} cm^{-2}. Using these values for the H I column densities rather than the lower resolution data of Shuter and Verschuur[4], the N/H values required by Konovalenko and Sodin's interpretation range from 5 to 2.6×10^{-2}. Molecules such as H_2CO (ref. 5) and CO (ref. 6) have also been detected in this direction, indicating that there are diffuse clouds along this line of sight. Assuming that all electrons come for carbon we find $n_e = 0.1$ for a cloud of density 300 cm^{-3}. This yields $E = 0.07$ cm^{-6} pc for a H I column density of 5×10^{21} cm^{-2}. If the C631α line is formed in LTE at a temperature of 50 K then $S = 110\ E = 8$ s^{-1}. This compares well with the value of 6 s^{-1} reported by Konovalenko and Sodin. The following more detailed discussion is necessary to establish the plausibility of an excitation temperature near the LTE value.

At very large n, T_{ex} must approach T_k because the cross-sections for electron collisions which change n become large (proportional to n^6 in the regime of interest). For lower (but still large) n, the galactic radiation field becomes important in determining T_{ex}. At still lower n, these processes dominate less strongly and the excitation temperatures tend to become negative. The available calculations[7,8] extend only up to $n = 500$, but extrapolation to $n \simeq 631$ suggests that collisions and the galactic background control the excitation temperature provided the electron density exceeds 0.1 cm^{-3}. In this limiting case we have for $n \sim 631$:

$$T_{ex}^{-1} = (R/T_r + C/T_c)/(R + C)$$

Here, T_r is the brightness temperature of the galactic background, R is the absorption or stimulated emission rate ($R = 500$ s^{-1} for $T_r = 10^4$ K), and C is the rate for $n = 631 \rightarrow 632$ collisional excitations ($C = 1{,}670$ s^{-1} for $n_e = 0.1$ cm^{-3})[9]. For $T_k = 50$ K, $T_r = 10^4$ K and $n_e = 0.1$ cm^{-3}, the above equation yields $T_{ex} = 65$ K and the line will be in absorption against the hot ($T_c > 10^4$ K) background of Cas A. Using $T_{ex} = 65$K and $T_k = 50$K, we predict an integrated line strength of 6 s^{-1}, in agreement with the observed value.

The excitation temperature may be lowered and the line strength increased by the influence of a dielectronic-like recombination process involving the fine-structure states of ionized carbon. This effect has been incorporated into level population calculations for $n \leq 200$ (ref. 10) and shown to produce departure coefficients that can exceed unity for $n \sim 200$. At certain larger values of n, the derivative of the departure coefficients will then be negative, and the excitation temperatures will, therefore, be small and positive.

A remaining question is whether the expected breadth of the C631α line is compatible with that of the observed line. At typical cloud temperatures, and for $n_e > 0.03$ cm^{-3}, broadening by electrons dominates that due to other processes. We utilize the method of Griem[11] but use the more recent cross-sections of Gee *et al.*[9] for the n-changing collisions which are the dominant cause of broadening. The FWHM is:

$$\Delta\nu_e = \frac{1}{2\pi}\sum_{n'\neq n}\langle v\sigma(n\rightarrow n')\rangle n_e$$

$$\simeq 200\ \text{Hz}\ (n_e/0.03\ \text{cm}^{-3})(T_k/50\ K)^{3/2}.$$

Therefore, $n_e \leq 0.3$ cm^{-3} is compatible with the observed 2-kHz linebreadth.

The fact that the C631α line agrees so well in frequency, strength, and linewidth (without assuming any anomalies in abundance, excitation or other conditions) with the observations leads us to believe that it is the most likely identification for the 26.131-MHz line towards Cas A.

The physical processes relevant for the alternate possibility—that the line is due to heavier atoms in hot, ionized gases—have been analysed by Shaver[12] in a differerent context. At the higher temperatures, dielectronic recombination produces large population enhancements in the high Rydberg levels. The populations reach a peak at $n \sim 200$ and decline towards the LTE values for larger n. Very low, but positive, excitation temperatures then occur for $n \sim 631$ and will produce an absorption line when observed towards a strong ratio source. For $N_H = 10^{21}$ cm^{-2}, $n_e = 0.1$ cm^{-3} and cosmic abundance, Shaver's calculations indicate that an absorption line near the observed strength towards Cas A would be produced by a blend of Ca, Mg and Fe.

Collisions with electrons also dominate line broadening in this case. From Brocklehurst and Leeman[13] we take for temperatures near 10^4 K,

$$\Delta\nu = 30\ \text{Hz}\ (n_e/0.1\ \text{cm}^{-3})(10^4\ K/T_k)^{1/2}$$

hence, $n_e \leq 5$ cm^{-3} is compatible with the observed breadth.

Our suggestion that the line of Konovalenko and Sodin is a recombination line can easily be tested by searching for the 630α or 632α lines. ●

Electromagnetic spectral determination of the material composition of penetrable radar targets

G. C. Gaunaurd & H. Überall*

Naval Surface Weapons Center, R-31 White Oak,
Silver Spring, Maryland 20910

The resonance theory of scattering, recently developed for the diffraction of acoustic and elastic waves[1], is applied here to radar backscattering from penetrable targets in an attempt to solve the inverse scattering problem. This means the extraction of sufficient material-composition information from the electromagnetic scattering amplitudes of the returned echoes, to permit target identification. We illustrate the principle for the case of a conducting spherical target coated with a dielectric layer. The principle of our method is to use the resonances contained in each of the partial waves making up the radar cross-section for material characterization purposes. We demonstrate that in the high frequency region, the spacing between consecutive overtones becomes uniform, and is related to the dielectric constant of the coating. The width of these overtones is proportional to the coating thickness. The resonances, therefore, make up a code that we have deciphered to solve an inverse scattering problem for penetrable radar targets of known shape, but unknown material composition.

The electromagnetic situation described here is analogous to the elastic case we considered earlier[2] where the material composition of fluid fillers contained within cavities in elastic solids, was determined from the resonances in the elastic echoes returned by the filled cavity, as analysed in the light of the theory of resonance scattering[1].

Figure 1 shows a spherical conducting core covered with a layer of dielectric material of dielectric constant ε_1 and thickness δ which is illuminated by an incident plane wave of propagation constant $k_0 = \omega/c_0$. The far-field amplitude of the scattered electric field is given by[3]

$$\vec{E}_{sc} = E_0 \frac{e^{ik_0 r}}{r}\left[\hat{\varepsilon}_\theta S_1(\theta)\cos\phi - \hat{\varepsilon}_\phi S_2(\theta)\sin\phi\right] \qquad (1)$$

where

$$S_1(\theta) = -i\sum_{n=1}^{\infty}(-1)^n \frac{2n+1}{n(n+1)}\left(a_n \frac{P_n^1(\cos\theta)}{\sin\theta} - b_n \frac{dP_n^1(\cos\theta)}{d\theta}\right) \qquad (2)$$

$$S_2(\theta) = -i\sum_{n=1}^{\infty}(-1)^n \frac{2n+1}{n(n+1)}\left(a_n \frac{dP_n^1(\cos\theta)}{d\theta} - b_n \frac{P_n^1(\cos\theta)}{\sin\theta}\right)$$

and where the 'Mie coefficients' are

$$a_n = -\frac{xj_n(x) - iZ_n(xj_n(x))'}{xh_n^{(1)}(x) - iZ_n(xh_n^{(1)}(x))'}$$
$$b_n = -\frac{xj_n(x) - iY_n(xj_n(x))'}{xh_n^{(1)}(x) - iY_n(xh_n^{(1)}(x))'} \qquad (3)$$

and $x = k_0 a$, where ω is the circular frequency of incident wave; c_0 the light velocity in the outer medium (Fig. 1); c_1 the light velocity in the dielectric coating; θ, ϕ the spherical angles of the observer; $\hat{\varepsilon}_\theta$, $\hat{\varepsilon}_\phi$ the unit vectors in the θ, ϕ directions; E_0 the amplitude of the incident electric field.

Expressions for the modal impedances Z_n and admittances Y_n are given elsewhere[3–5]. The target eigenvibrations correspond to the zeros of the real parts of the denominators of a_n and b_n as follows

$$\frac{1}{iZ_n} = Re\left\{\frac{[xh_n^{(1)}(x)]'}{xh_n^{(1)}(x)}\right\} \quad \text{and} \quad iY_n = Re\left\{\frac{xh_n^{(1)}(x)}{[xh_n^{(1)}(x)]'}\right\} \qquad (4)$$

for the *TE* and *TM* modes, respectively. These characteristic equations can be solved for the real eigenfrequencies $x = x_{nl}^{TE}$ and $x = x_{nl}^{TM}$, respectively. The electromagnetic resonances are illustrated in Fig. 2 for a perfectly conducting sphere with a dielectric coating of relative thickness $\delta_r = \delta/a = 0.1$, and dielectric constant $\varepsilon_1 = 6$. The backscattering cross-section[3]

$$\frac{\sigma}{\pi a^2} = \left|\frac{2}{ka}\sum_{n=1}^{\infty}(-1)^n(n+\tfrac{1}{2})(a_n - b_n)\right|^2 \qquad (5)$$

is plotted in decibels against $k_0 a$ up to 25. We have identified the numerous rapid oscillations visible in Fig. 2 as *TE* or *TM* resonances by actually solving equations (4), and we have marked them by arrows and denoted them by (nEl) or (nMl) labels, respectively. This figure can be viewed as the 'characteristic resonance spectrum' identifying the target. We have also evaluated numerically some of the partial wave coefficients a_n and b_n which exhibit the (nEl) and (nMl) resonances for a given partial wave index n. For $n = 10$, Fig. 3 presents the *TE* (top) and *TM* (bottom) moduli $(2n+1)/n(n+1)|a_n|$ and $(2n+1)/n(n+1)|b_n|$ plotted against $k_0 a$, clearly exhibiting some of the resonances. Using the known forms for Z_n and Y_n and the asymptotic forms of the Bessel functions we can now solve the inverse scattering problem. We can show that for $x \gg 1$, one has

$$\frac{1}{iZ_n} \rightarrow (\varepsilon_1)^{1/2}\cot k_1\delta \quad \text{and} \quad iY_n \rightarrow -(\varepsilon_1)^{1/2}\tan k_1\delta \qquad (6)$$

where $k_1 = \omega/c_1 = k(\varepsilon_1)^{1/2}$. The asymptotic spacing Δ_l between

---

0028–0836/80/430708—02$01.00

adjacent (*TE* or *TM*) resonances in this limit can be written as

$$\Delta_l \equiv x_{l+1}^{TE,TM} - x_l^{TE,TM} = \frac{\pi}{(1-\gamma)(\varepsilon_1)^{1/2}} \qquad (7)$$

where $\gamma = b/a$. A second equation for the two unknowns Δ_l and γ emerges from a consideration of the resonance widths. Our theory[1] gives these widths (for the *TE*-modes) as follows

$$\tfrac{1}{2}\Gamma_{nl}^{TE} = \lim_{x \to x_{nl}^{TE}} \frac{Im\left\{\dfrac{[xh_n^{(1)}(x)]'}{xh_n^{(1)}(x)}\right\}}{Re\left\{\dfrac{[xh_n^{(1)}(x)]'}{xh_n^{(1)}(x)}\right\} - \dfrac{1}{iZ_n}}(x - x_{nl}^{TE}) \qquad (8)$$

and when this expression is evaluated one halfwidth below any resonance (that is, at $x = x_{nl}^{TE} - \frac{1}{2}\Gamma_{nl}^{TE} \equiv X_{nl}^{TE}$) and we use the asymptotic expansion for the Bessel functions ($x \gg 1$) we find

$$(\varepsilon_1)^{1/2} = \tan\left[X_{nl}^{TE}(\varepsilon_1)^{1/2}(1-\gamma)\right] \qquad (9)$$

Substituting the value of $(\varepsilon_1)^{1/2}$ from equation (7) into equation (9) yields

$$\delta_r = \frac{\delta}{a} = 1 - \gamma = \frac{\pi}{\Delta_l}\cot\left(\pi\frac{X_{nl}^{TE}}{\Delta_l}\right) \qquad (10)$$

Substituting this value of $(1-\gamma)$ into equation (7) finally yields

$$(\varepsilon_1)^{1/2} = \tan\left(\pi\frac{X_{nl}^{TE}}{\Delta_l}\right) \qquad (11)$$

Equations (10) and (11) solve the inverse scattering problem, using our resonance formalism, for the dielectric constant and the thickness of the coating, from the uniform spacings Δ_l and widths X_{nl}^{TE} of the resonances in the high frequency region of the resonance spectrum.

A similar analysis may be carried out for targets of general shape but unknown composition. Shape information may be obtained, as in the case of nuclear photon scattering[6] from the splitting and relative weights of the resonances. The resonance frequencies of a penetrable prolate spheroidal target, for instance, are split into two different sets $f_{nm}^{(l)}$ and $f_{nm}^{(s)}$, corresponding to standing waves along a long or a short axis, respectively, with $f_{nm}^{(l)} < f_{nm}^{(s)}$. These two sets may be experimentally separated as follows. An incident polarized or unpolarized wave travelling along the long axis will excite only the $f_{nm}^{(s)}$ resonance. A wave incident along a short axis will excite the $f_{nm}^{(l)}$ or $f_{nm}^{(s)}$ resonances, depending on whether it is polarized either along the long or the short axis, respectively; if the wave is unpolarized it will excite both with equal weights. Incidence along any other direction will produce excitation of both sets of resonances with weights depending on the direction of incidence. This allows the lengths of the two axis and the target orientation to be determined. If both the shape and the composition of the target are unknown, these two types of analysis have to be combined.

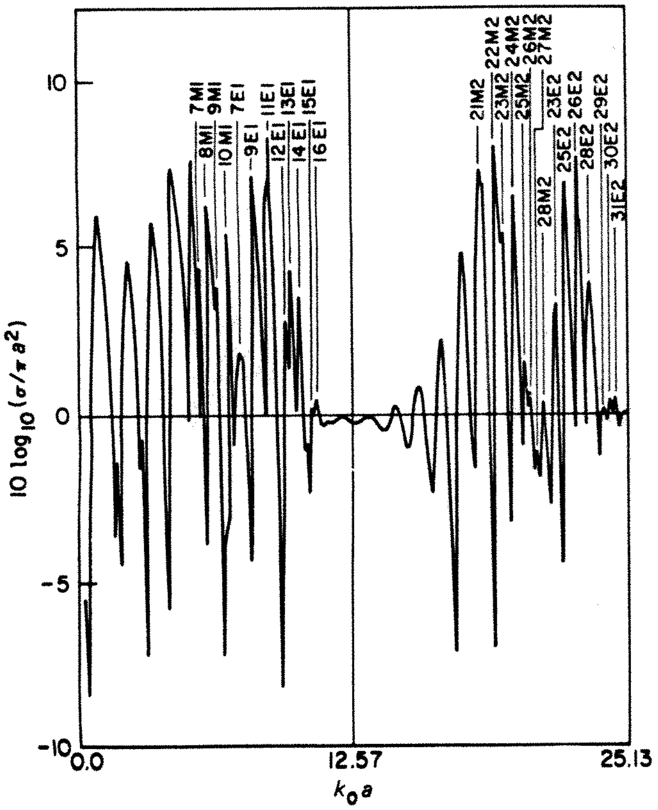

Fig. 2 Radar cross-section (in db) against k_0a for the coated target in Fig. 1 with $\varepsilon_1 = 6$ and $\delta_r = 0.1$. Numerous *TE* and *TM* resonances are identified and labelled using our theory[1].

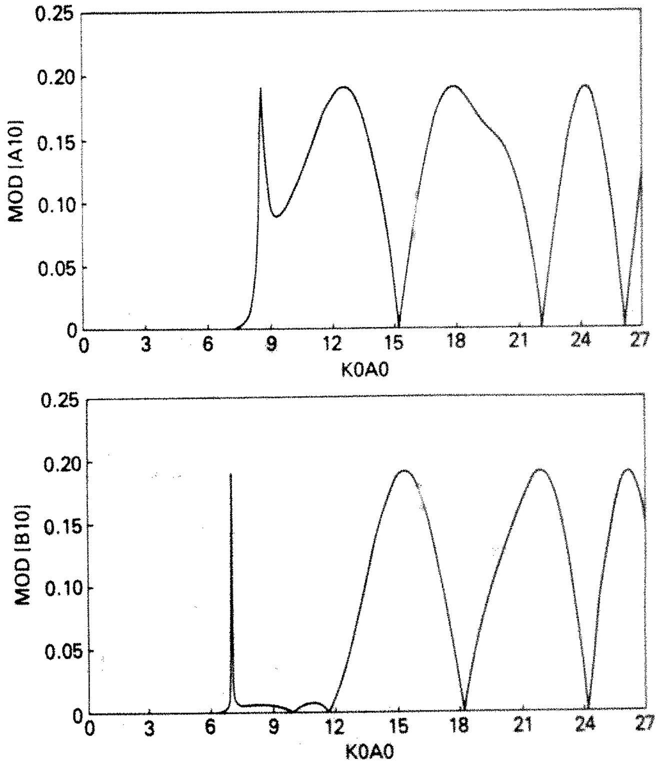

Fig. 3 Typical ($n = 10$) *TE* (top) and *TM* (bottom) partial-wave amplitude contained in the cross-section, clearly showing some of the resonances labelled in the (summed) radar cross-section of Fig. 2.

General areas where our resonance method of target characterization can be applied aside from radar backscattering have been given elsewhere[1,2]. Examples include the identification of radar targets (such as aircraft types) or of sonar targets (such as types of submerged objects); the identification of mineral or natural gas deposits in seismic prospecting; the characterization of flaws in elastic media by non-destructive evaluation, or of tumours in animal tissue (medical ultrasonics); or in the acoustic design of underwater sound absorbers, among others.

We conclude from the above example that the presence of resonances in the backscattered (radar) cross-section of simple targets can be used to solve material characterization problems in the light of the resonance theory of scattering as recently derived by us[1]. This example could be used as the start of a new scientific discipline of electromagnetic spectral analysis for more complex objects.

Ground-based measurements of atmospheric NO_2 by differential optical absorption

B. B. McMahon & E. L. Simmons

Meteorological Office, Bracknell, Berkshire RG12 2SZ, UK

Nitrogen dioxide is important to stratospheric ozone chemistry[1]. The few observations of vertical distribution of the gas are reviewed elsewhere[2]. Most available data relate to ground-based measurements of the total amount in the vertical column. Such observations are ideally made from a high altitude site to avoid local tropospheric sources. Noxon[3] observed a mean value of 5×10^{15} molecules cm^{-2} from Fritz Peak Observatory. Pommereau and Hauchecorne[4] obtained much higher values, of a few $\times10^{17}$ molecules cm^{-2}, at Haute-Provence Observatory. Noxon *et al.* have reported latitudinal gradients[5,6] and response to stratospheric warmings[7], reporting stratospheric column values in the range $1-5\times10^{15}$ molecules cm^{-2}. During the past year, several series of observations have been made from a low altitude rural site in the UK. Values obtained for the vertical column were in the range $0.8-5.6\times10^{16}$ molecules cm^{-2}. In view of the tropospheric contribution expected at this site[8], these values represent an upper limit to the stratospheric NO_2 column and we show here that the values reported by Pommereau and Hauchecorne were anomalously high.

The technique[3,4,9] used exploits characteristic structure in the absorption cross-section of NO_2 in the spectral range 435–450 nm. Series of direct solar spectra were obtained on clear mornings from sunrise until noon, using a grating monochromator to scan repetitively across this range with 0.5 nm resolution. Partial compensation for changes in atmospheric turbidity during scanning was achieved by normalizing each spectral channel output with respect to a simultaneous broadband solar luminance signal. The ratios were recorded digitally for subsequent computer analysis. A spectrum recorded at high solar elevation near midday, when slant-path NO_2 should be at a minimum, was used as a reference. The difference between the logarithm of each individual spectrum and the logarithm of this reference spectrum contains the information needed to derive the difference in slant-path NO_2. Care was taken to compensate for wavelength drifts in the monochromator which, because of pronounced solar Fraunhofer structure in the observed spectral range, lead to spurious features in the difference spectra. Difference spectra were corrected for attenuation by atmospheric Rayleigh scattering and by ozone, the latter based on the total ozone amount for the day measured at the same site with a Dobson spectrophotometer. Possible water vapour absorption channels[10] were omitted from the analysis.

Attenuation due to particulate scattering may be assumed to vary linearly with wavelength[11–13] over the narrow spectral band used. A straight line was fitted to every difference spectrum by the least squares method and the deviation from this line was used as the corrected (difference) spectrum. Corrected spectra were regressed against a spectrum of NO_2 absorption also expressed as a deviation from the best fit line. The shape of this spectrum was determined using the same monochromator and spectral resolution with a carefully purified NO_2 sample, but was quantified by comparison with the absorption coefficients tabulated by Wilkerson *et al.*[14]. Regression coefficients thus calculated correspond to the difference in slant-path NO_2 between the times of each solar spectrum and the reference spectrum. A typical series of corrected spectra are shown in Fig. 1, in which successive spectra have had their origin shifted obliquely with respect to the first by an amount proportional to the time difference; the lowest curve is the NO_2 absorption spectrum. The resemblance confirms that NO_2 absorption is being observed. Some of the uncertainty associated with recognizing particular dips and peaks in the attenuated solar spectra[5,9] is avoided by making full use of the spectrum in this way. Full details of the technique will be published elsewhere.

Differences in slant-path NO_2 relative to the reference, were plotted against the atmospheric mass number, μ, given by the secant of the solar zenith angle at an assumed height for the centre of mass of the NO_2 distribution. Figure 2 is an example of such a 'quasi-Langley' plot, derived from the spectra in Fig. 1. If the NO_2 is constant in time and uniform horizontally, and the assumed height is correct, then the quasi-Langley plot should be a straight line with slope equal to the vertical NO_2 column. Rapid photolysis of NO_2 is believed to occur at sunrise, followed

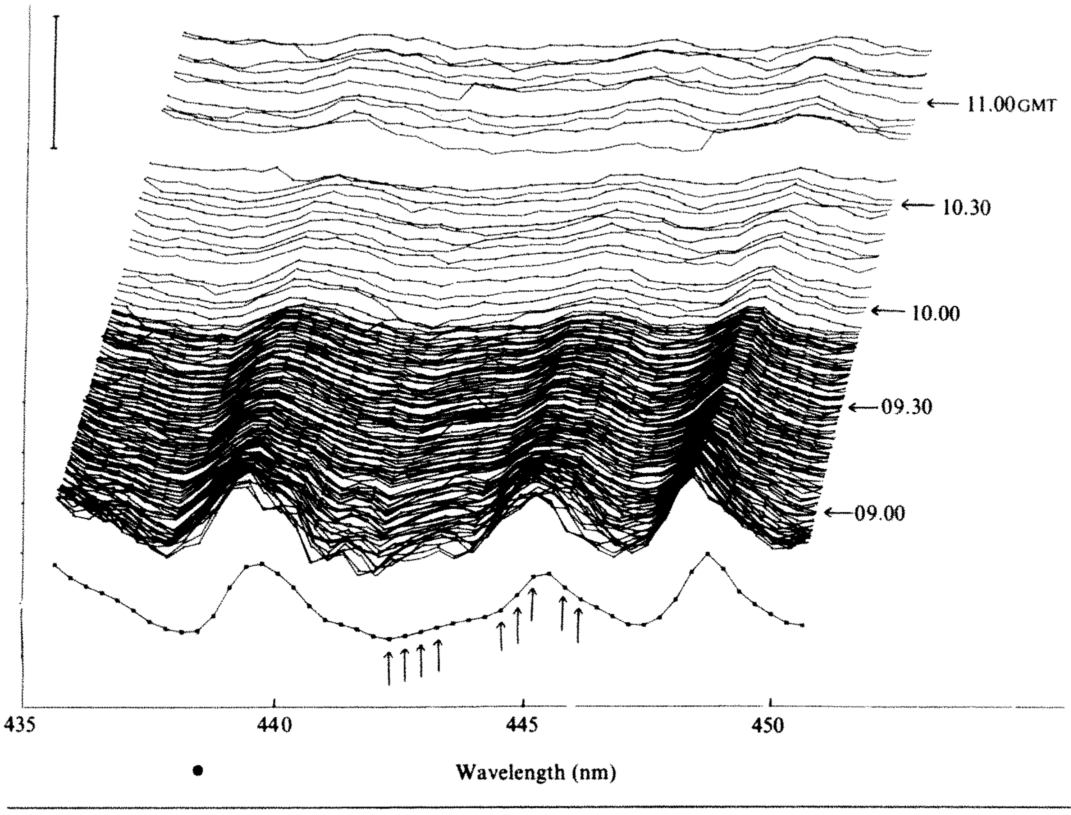

Fig. 1 Corrected spectra obtained using 21 December 1979 solar spectra. The bottom curve represents the NO_2 absorption spectrum used in the regression calculations, after suitable scaling to assist visual comparison with the corrected spectra. Solar spectra span the period 08.52–11.16 GMT on 21 December 1979; sunrise was at 08.06 GMT. Scale bar, optical depth of 0.1, relative to the reference. Note that the amplitudes of differential absorption decrease with time, indicating decreasing slant-path NO_2 during the morning. The smooth appearance of these spectra imply that good wavelength alignment of the solar spectra with the reference spectrum has been achieved. Arrows mark channels omitted from the analysis because of their susceptibility to H_2O absorption.

by a gradual increase in the daytime abundance due to slow N_2O_5 photolysis. Theoretical studies[15] of these processes predict that, by surface sunrise, the effect on slant-path NO_2 due to changes in the vertical NO_2 abundance is small compared with the effect of decreasing slant path, justifying the assumption of constant NO_2 at this time. However, because the above effects are predicted to become comparable near midday, solar spectra obtained within an hour of midday were ignored. Changes in slope were occasionally observed at relatively low μ-values, for which μ is insensitive to the assumed centre-of-mass height. This implies that significant advective changes in the NO_2 column were taking place, probably in the troposphere, which can lead to misinterpretation of the slopes. Consequently only those mornings were accepted on which the slope was essentially linear over a μ-range of at least 3. As our objective was to set an upper limit to the stratospheric NO_2 column, a stratospheric value[5] of 26 km was assumed for the centre-of-mass height. During episodes of high boundary-layer NO_2 this height would be much lower, so that our assumed mass numbers will be too low and our tabulated values will be an overestimate of the NO_2 vertical column. This source of bias error, which increases at low solar elevation, has been kept below 20% by ignoring solar spectra obtained at μ greater than 7. Noxon avoids this difficulty by using his twilight zenith sky technique[5]. We have not used this technique as we are not satisfied that in our viewing conditions it will yield valid results.

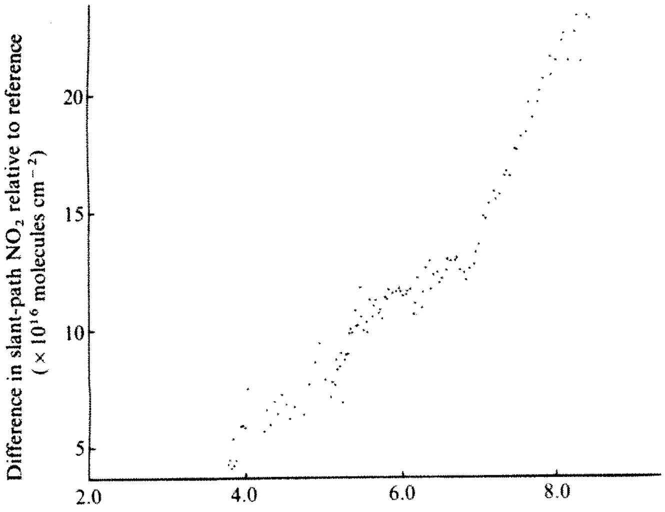

Fig. 2 Quasi-Langley plot for the corrected spectra of Fig. 1. Sunrise corresponds to $\mu = 11.1$. Some of the scatter in the points may be due to horizontal advection of boundary-layer NO_2 but the greater scatter exhibited towards midday (which was often found) may also be due to vertical convection of boundary-layer NO_2.

Estimates of the total NO_2 which were obtained, meeting the above criteria, are presented in Table 1, together with the μ-ranges and corresponding time intervals over which they were evaluated. Values are in the range $0.8\text{–}5.6 \times 10^{16}$ molecules cm^{-2}, which compare with Noxon's[3,5] findings of a mean total column value of 0.5×10^{16} molecules cm^{-2} and a mean stratospheric column value of around 0.25×10^{16} molecules cm^{-2}. If we subtract this stratospheric value from our totals and assume that the difference is uniformly mixed throughout a surface layer 1 km thick, then the mixing ratios are in the range 2–25 p.p.b. (parts per 10^9). These are within the range of surface mixing ratios (1–34 p.p.b.) reported[8] at Harwell which is less than 50 km from our measurement site. Noxon's relatively low total column value is understandable in view of the smaller tropospheric NO_2 component expected at his Fritz Peak site (3,000 m a.m.s.l.). However, it is difficult to explain the high values of a few 10^{17} molecules cm^{-2} reported by Pommereau and Hauchecorne[4], who observed from Haute-Provence Observatory (651 m a.m.s.l.).

Table 1 Values of the total vertical NO_2 column at Beaufort Park, Bracknell, Berkshire (51°23′ N, 0°47′ W, 70 m a.m.s.l.)

Date	Time interval (GMT)	μ-range	Total NO_2 estimated from slope (10^{16} molecules cm^{-2})
6 September 1979	06.10–08.39	1.9–7.0	0.9 ± 0.2
5 November 1979	07.56–08.57	4.0–7.0	0.9 ± 0.3
9 November 1979	08.07–10.44	2.8–6.8	0.9 ± 0.2
21 December 1979	09.11–10.58	3.9–7.0	3.0 ± 0.6
2 January 1980	09.13–10.03	4.0–7.0	1.9 ± 0.8
24 January 1980	09.01–11.12	3.1–6.4	1.7 ± 0.9
4 March 1980	07.29–08.40	3.4–7.0	5.6 ± 0.8
22 March 1980	07.01–08.31	2.6–5.8	0.9 ± 0.1
30 March 1980	07.47–10.00	2.0–5.5	$0.8 + 0.8 - 0.2$
20 April 1980	05.44–06.56	3.0–7.0	1.9 ± 0.4

The present apparatus and method of analysis have demonstrated the possibility of measuring the NO_2 total column at a site not having the best of viewing conditions, and have given some support to the relatively low values of NO_2 column reported by Noxon. A spectrophotometer system optimized for this type of measurement is being considered which could be used at a site well removed from continental tropospheric NO_2 sources.

A modified diabatic circulation model for stratospheric tracer transport

J. A. Pyle & C. F. Rogers

Department of Atmospheric Physics, University of Oxford,
Clarendon Laboratory, Parks Road, Oxford OX1 3PU, UK

The possible modifications of the ozone layer by various pollutants has created considerable interest in modelling of stratospheric minor constituents. A major limitation of such modelling work has been the treatment of eddy processes in one- and two-dimensional models. We now describe a two-dimensional model in which some problems associated with the cancellation of the mean and eddy terms in the species continuity equation are removed. If the eulerian mean meridional circulation is replaced by only that part of the circulation driven by the diabatic heating, part of the eddy transport term disappears, although the part associated with the chemistry of the transported species[1,2] must still be considered. The model explains the results of Prabhakara[3] who successfully used a modified diabatic circulation plus Fickian diffusion to model atmospheric ozone.

0028-0836/80/430711—04$01.00

In the usual eulerian mean approach zonal averages are taken at fixed points in space, defining a latitude–height grid. Thus, with $\overline{(\ )}$ the zonal eulerian mean operator $= 1/2\pi \int_0^{2\pi} (\ )\,d\lambda$, λ = longitude, and $(\ )'$ perturbation from the zonal mean, any variable χ can be written $\chi = \bar{\chi} + \chi'$. The zonally averaged continuity equation then contains terms involving just the zonal means and other terms (the eddies) involving zonal averages of the perturbation quantities. It has often proved useful to regard the stratosphic circulation as being composed of a zonally symmetric circulation plus eddies, or waves. The two-dimensional eulerian mean continuity equation for a species of mixing ratio χ is written

$$\frac{\partial \bar{\chi}}{\partial t} + \bar{v}\frac{\partial \bar{\chi}}{\partial y} + \bar{\omega}\frac{\partial \bar{\chi}}{\partial p}$$
$$= -\frac{1}{\cos\phi}\frac{\partial}{\partial y}(\overline{v'\chi'}\cos\phi) - \frac{\partial}{\partial p}(\overline{\omega'\chi'}) + \bar{S} \qquad (1)$$

where the first two terms on the right-hand side represent the eddy transport of χ. The velocities v and ω are in the y (northward) and p (pressure) coordinate directions respectively, ϕ is the latitude and $\bar{S}$ represents the net sources and sinks of χ.

The treatment of the eddy transport in equation (1) has traditionally followed the procedure of Reed and German[4] where the fluxes are written in terms of the mean gradients

$$\begin{aligned} \overline{v'\chi'} &= -K_{yy}\frac{\partial \bar{\chi}}{\partial y} - K_{yp}\frac{\partial \bar{\chi}}{\partial p} \\ \overline{\omega'\chi'} &= -K_{py}\frac{\partial \bar{\chi}}{\partial y} - K_{pp}\frac{\partial \bar{\chi}}{\partial p} \end{aligned} \qquad (2)$$

with $K_{yp} = K_{py}$. Equation (2) is then used for all quasi-conservative tracers with the same set of K values, generally derived from atmospheric statistics on rather shaky assumptions. Luther[5], for example, has determined Northern Hemisphere monthly mean values of K from heat flux data, and they have been widely used in modelling studies.

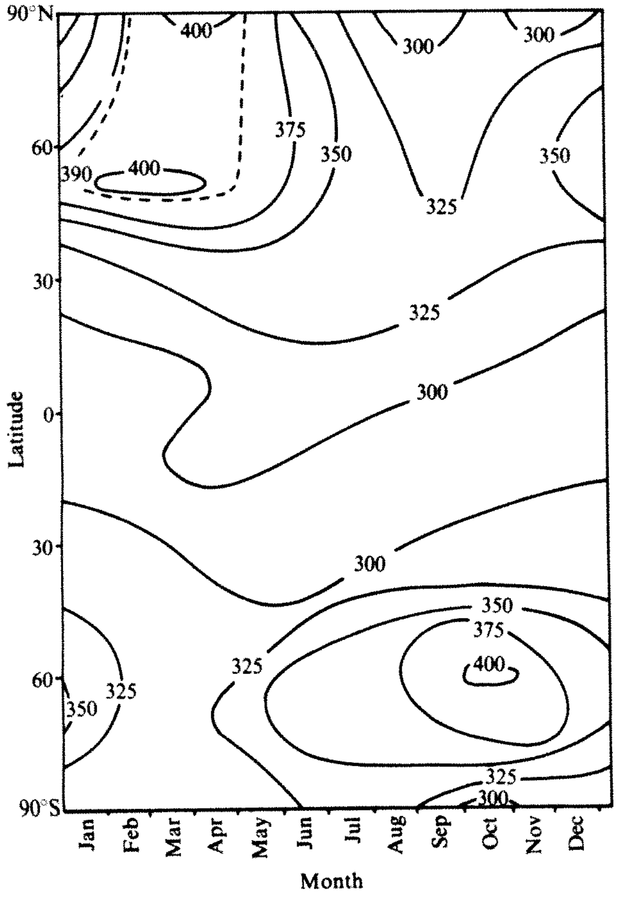

Fig. 1 Latitude–time section of total ozone (m atm-cm) from experiment 1.

Recent work has suggested improvements to two-dimensional models by using a more physically based K-theory[1,2,6–8]. By coupling a calculation of planetary wave propagation with solutions of the species perturbation continuity equation. We[2] have calculated tracer eddy fluxes and hence computed K fields. Of particular interest is that K varies between species, depending on their photochemical lifetimes. Matsuno[1] separated the K values into

$$\text{an anti-symmetric} \quad \begin{pmatrix} 0 & K'_{yp} \\ K'_{py} & 0 \end{pmatrix}$$

$$\text{and a symmetric} \quad \begin{pmatrix} K^{R}_{yy} & K^{R}_{yp} \\ K^{R}_{py} & K^{R}_{pp} \end{pmatrix} \quad \text{component.}$$

Note that $K'_{yp} = -K'_{py}$ but that $K^{R}_{yp} = K^{R}_{py}$. When the photochemical source is relatively weak, as, for example, with ozone in the lower stratosphere, the anti-symmetric component is independent of the species being transported, depending just on the wave structure: it is applicable to steady, conservative waves and an inert tracer. For photochemical tracers there is the additional symmetric component which depends on the photochemical lifetime, as well as the wave structure, and is, therefore, different for different species. Note that the symmetric component is large and can play a significant role. Matsuno[1] estimated that the anti-symmetric component dominated, but this was due to his choice of 100 days as a species lifetime.

A new approach to studies of tracer transport using a lagrangian framework has been suggested[9,10] in which the eddy terms apparently need not be calculated. Considering equation (1), in practice the mean and eddy flux terms almost cancel so that the small residual of two large terms must be found. The reasons for the cancellation are well understood in general theoretical terms[1,6–13]. For steady, non-dissipating waves (the eddies), an eulerian mean meridional circulation is induced which just cancels the effects of the eddies on the mean state. If, however, we consider a lagrangian description, the species continuity equation becomes particularly simple and no eddy terms appear:

$$\frac{\partial \bar{\chi}^{L}}{\partial t} + \bar{v}^{L}\frac{\partial \bar{\chi}^{L}}{\partial y} + \bar{\omega}^{L}\frac{\partial \bar{\chi}^{L}}{\partial p} = \bar{S}^{L}$$

where $\overline{(\ )}^{L}$ is some lagrangian average. (In a simple case this could be an average following an air parcel. Thus in a lagrangian frame we move with the flow; in a eulerian frame we observe the flow from a fixed point.) The problem now becomes one of finding $\bar{v}^{L}$ and $\bar{\omega}^{L}$ (and $\bar{S}^{L}$) rather than the eddies. Dunkerton[9] has identified the lagrangian mean circulation with that driven by the eulerian mean diabatic heating. Using the same approximations we can identify a 'residual meridional circulation' (the difference between the eulerian circulation and that part induced by the steady, non-dissipating waves)[13] as that circulation driven by the diabatic heating.

The cancellation of the eddy terms in equation (1) by an induced mean circulation is only exact in the case of steady waves, with no dissipation, away from critical lines and for an inert tracer. In these circumstances a mean circulation will be induced which will just cancel the transport modelled by the anti-symmetric K components[14]. There is, however, no cancellation of the chemically induced transport, modelled by the symmetric K values. The symmetric K component can be shown to be equivalent to the Stokes correction to the eulerian mean source, $\bar{S}$, where $\bar{S}^{L} = \bar{S}$ + Stokes correction. Thus in both the eulerian and lagrangian description this chemically induced transport must be considered. This is to be expected as they are simply different descriptions of the same physical process.

The three present model experiments all used the same ozone photochemical scheme but included different descriptions of the dynamical processes. All the experiments were carried out

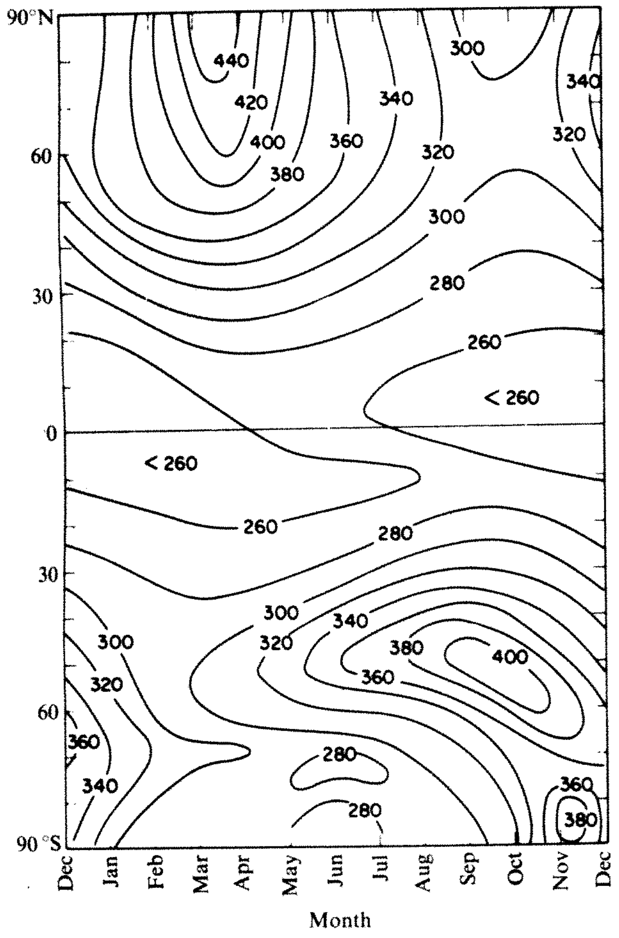

Fig. 2 Observed latitude–time section of total ozone (m atm–cm) after ref. 20.

within the framework of the University of Oxford two-dimensional model[15]. The photochemical scheme[16] included the effects of nitrogen and hydrogen compounds.

Figure 1 is a latitude–time section of total ozone from a run in which precomputed values of $\bar{v}$ and $\bar{\omega}$ were used, with the eddy transport calculated using Luther's[5] values of K. All the species use the same K fields and we assume that $K_{yp} = K_{py}$. Compared with the observed distribution in Fig. 2, Fig. 1 contains several satisfactory features with an equatorial minimum of total ozone and maxima at the spring pole in the Northern Hemisphere and at ~60° S in the Southern Hemisphere about seven months later. This asymmetry is reproduced using observed values of the eddy flux of angular momentum in calculating the $\bar{v}$ and $\bar{\omega}$ fields[17]. Although the broad features of the ozone distribution have been reproduced there are, however, important differences of detail. For example, the equatorial minimum should reach lower values whereas the Northern Hemisphere maximum should possibly be higher. This experiment is a typical example of present eulerian mean two-dimensional models.

In the second experiment the eddies were excluded, in both the calculation of the mean circulation and in the species continuity equations. Thus the calculated circulation is driven just by the radiative heating and the release of latent heat. The radiative heating scheme is described in Haigh and Pyle[18]. In the lower stratosphere, however, Rodgers[19] heating rates are used. The experiment can be considered from two viewpoints. The diabatic circulation can be considered as the residual circulation after the cancellation of the eddies and the ensuing induced circulation. Alternatively, Dunkerton suggested that the mass transport in the stratosphere is accomplished by the lagrangian mean circulation which he identified to a leading order with the eulerian diabatic circulation, which is used here.

Figure 3 shows the latitude–time section of total ozone from the run. The behaviour is mostly poor. Ozone is moved from equatorial to mid-latitudes where the modelled values are too large. The high latitude values, however, are too low, due to lack of eddy transport. Because negative mixing ratios can develop without any diffusion, the experiment was not run to a steady state. However, in a similar study including diffusion, Prabhakara[3] also failed to reproduce the polar maximum with low values of the diffusion coefficients. Maximum values occurred in middle latitudes. Failure to reproduce the observed ozone behaviour in this experiment is evidently not due to the omission of sub-grid scale diffusion.

The omission of eddies in the previous experiment is justified by the cancellation of the eddy circulation and the induced mean circulation. This cancellation does not occur if the waves are growing or decaying, near critical lines or when the tracer being transported is not inert. In a third experiment the uncancelled chemical eddy transport has been modelled. Thus, along with the diabatic circulation, the (chemical) symmetric part of the K-tensor is included. In lagrangian terms, this is equivalent to including the Stokes correction to the eulerian mean source to give the lagrangian mean source. Though we can calculate the symmetric K components[2], for simplicity we have used Luther's values, which are, of course, symmetric. Our calculated K values[2] are roughly similar in magnitude to Luther's values in the winter hemisphere, but much smaller in summer.

The total ozone distribution in this run is shown in Fig. 4. The behaviour is good with both an improved equatorial minimum and Northern Hemisphere polar maximum over those found in the first experiment (Fig. 1). By comparison with Fig. 3, the chemical eddy transport plays a major part in transporting ozone polewards.

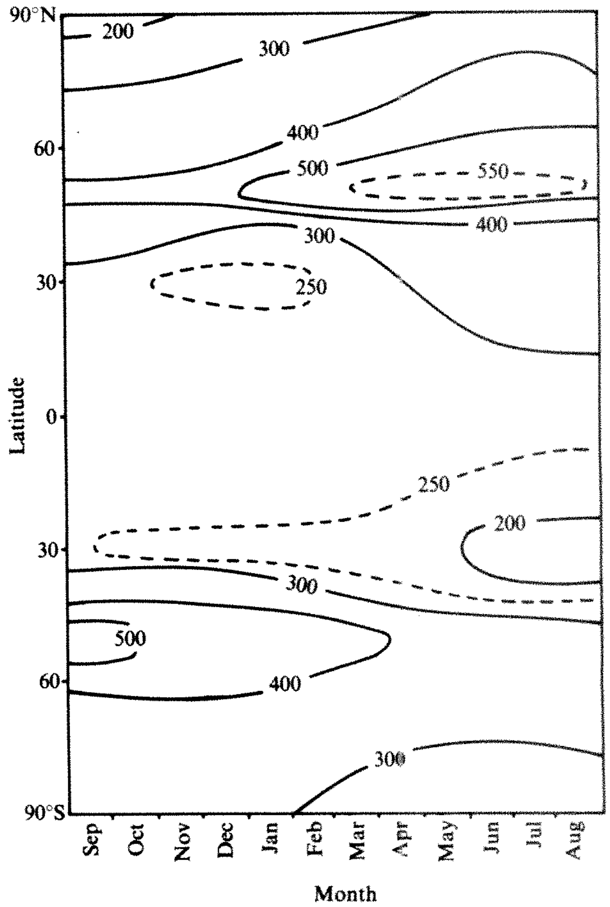

Fig. 3 Latitude–time section of total ozone (m atm-cm) from experiment 2.

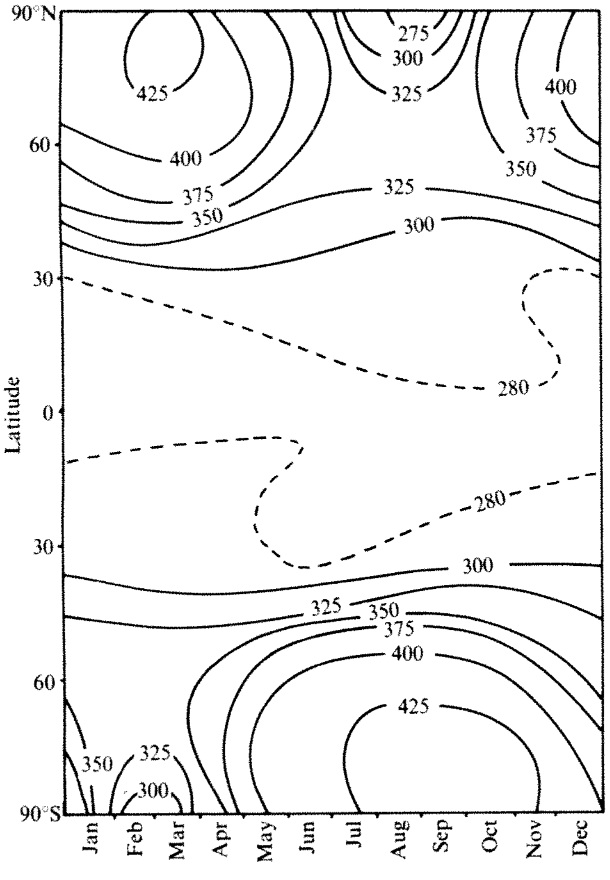

Fig. 4 Latitude–time section of total ozone (m atm-cm) from experiment 3.

The Southern Hemisphere is less well reproduced. Possibly because the eddy activity is less strong in the Southern Hemisphere, the *K* components should, therefore, be smaller there. Certainly the summer *K* in both hemispheres should be smaller than used here. In assessing the performance of the model, remember that *K* ought to vary with the species, whereas here the same *K* has been used for all species.

The above experiment is crude in that the *K* values are not calculated within the model. However, the results are encouraging and attempts at a more self-consistent calculation are in progress. An early indication is that the calculated *K* in winter high latitudes is not sufficient to account completely for the spring build up of ozone and an important role for wave transience is possibly indicated.

An advantage over the usual eulerian models is that the close cancellation between the eddies and the mean motions is removed. In models where the mean circulation is specified, problems of the compatibility of the chosen circulation and the eddy transport coefficients are also partly removed. Another advantage is that experiments with the radiative schemes, including possible perturbation experiments including radiative and hence dynamical feedbacks, are quite simple to perform in this model. Some knowledge of the eddy fields is, of course, still necessary but the model is simpler than the usual eulerian models. Furthermore, note that the cancellation of the eddy terms does not arise when the waves are transient or dissipating. However, because the modelled ozone distribution is quite good it suggests that the chemical eddy contribution may be the most important. Plumb[8] has shown that the tracer fluxes are oppositely directed during the growing and decaying phases of wave development (see also ref. 14). However, in explosive events like the sudden stratospheric warming we do expect wave transience to play a major part.

Finally, the model explains the success of a similar model by Prabhakara[3]. His success in a model which used the diabatic circulation was due to the inclusion of a large diffusion term in the ozone continuity equation. With small values of the diffusion coefficients, the behaviour was similar to that shown in Fig. 3. A good ozone distribution was obtained only with the larger values, comparable with the K_{yy} used in experiment 3. The transport modelled by Prabhakara's larger *K* values was of planetary scale, rather than a sub-grid scale diffusion, and is presumably mainly the chemical contribution discussed above.

The modelling work at Oxford is supported by the NERC.

Chloride ions in aqueous solutions

In spite of much experimental and theoretical work during the past 80 yr, there is at present no generally agreed structural model for concentrated aqueous solutions, even for a relatively simple system like NaCl dissolved in H_2O (ref. 1). Aqueous solutions contain four chemical species and so require 10 pair correlation functions to describe the structure, thus complicating attempts to isolate, for example, ion–water correlations unambiguously from diffraction experiments. The combination of long-range Coulomb potentials, quantum-mechanical hydrogen bonding effects and the intractability of the liquid state has proved an obstacle to theoretical understanding. We have investigated the coordination of water molecules around Cl^- ions in aqueous solution by the isotopic substitution method. A range of counter-ions and concentrations was used to answer questions about the sensitivity of Cl^- hydration to the nature of the counter-ion and the ionic strength. We show here that Cl^- hydration is essentially independent of the cation and of ionic strength with the possible exception of a transition metal counter ion (Ni^{2+}). The insensitivity of Cl^- hydration to cation type should lead to a major simplification in the theory of solutions.

The unique role of neutron diffraction applied to aqueous solutions has been emphasized by two groups[2,3]. Narten *et al.*[2] demonstrated ion–water effects by comparing the neutron and X-ray scattering intensity from solutions of LiCl in D_2O. The Bristol/Leicester group[3–5] emphasized the use of isotopic substitution and showed that the coordination of water molecules around a given ion can be derived unambiguously from the algebraic difference, as a function of momentum transfer, $\hbar k$, of the absolute neutron-scattering cross-sections between two samples identical in all respects except that the isotopic state of the ion has been changed[4]. We have also shown that the recoil corrections which apply to neutron diffraction from aqueous solutions essentially vanish when this difference is used. Using this method the nature of the hydration of Ni^{2+} has been shown[5] to be concentration dependent, an unexpected result.

We now report on an investigation of the Cl^-–H_2O coordination (loosely referred to as hydration) in a range of different ionic solutions (Table 1) to establish the extent to which the geometry of ionic hydration is sensitive to the counter-ion. The parameters which define this geometry are shown in Fig. 1. This sensitivity has long been a controversial matter and has not previously been satisfactorily resolved either by theory[6] or experiment[7]. The experiments were carried out at the ILL Grenoble and a full account of the method has been given elsewhere[4].

For a given solution, two electrolytes $M^{35}Cl_n$ and $M^{37}Cl_n$ are dissolved in (heavy) water. The isotopic substitution made, $^{35}Cl \rightarrow {}^{37}Cl$, changes the Cl scattering length f from 11.7 fm to 3.50 fm. This yields[4] a first-order difference $\Delta_{Cl}(k)$ between two sets of diffraction data given by

$$\Delta_{Cl}(k) = A(S_{ClO}(k)-1) + B(S_{ClD}(k)-1) + C(S_{ClM}(k)-1) + D(S_{ClCl}(k)-1) \qquad (1)$$

where

$$A = \tfrac{2}{3}nc(1-c-nc)\,f_O(f_{Cl}-f'_{Cl})$$
$$B = \tfrac{4}{3}nc(1-c-nc)\,f_D(f_{Cl}-f'_{Cl})$$
$$C = 2nc^2 f_M(f_{Cl}-f'_{Cl})$$
$$D = n^2c^2(f^2_{Cl}-(f'_{Cl})^2)$$

c is the atomic fraction of cations, n is the cation valence and S_{ClO}, S_{ClD}, S_{ClM} and S_{ClCl} represent respectively the partial-structure factors related to chlorine–oxygen, chlorine–deuterium, chlorine–cation and chlorine–chlorine correlations. The numerical coefficients $A \ldots D$ are shown in Table 1 and the method exploits the fact that A and B are much larger than C and D. The Fourier transform of equation (1) yields[4] a weighted radial distribution given by

$$G_{Cl}(r) = A[g_{ClO}(r)-1] + [Bg_{ClD}(r)-1] + C[g_{ClM}(r)-1] + [Dg_{ClCl}(r)-1]$$

where $g_{\alpha\beta}(r)$ is the partial radial distribution function for β ions as seen from an α ion. However, A and B are much greater than C and D and because water is molecular in character, $G_{Cl}(r)$ gives the distribution of water around the Cl^- ion.

The characteristic form for $G_{Cl}(r)$ has been published previously for solutions of NaCl (ref. 4) and $CaCl_2$ (ref. 8) and turns out to be typical for all solutions studied. The significant results from these data are presented in Table 2, from which conclusions about the character of Cl^- hydration can be drawn.

(1) r_{ClO} falls in the range 3.20 ± 0.04 to 3.34 ± 0.04 Å. In general these distances are greater than those found in X-ray studies[7]—a consequence of the inherently poor discrimination of total X-ray patterns from solutions and the need to analyse the data in terms of a rather simple model[9]. They are in excellent

$BaCl_2$	1.10	2.24 ± 0.04	3.26 ± 0.05	–	0–6	6.2 ± 0.4

* Assuming that r_{OD} is 1 Å.

agreement with the recent quantum-mechanical calculation of Clementi *et al.*[10]. r_{ClD} spans the range 2.23 ± 0.02 to 2.29 ± 0.02 Å.

(2) The data favour the D-bond configuration (Fig. 1)[4] but with a tilt angle which is always less than 11°. Clearly the influence of the counter-ion on Cl-hydration is a second-order effect and this explains why it had not been unambiguously identified experimentally. Computer simulations based on the so-called ST2 potential predict significant counter-ion effects. Clearly, this widely used potential function needs critical re-examination and, indeed the alternative 'central force' model is also worth studying[11].

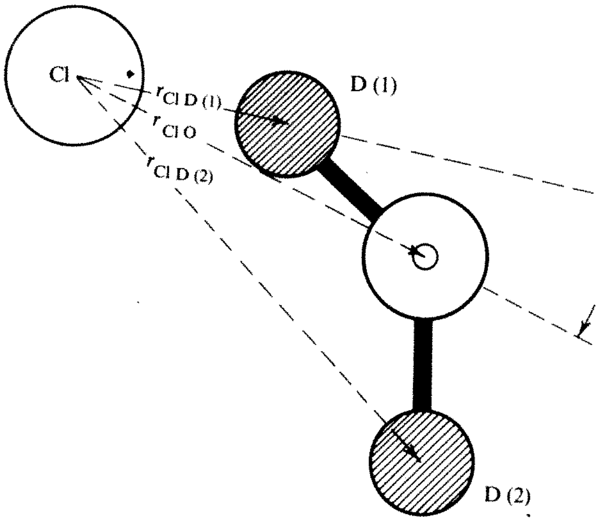

Fig. 1 The geometry of $\mathrm{Cl^-}$ hydration.

(3) The experimental uncertainty in r_{ClD} and r_{ClO} is such that all the solutions, except $\mathrm{NiCl_2}$ at high concentrations, could be characterized by $\psi = 0$. Whether the data for $\mathrm{Ni^{2+}}$ represent a general transition metal counter-ion effect must await further studies involving $\mathrm{Fe^{2+}}$ and $\mathrm{Co^{2+}}$

(4) The coordination number obtained by integrating G_{Cl} (ref. 2) over the first peak cannot necessarily be identified as a 'hydration' number[12]. This is because water molecules are entering and leaving the neighbourhood of a $\mathrm{Cl^-}$ ion on a time scale of $\sim 10^{-12}$ s (compared with cation–water residence times which are often $\sim 10^{-6}$ s (ref. 13) and where the equivalence of coordination and hydration is much clearer). Hence the conclusion that the 'hydration number' for $\mathrm{Cl^-}$ in solution may be concentration dependent needs care. The dynamical aspects of hydration have to be looked at in detail and such an experiment is in progress (Hewish and Howells, personal communication).

We conclude that the counter-ion effects are sufficiently small to be disregarded in a first-order theory and that quantum-mechanical calculations based on a single $\mathrm{Cl^-}$ surrounded by a small number of water molecules are the best guide to ion–water conformations in solution. The possibility that transition metal ions at high concentration may produce measureable counter-ion effects cannot, however, be ruled out.

Chemical alkylation of lead (II) salts to tetraalkyllead (IV) in aqueous solution

I. Ahmad*, Y. K. Chau*, P. T. S. Wong*, A. J. Carty† & L. Taylor†

* Canada Centre for Inland Waters, Burlington, Ontario, Canada L7R 4A6

Methylation of lead in the environment would have serious consequences for water quality and for the well being of aquatic biota. As there is strong evidence that tetraalkylleads, the end products of lead alkylation, are considerably more toxic than lead (II) compounds[1,2], the elevated levels of inorganic lead now present in inland waterways and sediments as a result of industrial and motor vehicle emissions will pose a serious environmental hazard if mechanisms exist for the conversion to alkyllead (IV) species in aquatic systems. In the belief that the key to biological Pb(II) methylation lies in methyl transfer to Pb(II) from a carbonium ion donor (for example, *S*-adenosylmethionine), we recently initiated chemical and biological studies on the reactions of $\mathbf{CH_3^+}$ donors with neutral and anionic Pb(II) compounds. We describe here the unequivocal synthesis of volatile tetramethyllead and other tetraalkylleads from Pb(II) salts and simple chemical reagents in aqueous solution. The known occurrence of methyl iodide in natural waters[3] and our demonstration that $\mathbf{Me_4Pb}$ is readily synthesized from this reagent and Pb(II) salts in aqueous solution could have far reaching significance not only for the chemical synthesis of toxic organoleads but also for possible mechanisms of microbiological methylation.

Since the initial report by Wong *et al.*[4] of microbiological conversion of trimethyllead acetate ($\mathrm{Me_3PbOAc}$) and Pb(II) salts into tetramethyllead ($\mathrm{Me_4Pb}$) in active sediments and by pure strains of bacteria, it has been increasingly accepted that trimethyllead salts can be converted to tetraalkylleads via biological mechanisms in addition to disproportionation reactions (refs 5–8 and P. J. Craig and J. M. Wood, personal communication), even though the latter may be catalysed by the presence of sulphide ion[9]. For inorganic Pb(II), however, several questions concerning the facility and mechanism of the initial step to methylate a Pb(II) species remain unresolved. There are conflicting reports as to whether tetramethyllead can be formed from Pb(II) salts in aqueous systems. A report from Huber's laboratory[7] claimed formation of $\mathrm{Me_4Pb}$ from Pb(II) acetate with microorganisms cultivated in aquarium water, but workers from Ethyl Corporation (J. Bentz, M. Brandt, A. Pallay and G. Ter Haar, personal communication) failed to note increased levels of $\mathrm{Me_4Pb}$ above sediments enriched with Pb(II) nitrate. There was no reported reaction between Pb(II) and methylcobalamin in aerobic or anaerobic conditions[6,9,10]. In contrast, Witman and Weber[11] presented evidence for the demethylation of a synthetic $\mathrm{B_{12}}$ analogue by $\mathrm{Pb(ClO_4)_2 \cdot 3H_2O}$ in 2-propanol, implying synthesis of a transient methyllead (II) species. More recently, Harrison and Laxen[12] observed abnormally high alkyllead/total lead ratios in atmospheric samples in Morecambe Bay, UK, attributing these levels to natural methylation of inorganic lead in coastal/estuarine mud flats. An indirect pointer to the existence of a biological mechanism for Pb(II) methylation is the observation that 10–24% of fish from natural environments contain elevated levels of Me_4Pb in lipid fractions[13,14].

Of the potential mechanisms available for Pb(II) methylation in water, nucleophilic displacement of X^- in PbX_2 (where X is, for example, halide, acetate) by CH_3^- to generate $Me_2Pb(II)$ which could subsequently disproportionate to Me_4Pb and Pb(0) is rendered unfavourable by the extreme hydrolytic instability of Pb(II) alkyls[15]. Electrophilic attack by CH_3^+ on $Pb(II)X_2$ (PbX_3^-) is more attractive but the initial intermediate of the oxidative addition $(MePb(IV)X_2)^+$ has also been presumed unstable because no monomethyllead (IV) compounds have been characterized. Subsequent conversion of monomethyllead (IV) to tetramethyllead (IV) could occur either by disproportionation or by methylation by CH_3^- donors[6]. In our initial experiments we have attempted to demonstrate the feasibility of tetraalkyllead synthesis from simple carbonium ion reagents.

Table 1 Methylation of Pb(II) salts with methyliodide in water

Pb(II) salt	Pb as Me_4Pb (ng) *p*H 5–6	 *p*H 13*
$Pb(OAc)_2 \cdot 3H_2O$	65.4	370.5
$Pb(NO_3)_2$	90.1	176.8
$Pb(ClO_4)_2 \cdot 3H_2O$	72.7	261.9
$Pb(COO)_2$	2.3	147.2

Reaction conditions: lead salts, 1.0 mmol; water, 200 ml; MeI, 0.1 ml; reaction time, 5 days at 19 ± 1 °C.

* *p*H was adjusted by addition of 10 ml of 10% NaOH.

Lead (II) acetate ($Pb(OAc)_2 \cdot 3H_2O$) (1.0 mmol) was dissolved in 200 ml of deionized water in a 250-ml filtration flask fitted with an aluminium foil-wrapped stopper. Methyl iodide (0.1 ml, >1 mmol) was added and the flask was sealed with Parafilm. After 5 days at room temperature the head space gases above the solution were withdrawn through the side arm by means of a peristaltic pump and transferred to a U-tube containing 3% OV-1 at −70 °C. The trapped sample was then swept into a sensitive GC–AA system[16] for chromatographic separation and analysis. Tetramethyllead was positively identified by comparison with the retention time of an authentic sample and by molecular weight measurement using mass spectrometry. Standard samples consisting of $Pb(OAc)_2 \cdot 3H_2O$ alone in deionized water and methyl iodide in deionized water were also analysed to eliminate the possibility of artefacts.

The results summarized in Table 1 indicate that methyl iodide can methylate inorganic Pb(II) compounds in aqueous solution to produce various amounts of Me_4Pb. The lesser amount of Me_4Pb produced from $Pb(COO)_2$ might well be due to the slight solubility of the lead compound. With low concentrations of $Pb(OAc)_2 \cdot 3H_2O$ (0.001 and 0.002 mmol) in identical experimental conditions, 2.5 ng and 20.4 ng of Me_4Pb were produced, respectively. The amount of Me_4Pb produced in each case was increased when the reactions were carried out in highly basic conditions. A possible role for sodium hydroxide is to remove iodide ion, thus favouring tetraalkyllead formation over alkyllead iodides. In similar conditions, ethyl iodide (0.1 ml) also reacted with $Pb(OAc)_2 \cdot 3H_2O$ (1 mmol) to produce tetraethyllead (64.5 ng at *p*H 5–6 and 190.0 ng at *p*H 13) along with trace amounts of triethylmethyllead (Table 2).

Mixtures of methyl iodide and ethyl iodide in water without added base gave $MeEt_3Pb$ (1.5 ng) and Et_4Pb (12.0 ng) whereas at *p*H 13 Me_4Pb (1.3), Me_3EtPb (6.7 ng), Me_2Et_2Pb (97.1 ng), $MeEt_3Pb$ (231.4 ng) and Et_4Pb (349.1 ng) were obtained. In these competition experiments the amounts of tetraalkyllead produced thus increased with increasing ethyl substitution (Table 2). This may reflect different stabilities for initial $(RPb^{IV}X_{3-n})^{n+}$ intermediates (R = Me, Et) in the methylation sequence. It is interesting in this regard that the first examples of $EtPbX_3$ compounds have recently been described[17].

Table 2 Alkylation of $Pb(OAc)_2 \cdot 3H_20$ with different alkylating agents in water

Reagents	*p*H	Lead as tetraalkyllead (ng) Me_4Pb	 Me_3EtPb	 Me_2Et_2Pb	 $MeEt_3Pb$	 Et_4Pb
MeI	5–6	23.2	—	—	—	—
MeI	13*	224.3	—	—	—	—
EtI	5–6	—	—	—	0.2	64.5
EtI	13	—	—	—	14.5	190.0
MeI + EtI	5–6	—	—	—	1.5	12.0
MeI + EtI	13	1.3	6.7	97.1	231.4	349.1
$Me_3S^+I^-$	5–6	—	—	—	—	—
$Me_3S^+I^-$	13	1.9	—	—	—	—
$Me_3SO^+I^-$	5–6	0.1	—	—	—	—
$Me_3SO^+I^-$	13	3.4	—	—	—	—
$Me_3O^+SbCl_6^-$	5–6	0.2	—	—	—	—
$Me_3O^+SbCl_6^-$	13	0.1	—	—	—	—

Reaction conditions: $Pb(OAc)_2 \cdot 3H_2O$, 1.0 mmol; water, 200 ml; MeI, EtI, each 0.1 ml; $Me_3S^+I^-$, $Me_3SO^+I^-$, $Me_3O^+SbCl_6^-$, each 1.0 mmol; reaction time, 5 days at 19 ± 1 °C.

* *p*H was adjusted by addition of 10 ml of 10% NaOH.

Apart from alkyl iodides, other potential methyl carbonium ion donors react with Pb(II) salts in aqueous solution to generate Me_4Pb (Table 2). Trimethylsulphonium iodide, trimethylsulphoxonium iodide and trimethyloxonium hexachloroantimonate all yielded the volatile lead alkyl in similar conditions despite the precipitation of insoluble lead-containing compounds in these reactions.

Chemically, the synthesis of organoleads from inorganic reagents is traditionally carried out in strictly anhydrous conditions using, for example, Grignard, organolithium or organomercury reagents. We believe our observations that Pb(II) salts in aqueous solution can react with alkyl iodides to produce Me_4Pb to be unprecedented. It is interesting that the occurrence of methyliodide (3.1×10^{-7} g l^{-1}) in natural water has been reported[3]. We are investigating the possibility of chemical tetraalkyllead synthesis with such an environmental level of MeI and studying other mechanisms for the reactions, including catalysis by other metals.

We thank the Department of the Environment for support of this work through the Water Resources Support Program and the award of a visiting fellowship to I.A.

Kimberlites in the south-west Pacific

P. H. Nixon*

Geology Department, Box 4820, University PO, Papua New Guinea

Pipe-like bodies revealed by seismic refraction surveys over the Ontong Java Plateau (OJP), south-west Pacific, have characteristics of volcanic plugs[1,2]. The oceanic crust is old (Lower Cretaceous, possibly Jurassic) and unusually thick[3] (40 km), similar to that of some continental sections. The Island of Malaita, Solomon Islands, at the thinner periphery of the OJP contains several alnöite intrusions with suites of mantle inclusions, similar to those of the diamond-bearing rock, kimberlite, found in continental areas. Pyroxene geotherms calculated from the inclusions show alnöites to have formed in the Earth's mantle in warmer, shallower conditions compared with kimberlites[4]. However, by analogy with continental cratons, I suggest here that the thicker, northwestern parts of the OJP had lower geothermal gradients suitable for the formation of kimberlite pipes. These could be the bodies revealed by seismic prospecting.

The OJP occupies a 1,600 × 800-km area of the Pacific Ocean to the north-east of Bougainville Island (Papua New Guinea) and the Solomon Island chain, and is broadly defined by a water depth of less than 2,500 m (Fig. 1). Marine seismic studies[1,2] over the OJP have revealed the presence in the ocean-floor sediments of pipe-like bodies (Fig. 2) which Kroenke has suggested may be of igneous origin. They vary up to 2.5 km across[3] and show features which are similar to those produced experimentally by gas fluidization, in particular the presence of marginal faults and the development of crudely bedded conduit filling with inward dips and detached subsided blocks[5]. Such a mechanism operates in narrow vents and fractures within diatreme volcanoes, including diamond-bearing kimberlites, which could be produced phreatomagmatically, that is, by rising hot magma encountering groundwater[6]. Subsequent subsidence (caldera collapse) along concentric fractures may produce displacements up to 1,280 m (refs 7, 8). It is an important process in enlarging the vent and it also gives rise to a shallow crater or maar into which sediments are washed from a surrounding tuff ring. Progressive post-volcanic subsidence over an extended period may lead to deposition of water-laid sediments[7] ranging up to more than 300 m thick over the diatremes of some kimberlites and related volcanoes[9-11].

The seismic reflection profiles of the pipe-like bodies in the OJP also indicate collapse features (Fig. 2). Furumoto (personal communication) states that "none of these intrusives in the Ontong Java Plateau has penetrated the surface of the ocean floor. There are some cases where the intrusives have reached very close to the surface. In those cases the ocean floor dips downward directly over it, suggesting a collapse crater or depression".

The features are consistent with the idea that the pipe-like bodies are volcanic intrusions of the kind described above, but it is thought that they broke through to the ocean floor and were subsequently covered by pelagic oozes. Post-volcanic subsidence affected the oozes but with diminishing intensity. Several seismic profiles show a contraction of the disturbed zone overlying the pipe and fading displacements towards the top younger sedimentary layers. The long continued post-volcanic subsidence could be due to progressive solution of carbonate, or other soluble minerals, in the pipe tuffs at such times as they are below the ocean carbonate compensation depth (~4,000–5,000 m). There do not seem to be other deep oceanic volcanic centres with which these types can be readily equated (J. R. Cann, personal communication).

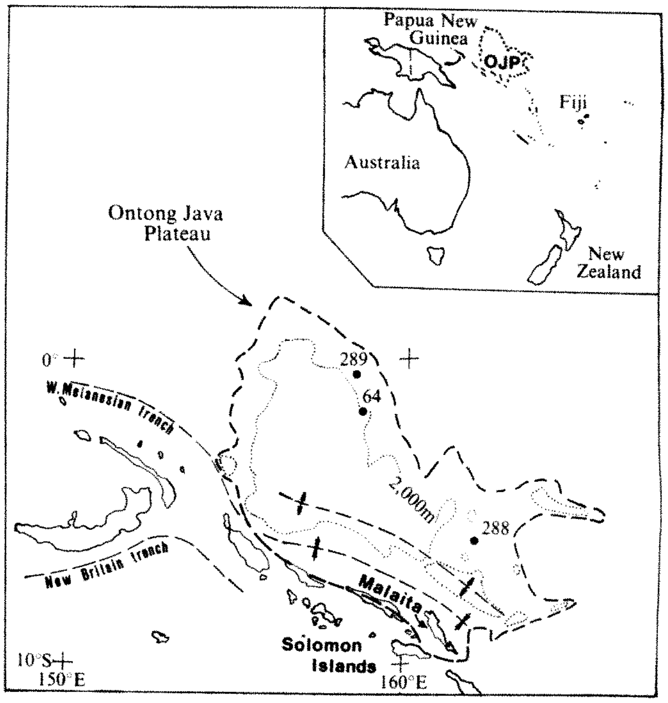

Fig. 1 The Ontong Java Plateau in relation to the islands of the south-west Pacific. The outline follows approximately the 2,500-m isobath, but the buckled southwestern margin is bounded by a thrust[15,22]. The main north-west trending structures on the OJP are: the Roncador Homocline–Stewart Arch[2], the North Solomon trench and (not shown) the Malaita Anticlinorium[2,12,21]. These resulted from collision of the Solomon Islands arc with a westerly moving OJP in late Tertiary times[16,20]. Deep Sea Drilling Sites 64, 288 and 289 are shown.

Kroenke[2] has pointed out similarities of the sedimentary succession of the OJP at Deep Sea Drilling Site 64 with that on northern Malaita (Fig. 1) mapped by Rickwood[12]. Subsequent mapping[13,15] and comparison with borehole cores at sites 288 and 289 (ref. 16) confirm that they are ocean-floor deposits ~1,500-m thick. They comprise pelagic foram-nannofossil oozes and chalk down to Oligocene beds, but below this there is an increasing amount of interbedded cherts and siliceous oozes. The oldest sediments encountered are Lower Cretaceous (Aptian). At site 289 and on the island of Malaita and neighbouring Santa Isabel to the north-west, the pelagites overlie, or are interbedded with, ocean-floor tholeiite basalts. These seem to be the topmost representatives of an extremely thick crustal succession of flood basalts which Kroenke[17] suggests mark the beginning of continent formation, that is, the OJP is a protocontinent. The age of the lower members is not known but could extend to the Jurassic.

Furumoto *et al.*[3,18] have demonstrated a crustal thickness of between 20 and 30 km in the trench and arched region north of Malaita (Fig. 1). The northwestern part of the OJP has an even greater crustal thickness of 35–42 km which is comparable with that of continents, for example, the Colorado Plateau area of North America. This part of the OJP also has a basal layer with a P-wave velocity range of 7.1–7.7 km s^{-1} immediately overlying the mantle[3,18]. From this, and the existence of a free air positive gravity anomaly[4] over the OJP, it has been suggested that burial metamorphism has produced a lower crustal granulite layer similar to that postulated for continents[19].

The southwestern portion of the Ontong Java Plateau, including Malaita, underwent deformation during the Pliocene[14]. This resulted in the northwesterly trending folds and the topographic low, the North Solomon trench, which now separate Malaita from the main portion of the OJP[2]. The

deformation was the response to the collision of westerly moving OJP into a structurally complex Solomon Island arc (Fig. 1) and the more usual subduction process was prevented, or arrested, due to the great thickness of the OJP[20,21]. The southwestern boundary of the Plateau and its island members—the Pacific Province of P. J. Coleman—is represented by the Korigole thrust[22] and associated upthrust mantle ultrabasic rocks[15,16]. To account for its tectonic behaviour not only the crust but the whole lithosphere of OJP must possess an unusual thickness and rigidity.

Until 1979 only one volcanic centre, at Babaru'u, with possibly a second related intrusion 2 km away, was known[23]. Another (Kwaikwai) has since been found and at least three more are indicated by 'shows' of heavy minerals in soils and stream gravels. These minerals include garnets, ilmenites and zircons which can be unusually abundant (Fig. 3). Zircons from two separate localities gave U/Pb ages of 33.9 Myr (ref. 24) and 34.1 Myr (Davis, personal communication). Further prospecting in the dense rain forests will reveal more outcrops.

Although field relationships are uncertain, and no crater sediments have been observed, the alnöites (biotite olivine melilitites) are important as they may be related to the intrusive features in the main part of the OJP described above. The tuffaceous textures and nucleated autoliths[23] are similar to those ascribed to gas fluidization and related phenomena of the olivine melilitite diatrems of the Swabian Alb, Germany[26]. The rounded, highly polished nature of some of the constituent minerals (Fig. 3) is further evidence of a gas-fluidized origin. From the zircon ages of the alnöites (Lower Oligocene) it is evident that eruptions took place before the folding of the leading edge of the OJP and emergence of Malaita, when the plate was east of its present position.

From stratigraphical considerations it can be seen that anything up to 1,000 m of pelagic oozes could have been laid down after intrusion and before the emergence of Malaita in Plio–Pleistocene times. Although fold movements and erosion have locally revealed the intrusions on Malaita, there is no reason why they should not also occur off-shore. Indeed, this is considered likely in view of the accumulating evidence for increasing numbers of occurrences in northern Malaita itself. There do not seem to have been any seismic reflection traverses in the vicinity of Malaita which could substantiate this claim; most of the pipe-like bodies have been recorded from the northwestern part of the OJP. However, it is this area where the crust is thickest, a factor which could have a profound influence on the kind of volcanicity produced.

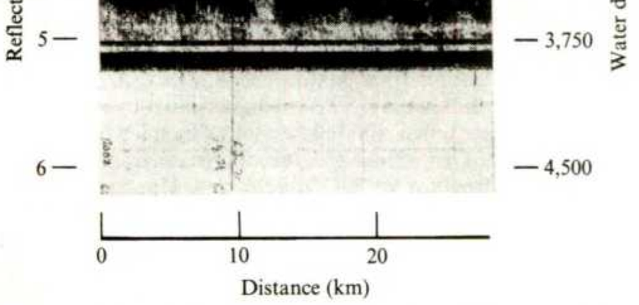

Fig. 2 Seismic reflection profile of a plug-like feature on the Ontong Java Plateau, taken from Kroenke[3] (Fig. 19, vertical exaggeration ~12:1. Location about 2°20′S, 161°45′E—slightly outside the OJP boundary as arbitrarily defined in Fig. 1). Note the apparent collapse of bedded vent material.

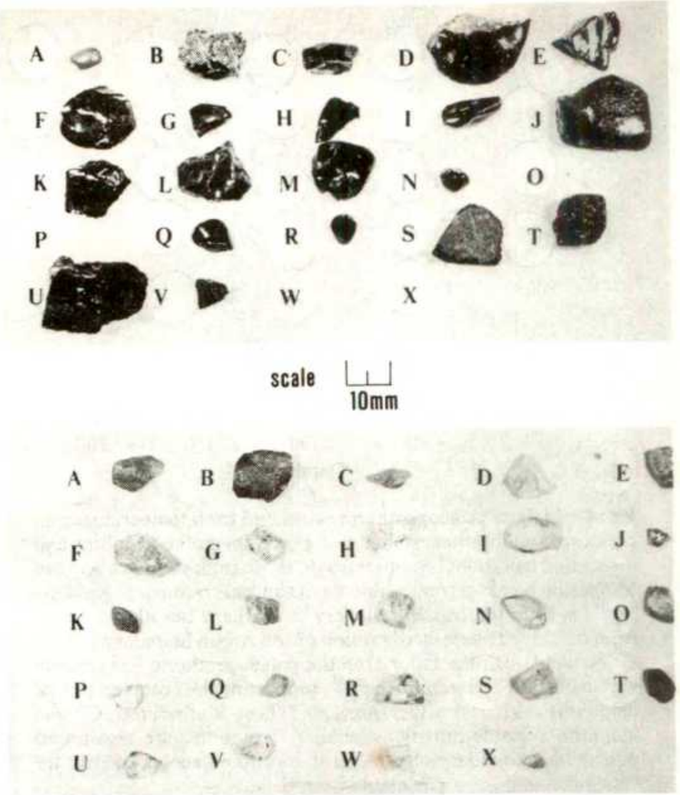

Fig. 3 Ilmenites (top) and zircons (bottom) from an alnöitic intrusion, North Malaita. Their rounded, highly polished nature is attributed to a gas-fluidized emplacement.

Although alnöites are mineralogically and chemically distinct from kimberlites[25] they contain similar suites of deep-seated garnet lherzolite (garnet, olivine, orthopyroxene, clinopyroxene) inclusions which give information about the composition and temperature distribution in the mantle at the time of eruption, and also the limiting depth of origin of the host volcanic rock itself[4,27]. Alnöite seems to have formed at depths[25] of ~120–130 km which are shallower than those for kimberlite.

The temperatures and depths of origin of the garnet lherzolites are estimated through the application of experimental and theoretical studies of relevant (Mg-rich) co-existing phases, the Mg orthopyroxene–clinopyroxene solvus for temperature determinations[28], and alumina solubility in Mg orthopyroxene for pressure (depth) determinations[29] as described by Boyd[30,31]. More recent experimental data do not significantly affect the results shown in Fig. 4 which are, therefore, used to provide a useful comparison with earlier determined curves from kimberlitic garnet lherzolites. The curves represent the Earth's temperature gradients (palaeogeotherms) below specific intrusions at the time of eruption. The Malaita plots show features which are intermediate between those of 'cool continents', where kimberlites are intruded, and 'hot oceanic' areas. The inflected steeper portion of the geotherms (Fig. 4) has been ascribed to shear heating at the base of lithospheric plate or to diapiric upwelling of asthenospheric mantle (review by Boyd[32]). Either interpretation, or combination of both, suggests that the point of inflection is a measure of depth to the base of the lithosphere. The lithospheric thickness calculated by this method in Malaita (southern OJP) is 110 km, which is thinner than that deduced by comparable methods for continents. It is, however, thicker than that in other oceanic areas determined by geophysical methods where values[33] usually average 50–70 km.

Even within a stable continental area (craton) mantle xenoliths from broadly contemporaneous kimberlite pipes indicate

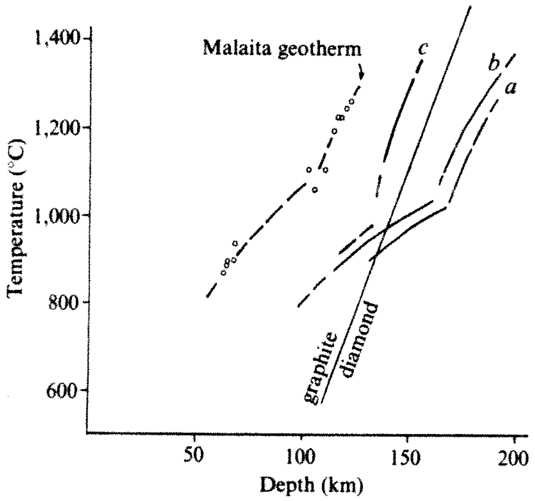

Fig. 4 Malaita palaeogeotherm calculated from temperature and pressure equilibration estimates of garnet lherzolite xenoliths and associated inclusions[4] compared with those from southern African kimberlite pipes: *a*, from within the Kaapvaal craton near Kimberley[34]; *b*, from the craton periphery in northern Lesotho[31]; and *c*, from outside the accepted position of the craton boundary in East Griqualand[35]. In the latter area the palaeogeotherm lies entirely within the graphite stability field[36], supporting the observed lack of diamonds within the inclusions and host kimberlites. Olivine melilitite volcanic intrusions, similar to alnöites, are also found outside the boundary of the craton but no palaeogeotherms are available from these.

lateral differences, notably increasingly higher palaeogeotherms (hotter for a given depth) towards the periphery, with an attendant decrease in lithospheric thickness and with lessening probability of diamond formation (Fig. 4) (refs 31, 34, 35).

If the OJP can be regarded as a proto-continent, then by analogy with cratons it could show similar variations in geothermal gradient and lithospheric thickness possibly reflecting the differences in crustal thickness. It follows that the thickest, coolest lithosphere is most likely to be found in the northwestern part of the OJP.

It is suggested that contemporaneously with the Malaita alnöites the thicker northernwestern OJP was also intruded by volcanic rocks represented by the pipe-like seismic reflection features. Although these could be alnöites the present evidence favours rocks of a deeper seated provenance, that is, kimberlites. If this is the case then diamonds may exist within the OJP.

I thank the Solomon Islands Government and officers of the Geological Survey, and Malaita Islands officials for facilitating research in the area. The work is part of a project being undertaken with F. R. Boyd whose suggestions (about drilling the plug-like features) inspired this paper. A. S. Furumoto, D. Erlandson and D. M. Finlayson provided seismic reflection profiles, M. E. McCallum and T. Woolsey, data on fluidization experiments, G. L. Davis, an unpublished zircon age and W. Manser, relevant S.W. Pacific literature. F. R. Boyd, A. S. Furumoto, V. Lorenz, C. McNulty, N. W. Rogers and J. Oliver provided helpful comments.

Sedimentological evidence for a stratigraphical break in the Durness Group

T. J. Palmer & W. S. McKerrow

Bristol BS8 1TR, UK

Around Durness north-west Scotland, the top of the Sailmhor Formation, Durness Group, is developed as a palaeokarstic surface deeply penetrated by breccia-filled fissures. Fossil evidence for the age of the Sailmhor Formation is equivocal, but we suggest here that the brecciated surface probably represents a break corresponding to the whole of the Middle and Upper Cambrian. Such a break is also seen in the contemporaneous carbonate successions in Greenland and Spitzbergen.

The limestones and dolomites of the Durness Group include both Lower Cambrian and Lower Ordovician (including Tremadoc or Lower Canadian) fossiliferous beds. It has been held that a continuous sequence of carbonates in north-west Scotland, spanning the whole of this time, is incompatible with contemporaneous deformation and metamorphism of the Dalradian rocks of the Grampian Highlands. As the Dalradian rocks extend from the Precambrian up into the Cambrian system, many authors have considered that the Grampian orogeny must have post-dated formation of the youngest Durness rocks. Strong evidence for the absence of Middle and Upper Cambrian sediments in the Durness sequence will now permit serious consideration of a major orogeny in the Grampian Highlands during this time. This break occurs above all known Lower Cambrian faunas and below rocks which we interpret to be exclusively of Ordovician age. It is not necessary to postulate diagenetic destruction of all Middle and Upper Cambrian fossils.

The Lower Cambrian age for the lowermost Ghrudaidh Formation, is based on the occurrence of *Salterella*[1–3]. Recently, Lower Cambrian microfossils have been recovered from cherts near the base of the succeeding Eilean Dubh Formation at Inchnadamph, 50 km south of Durness[4]. The ages of the following two formations (Sailmhor and Sangomore) are more doubtful. The lower (Sailmhor) is reported to have produced an age-diagnostic fauna at one locality. The species originally

0028–0836/80/430720—03$01.00

reported[1] included *Murchisonia* sp., *Euconia* (*Pleurotomaria*) spp., *Cyrotoceras* spp., ?*Orthoceras* sp., *Planolites* and *Asaphus* (*Isotelus*) *canalis*. Doubt has been thrown on the existence of the one specimen of the last-named species, as it is now missing[2]. The rest of the Sailmhor fauna suggests a Lower Canadian (Tremadoc) age[2]. Until now, no body fossils have been reported from the Sangomore Formation which are diagnostic of its age, but a new fossiliferous locality within the Balnakeil Bay outcrop of this unit (NC 3862 6887, see Fig. 1) has yielded *Murchisonia* sp., *Pleurotomaria* sp., and *Orthoceras* sp., suggesting a Lower Canadian (Tremadoc) age. The later formations of the Durness Group (in ascending order, Balnakiel, Croisaphuill and Durine) are of Arenig (and possibly Llanvirn) age[5,6].

The absence of Middle and Upper Cambrian calcareous fossils has been attributed to their destruction during the process of dolomitization[7]. It is more likely[3] that there is a major stratigraphic break comparable with that which occurs at approximately the same stratigraphical level in the carbonate successions in Ellesmere Island; north-west, north-east and east Greenland; and Spitzbergen[8,9].

We have examined the most complete section of the Durness Formation, which is that exposed along the southern shore of Balnakeil Bay (as spelt on the Ordnance Survey New Series 1:50,000 map), west of Durness, north-west Scotland (NC 374688–NC 390687). Rocks from the Eilean Dubh to the Balnakiel Formation are seen here with only minor tectonic disturbance. Our conclusions about the positions of the boundaries between the formations (Fig. 1) correspond to those shown on the 6 inch to 1 mile geological map deposited with the Institute of Geological Sciences in Edinburgh.

The transition between the whiter dolomites of the Eilean Dubh Formation and the darker dolomites of the Sailmhor Formation is gradational and does not suggest a major episode of non-sedimentation. The main changes are an increase in the number of beds with continuous or nodular horizons of chert, and an increase in the number of beds of black and white mottled dolomite. This mottling is almost certainly due to differential dolomitization in branching burrow systems of the *Spongeliomorpha paradoxica* type, such as have been described from other Lower Palaeozoic carbonate sequences[10,11]. In contrast, the junction between the Sailmhor and the overlying Sangomore Formation is sharp. The lowest beds of the latter form a low cliff between NC 3841 6887 and NC 3837 6886. Extending out from the base of this cliff is the upper surface of the Sailmhor. On close examination, it is immediately apparent that the upper part of the Sailmhor Formation is extensively brecciated, whereas this is not so in the base of the Sangomore Formation. The breccias occur, not in planar or lensoid units parallel or subparallel to bedding, but as the fillings of vertical fissures. These fissures dissect the Sailmhor Formation, descending from its top down to levels a considerable distance below. They are most abundant in the top 30 m, but at least two of them (Y in Fig. 1) seem to extend right down into the underlying Eilean Dubh Formation, and are, therefore, at least 150 m deep. They range in width from 4 m down to a few centimetres, merging below this range into cracks filled by growth of sparry dolomite. Most are of the order of half a metre to a metre or so wide, and trend in an east–west direction. Others trend north-west–south-east.

The breccias which form the fissure fills consist of angular and sub-angular clasts of dolomite, with subordinate chert fragments. The dolomites appear identical to those forming the beds of the Sailmhor Formation, and many of the fragments show the same burrow mottling. The size of the clasts ranges from sand size up to around 20 cm across. They are very poorly sorted, with the larger fragments being set at all angles in a matrix of the finer material. In some of the fissures, this finer-grained matrix is not present and the voids between the larger clasts has been filled with a crystalline dolomite cement. Towards the bottom of one of the deep fissures which penetrates the Eilean Dubh Formation, the sediment becomes much finer and shows bedding. To establish the density of the fissuring in the plane of bedding, we measured the proportion of fissures to country rock in a 65-m transect along a bedding plane about 40 m below the top of the Sailmhor Formation (A–B in Fig. 1); 18.2 m of this transect was accounted for by breccia-filled fissures, and the remainder consisted of undisturbed country rock and country rock with dolomite veins.

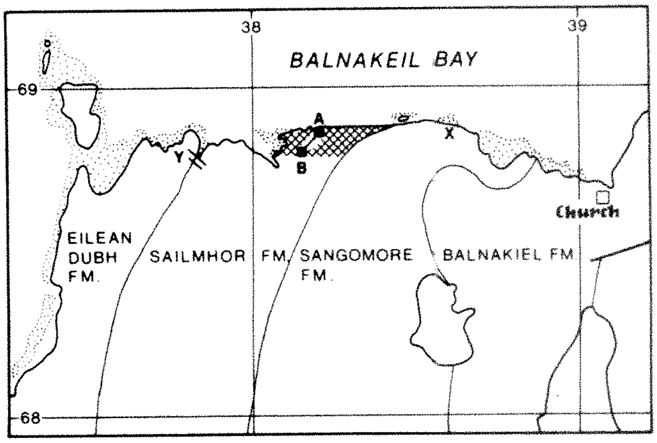

Fig. 1 Map of the south shore of Balnakeil Bay, west of Durness. The boundaries of the formations are after the Institute of Geological Sciences 6-inch geological maps, as modified by T. Robertson. X, Fossil locality; Y, fissures penetrating the top of the Eilean Dubh Formation; A–B transect showing 18.2 m of fissure-fill over a total distance of 65 m. Cross-hatching denotes area of maximum fissure development. Kilometre grid squares are indicated.

In view of the conspicuousness of the fissures with their breccia fills, and the thickness of sediment which they penetrate, why have they not been recognized previously? In fact, the breccias have been noticed, but have apparently always been ascribed to tectonism a long time after deposition. There are local fault breccias, usually of small width, which show displacement of the beds on either side. No vertical displacement at all occurs across the fissures that descend from the top of the Sailmhor Formation. There is also evidence of other sedimentary and diagenetic processes, which produce breccia horizons in the Durness Group as a whole. Young[12] has demonstrated the former presence of evaporite minerals in the Balnakeil Bay section, and locally there are horizontal breccia beds which closely resemble those formed by bed collapse after dissolution of evaporites in the Purbeck Broken Beds of Dorset[13]. Also seen are tepee structures resulting from interstitial cement growth during early diagenesis, and flake breccias which were produced by desiccation[14] and deposited either as horizontal beds or in the quiet micro-environments between stromatolite heads. Furthermore, in most of the other areas in Scotland where the Durness Group is seen (in contrast to the situation around Durness itself), it has been heavily affected by movement along the Moine Thrust zone. In these regions, tectonic brecciation and veining do become prominent. It seems, therefore, that brecciation has previously been regarded as a ubiquitous inconvenience whose effects have to be discounted before the rocks are interpreted.

The junction between the Sailmhor and the Sangomore Formations is well exposed only around Durness. The extensive development of breccia-filled fissures in the Sailmhor Formation is seen in the Balnakeil Bay section, in Durness village itself, and immediately inland. Elsewhere in north-west Scotland, we noted rare, small fissures of a similar type in the upper part of the Eilean Dubh Formation at Kishorn (NG 862443), but we have no way of telling if they originally descended from the top of the Sailmhor Formation.

This extensive and striking development of fissures suggests a major episode of non-deposition during which uplift and extensive erosion of the Sailmhor carbonates occurred. The top of the formation may be regarded as a major karstic surface. Petrographical details which might throw further light on the process are likely to have been destroyed by the extensive subsequent dolomitization and silicification[14,15]. The junction between the Sailmhor and Sangomore Formations represents a break corresponding to the Middle and Upper Cambrian. This break justifies the use of the terms Lower Durness Group for the Ghrudaidh, Eilean Dubh and Sailmhor Formations, and the Upper Durness Group for the Sangomore, Balnakiel, Croisphuill and Durine Formations. The non-sequence seems to correlate with those mentioned above from elsewhere in the Cambro–Ordovician of the North Atlantic region.

Our conclusion seems at first incompatible with the Lower Ordovician (Tremadoc) age assigned to the Sailmhor Formation on fossil evidence[1]. However, the diagnostic fauna only comes from a single locality, near the top of the Sailmhor. Its field relationships are unknown and we have not been able to relocate it. We feel that if this fauna does indeed come from below the Sailmhor/Sangomore boundary, then it represents material from the Upper Durness Group that has fallen into one of the fissures in the Lower Durness Group.

The timing of the Grampian Orogeny is still not definite, but it now seems probable that it occurred before the deposition of the late Tremadoc/early Arenig Lough Nafooey Group of western Ireland[16]. The early Ordovician rocks along the Highland Border (in Arran and near Aberfoyle) are perhaps (together with the Macduff Slates) younger than the main episodes of the orogeny. If this is so, the interval between the Lower Cambrian and Lower Ordovician (Tremadoc) rocks at Durness would correspond in time to the peak of the Grampian Orogeny.

We thank the Scottish Office of the IGS for access to the 6-inch field maps of Balnakeil Bay.

Palaeoceanographic change in the Pacific at the Eocene–Oligocene boundary

L. D. Keigwin Jr

Graduate School of Oceanography, University of Rhode Island, Kingston, Rhode Island 02881

Oxygen isotopic studies both of benthic formanifera[1-5] and shallow-marine carbonates[6-8] have provided a useful monitor of marine palaeotemperatures. The Deep Sea Drilling Project (DSDP) has provided cores from many ocean basins to conduct detailed stable isotopic and palaeoceanographic studies of the Cenozoic and late Mesozoic. DSDP Sites 277 and 292, separated by ~60° latitude in Palaeogene times, each record an ^{18}O enrichment in benthic foraminifera of nearly 1‰ beginning at the Eocene–Oligocene boundary. Planktonic foraminiferal trends are similar to benthic trends in the high latitude south-west Pacific Ocean, but tropical planktonics show only a minor (~0.3‰) increase which may reflect a change in seawater composition. These results suggest a sudden cooling of Pacific deep waters and high latitude surface waters forms a useful stratigraphic marker for the Eocene–Oligocene boundary. This boundary is particularly important because of its association with several worldwide palaeo-oceanographic and biogeographic changes. These include a sudden drop in the calcite compensation depth of 1–2 km (refs 9, 10); a decrease in planktonic microfossil diversity[11-13]; a change in planktonic biogeographic patterns[12-14]; and increased erosion of deep-sea sediments over wide areas[15,16].

Most studies of the Eocene–Oligocene boundary (Table 1), based on coarse sampling, have revealed an early to middle Eocene temperature maximum in both surface and deep waters followed by cooling through the late Eocene into the early Oligocene. This is manifested as an oxygen isotopic enrichment of ~2‰ (equal to an 8 °C cooling) over a period of about 10 Myr. The temperature record at high latitudes reveals synchronous cooling in both surface and deep waters[3] whereas if low and middle latitudes were included the surface waters are shown to cool more gradually[5]. Most studies also record a benthic foraminiferal oxygen isotopic enrichment of ~1‰ (~4 °C cooling) at or near the Eocene–Oligocene boundary. Only in a detailed study[4] of this change at DSDP Site 277 is it shown to occur in the earliest Oligocene.

DSDP Site 277 was drilled in 1,214 m water depth on the Campbell Plateau in the south-west Pacific (52° 13.43′ S; 166° 11.48′ E). The Campbell Plateau is continental in origin[17] and plate tectonic reconstructions place it only a few degrees farther south 38 Myr ago[18,19]. Site 292 (ref. 20) is located at 2,943 m on the Benham Rise in the west Philippine Sea (15° 49.11′ N; 124° 39.05′ E). This is a tectonically complex region of anomalously shallow oceanic crust[21] which has been drifting northward since the early Palaeogene[22] so the location of Site 292 was tropical in Eocene–Oligocene times.

Microfossil ranges[23-27] of potential stratigraphic value shown in Figs 1 and 2. The biostratigraphic sequence at Site 277 is marked only by last appearances. The Eocene–Oligocene

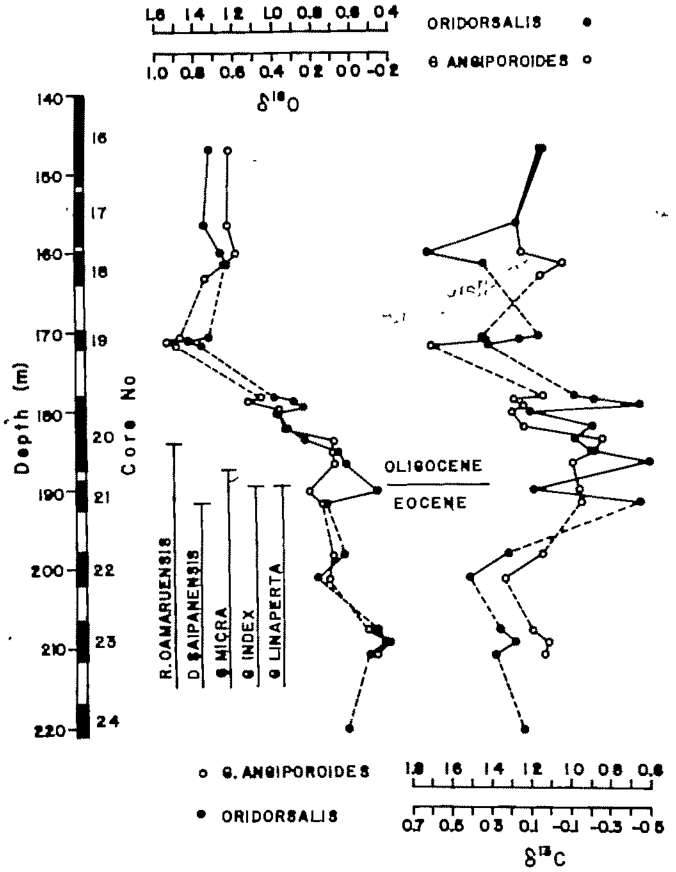

Fig. 1 Stable isotopic results (‰, PDB) at high latitude Site 277 on the Campbell Plateau, South-west Pacific Ocean Intervals of core recovery are in black along the vertical axis. Microfossil ranges are from refs 23, 24 Benthic and planktonic foraminiferal δ^{18}O suggests the entire water column at this location cooled by 3 to 4 °C beginning at the Eocene–Oligocene boundary.

boundary is defined in New Zealand by the last appearances of the planktonic foraminifera *Globigerapsis index* and *Globigerina linaperta* which are considered[28] to occur within planktonic foraminiferal zone P17. Nannofossil markers[24] place the Eocene–Oligocene boundary within a few metres of that defined by planktonic foraminifera (Fig. 1).

Although there are first and last appearances of taxa throughout the latest Eocene and earliest Oligocene at Site 292, several last appearances suggest that the Eocene–Oligocene boundary lies within core 35 (Fig. 2). Ujiie[25] places the boundary at the last appearance of the foraminifera *Globorotalia cerroazulensis* and *Hantkenina primitiva* (approximately equivalent to the top of zone P17). The base of zone P17 is defined by the last appearance of *Cribrohantkenina inflata*[28], so core 35 of Site 292 is probably time-equivalent to core 21 of Site 277. Ellis[26] finds important nannofossil markers (last appearances of *Discoaster barbadiensis* and *Discoaster saipanensis*) 8–13 m lower in the section. The presence of the short ranging latest Eocene radiolarian *Lophocyrtis jacchia* suggests that the sequence is nearly complete at this location[27].

Isotopic analyses followed standard procedures[29]. B-1 was used as a working standard and was calibrated to PDB using NBS-20 (Solenhofen limestone) as an absolute standard. For NBS-20 we take δ^{18}O = −4.18‰ and δ^{13}C = −1.07‰ with respect to PDB[30]. Eleven analyses of NBS-20 have been performed giving δ^{18}O B-1 = −4.12 ± 0.12‰ (1σ of the isotopic difference of samples run on a single day) and δ^{13}C B-1 = −1.71 ± 0.06‰. As a check we have run 10 samples of the standard TKL-1, giving δ^{18}O PDB = −4.43 ± 0.10‰ and δ^{13}C = −1.78 ± 0.28‰ which compare well with the mean isotopic compositions and standard deviations determined by 15 different laboratories of −4.26 ± 0.18‰ and −1.69 ± 0.13‰ for δ^{18}O and δ^{13}C respectively[30]. We have also run 11 Yule Marble samples as part of the CENOP intercalibration, giving δ^{18}O = −6.63 ± 0.08‰ and δ^{13}C = −2.30 ± 0.05‰ which compare well with −6.49, −2.28 and −6.57, −2.30 of J. Killingley (personal communication) and S. Savin (personal communication) respectively.

The benthic foraminifera *Oridorsalis* was chosen from the size fraction greater than 175 μm at both locations. There was no single abundant, long-ranging species of planktonic foraminiferal fauna common to each site that could be used for the isotopic analysis. Thus, *Globigerina angiporoides* was selected from Site 277 and *Globigerina ampliapertura* from Site 292. Both are from the 175–295 μm size fraction. I have assumed that both of these planktonic species previously inhabited near-surface waters and thus their isotopic composition mostly reflects variation in surface-water temperature.

Benthic foraminiferal calcite becomes enriched in ^{18}O at both Sites 277 and 292 beginning at the Eocene–Oligocene boundary (Figs 1 and 2). At high southern latitude Site 277, the change in $\delta^{18}O$ between 170 and 190 m is about 1‰, whereas the average difference before and after the transition is slightly less (0.8‰). At Site 277 the planktonic and benthic $\delta^{18}O$ records are highly correlated. Site 292 also shows a large change in benthic $\delta^{18}O$ which is between 312 and 320 m, and is greater than the average difference below and above the transition (about 1.5 versus 0.9‰). The most important difference between the two sites is that unlike the high latitude site, at tropical Site 292 the planktonic foraminifera become gradually enriched in ^{18}O by about 0.3‰ over the interval examined. There is no abrupt change in Site 292 planktonic foraminiferal $\delta^{18}O$ at the Eocene–Oligocene boundary, but the average above and below the benthic transition are significantly different (0.28‰).

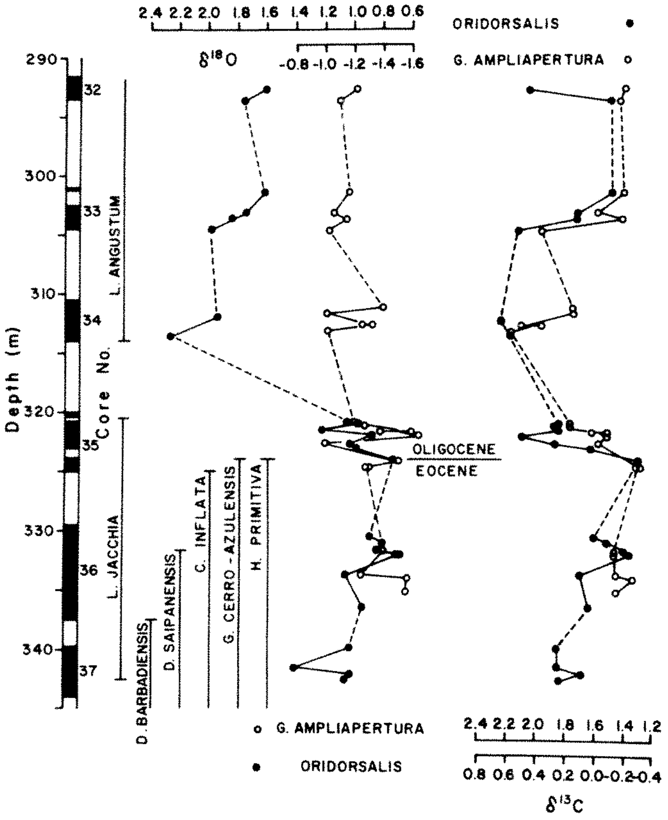

Fig. 2 Stable isotopic results (‰, PDB) at tropical Site 292 in the Philippine Sea. Intervals of core recovery are in black along the vertical axis. Microfossil ranges are from refs 25–27. Only benthic foraminiferal $\delta^{18}O$ suggests a 3 to 4 °C cooling beginning at the Eocene–Oligocene boundary. The slight enrichment in planktonic foraminiferal ^{18}O may record a minor change in seawater composition.

The $\delta^{13}C$ records of benthic and planktonic foraminifera appear subparallel at both locations (Figs 1 and 2). At Site 277 there is evidence that foraminiferal carbon across the Eocene–Oligocene boundary is lighter on average by a few tenths of a permil than before or after. Site 292 is marked by isotopically heavier foraminiferal carbon in the earliest Oligocene.

The oxygen isotopic results agree with an abrupt earliest Oligocene enrichment[4] in benthic foraminiferal ^{18}O (Figs 1, 2). My results differ from those of Kennett and Shackleton[4] for Site 277 in that the isotopic enrichment begins at the Eocene–Oligocene boundary and the transitional change is less by 0.2‰. This is due to my use of monogeneric samples (*Oridorsalis* sp.) compared with mixed benthics of Kennett and Shackleton[4]. This is important because the oxygen isotopic composition of different benthic foraminifera from the same sample may vary by nearly 1‰ (refs 31, 32). I have also used a closer sampling interval, especially in core 20; plotted core 19 at the top of the cored interval rather than the bottom; and used Jenkins'[23] range of *G. index* rather than that of the Site Report, Site 277 (ref. 17). The more accurate placement of the last appearance of *G. index* raises the boundary about 2 m from 192 to 189.6 m. I have checked samples between the two reported last appearance levels of *G. index* (21-2, 60 and 21 cc) and found it present in 21-2, 140 but absent from 21-3, 140. Thus its uppermost range is sporadic and partly leads to uncertainty in placement of the Eocene–Oligocene boundary.

The maximum duration of the oxygen isotopic transition may be estimated from published sedimentation rates. At Site 292 the late Eocene to early Miocene sedimentation rate is ~12 m Myr^{-1} (ref. 20), so the interval from the middle of core 35 to the base of core 34 represents a maximum duration of about 0.9 Myr. The sedimentation rate of Site 277 above core 21 is ~22 m Myr^{-1} (ref. 17). The $\delta^{18}O$ increase occurs over a maximum interval of ~18 m, giving a maximum duration of about 0.8 Myr, in good agreement with Site 292.

Three mechanisms which may account for the observed oxygen isotopic records, either singly or combined, are post-depositional alteration, a change in the isotopic composition of seawater, or a change in surface and bottom-water temperatures. Taken alone, the $\delta^{18}O$ record at Site 277 might be suggestive of diagenetic change or seawater compositional change because both benthic and planktonic foraminifera respond in the same way. Diagenetic effects at both sites are ruled out by scanning electron microscopic studies of foraminifera which show the fauna is well-preserved at both sites. Preservation of nannofossils is mostly 'moderate' between cores 16 and 25 at Site 277 (ref. 24), and although there are intervals of poor preservation at Site 292 (ref. 26), they bear no relation to the isotopic change.

A seawater compositional change could explain the shift in isotopic values of both planktonic and benthic species at Site 277, but Site 292 results argue against this. At the tropical location the benthics become markedly enriched in ^{18}O during the earliest Oligocene but the planktonics do not (Fig. 2). This suggests that the maximum seawater compositional change is the maximum enrichment in ^{18}O common to planktonics and benthics at both locations, ~0.3‰ between cores 32 and 36 at Site 292. Nevertheless, warming of tropical surface waters at the same time as a large oceanic enrichment in ^{18}O could produce the observed results and cannot be ruled out. Growth of continental ice is a possible mechanism of increasing $\delta^{18}O$ by 0.3‰. Evidence for Eocene–Oligocene continental ice in Antarctica is equivocal and is discussed by Mercer[33]. The sea level record based on seismic stratigraphy indicates a small Eocene–Oligocene regression relative to other Cenozoic changes[34]. If the ^{18}O enrichment in Site 292 planktonic foraminifera reflects an ice volume growth then the effect was to lower sea level by a few tens of metres.

Most oxygen isotopic studies of Cenozoic marine carbonates follow the interpretation that major Antarctic ice growth began in the middle Miocene, so pre-middle Miocene $\delta^{18}O$ values from well-preserved foraminifera essentially reflect seawater temperature[3]. Planktonic microfossils provide evidence of dramatic cooling from the Eocene to the Oligocene. Lipps[11] noted that, relative to the Eocene, Oligocene microfossil assemblages were marked by abundant cosmopolitan species of simple morphology. Subsequently Kennett[12] found planktonic microfossil diversity in the Southern Ocean during the Oligocene to be the lowest of the entire Cenozoic. Low faunal and floral diversity and abundant cosmopolitan species are inferred to reflect low marine temperatures in the earlier Cenozoic, as they do today.

If $\delta^{18}O$ changes are assumed to reflect only temperature changes rather than oceanic compositional changes, then the isotopic results of this study may be used to estimate latest

Table 3 Comparison of foraminiferal $\delta^{18}O$ data before and after earliest Oligocene cooling

† Computed by subtracting planktonic foraminiferal $\bar{x}$ from benthic foraminiferal $\bar{x}$.

Eocene and earliest Oligocene latitudinal temperature contrasts, and surface to deep-water temperature contrasts at a particular location (Table 3). Such reconstructions must assume that planktonic foraminiferal $\delta^{18}O$ largely reflects near-surface water temperature. It remains to be confirmed where *G. angiporoides* lived in the water column. An isotopic study of Oligocene planktonic foraminifera suggested *G. ampliapertura* inhabited intermediate-depth waters[35]. However, as *G. ampliapertura* does not show an earliest Oligocene $\delta^{18}O$ increase similar to the benthic foraminifera, I assume that its isotopic composition mostly reflects near-surface conditions.

Table 3 summarizes oxygen isotopic data from before and after the earliest Oligocene cooling. The vertical oxygen isotopic contrast between near-surface waters and the sea floor remained the same throughout the late Eocene and early Oligocene at Site 277, so it seems the entire upper water column chilled. At the lower latitude site (292) the vertical $\delta^{18}O$ contrast increased from 2.4 to 3.0‰, equal to an increase in the shallow to deep temperature contrast of ~2.4 °C. This increase is inferred to be mostly due to a temperature drop in deeper waters[4]. The latitudinal $\delta^{18}O$ contrast in near-surface waters increased from 1.5‰ in the late Eocene to ~1.9‰ in the early Oligocene, equal to a cooling of ~1.6 °C. This is due to a nearly 3 °C surface-water cooling in high latitudes, while low latitude near-surface waters cooled by only ~1 °C.

Two triggering mechanisms are proposed for the Eocene–Oligocene boundary event. Kennett and Shackleton[4] interpret the benthic foraminiferal oxygen isotopic enrichment to represent the sudden evolution of cold, thermohaline circulation (the 'psychrosphere'), perhaps in response to the opening of the Tasman Seaway and subsequent sea-ice accumulation around Antarctica. Thierstein and Berger[36] argue that this event may have been caused by the injection of water of greatly different density than normal seawater from an isolated basin to the open sea. In particular they propose that brackish water from a previously isolated Arctic Ocean rapidly spread across the surface of the world ocean and disrupted the heat exchange between the deep and surface waters. This is believed to have reduced the moderating influence of the ocean on climate, resulting in snow accumulation on Antarctica, northward migration of the polar front, and the subsequent production of cold bottom water.

The latter hypothesis[36] proposes Artic tectonic events (opening of the Greenland Sea passage) as the trigger of the Eocene–Oligocene cooling rather than the opening of the passage over the Tasman Rise[4]. Thierstein and Berger[36] stress the importance of carbon isotopic data: their 'injection event' hypothesis predicts isotopically light carbon in benthic foraminifera at the boundrary event and may be tested by detailed studies. At Site 277 benthic carbon is indeed lighter across the boundary (Fig. 1) but it is not so at Site 292 (Fig. 2). Data from more cores are necessary to evaluate mechanisms for the Eocene–Oligocene boundary cooling and the significance of $\delta^{13}C$ variability.

Manganese nodule growth rates determined by fossil diatom dating

David Kadko & Lloyd H. Burckle

Department of Geological Sciences, Lamont-Doherty Geological Observatory of Columbia University, Palisades, New York 10964

We report here that a manganese nodule from the Central Pacific manganese nodule province has been dated by fossil diatoms found in mud scraped from near the nodule's centre. The nodule was taken at DOMES Site B from Core B55-56 at 11°50.3′N and 137°28.2′W in a water depth of 4,892 m. It was resting on the sediment surface, with about 1.5 cm of the nodule bottom (of a total nodule height of 4.2 cm) buried in the mud. The top surface of the nodule was covered with a smooth manganese coating, but the bottom had a very rough, crusty texture. It was found that recent mud had leaked in through cracks in the nodule bottom, but that there were no pre-Pleistocene diatoms in this material. The date obtained was compared with the growth rate determined by the ^{230}Th excess method and found to be in reasonable agreement. This study adds to the work of Harada[1,2] on the biostratigraphy (mainly coccoliths) of manganese nodules.

Figure 1 shows the results of the ^{230}Th dating of the nodule; these are consistent with growth rates found by others using this method for other nodules[3–5]. The nodule's top 3 mm indicate a growth rate of 3 mm Myr^{-1}, and the bottom yielded a rate of

0028-0836/80/430725—02$01.00

4.5 mm Myr^{-1}. (The bottom result is only an approximation as the ^{230}Th excess was quite low.) From the nodule's radius (normal to the sampled section) of 2.7 cm, and assuming a constant growth rate, an age of 9 Myr BP is suggested as the time of initial growth. However, we are aware that the constancy of growth has been questioned[5].

Two mud samples (B and C in Fig. 2) were taken from the nodule and examined for diatoms. One sample was from the nodule's centre and the other from 0.5 cm below the centre. Both samples contained many fragments of robust, well silicified diatoms. Essentially the only form that was identifiable was *Actinocyclus ingens* Rattray. This form is found sporadically in the early Miocene but is most common in the equatorial Pacific in the early middle and middle middle Miocene (~12–15 Myr BP, close to the ^{230}Th age). We also encountered occasional specimens (<1%) of the diatom *Pseudoeunotia doliolus* (Wall.) Grunow, an exclusively Pleistocene form.

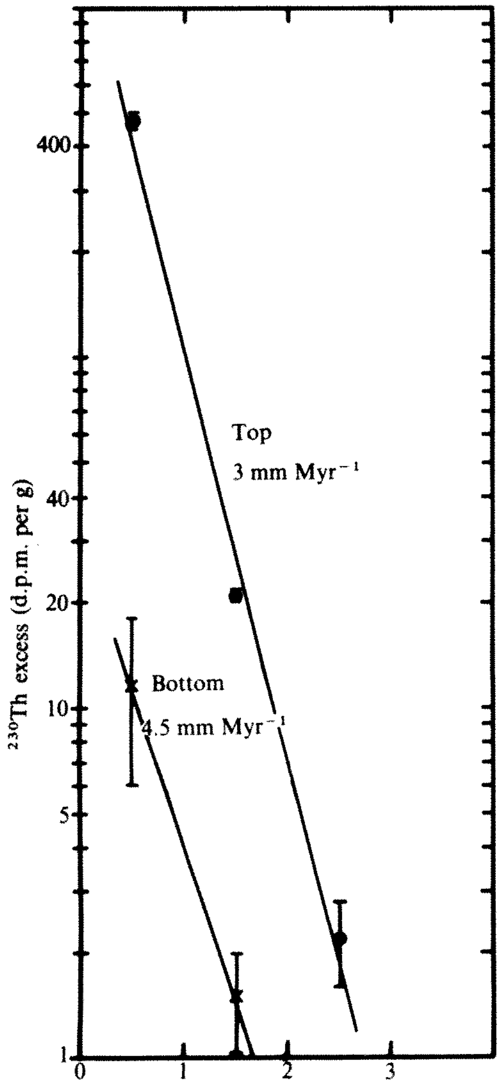

Fig. 1 A log-linear plot of ^{230}Th excess as a function of depth from the nodule's top and bottom surfaces.

To determine if the Miocene diatoms represented contamination from surface sediment, samples from the mud surrounding the nodule were also analysed for diatom species. The diatoms from 0–11 cm depth were representative of Pleistocene or Recent assemblages. The presence of *P. doliolus* indicates that this interval is younger than the Olduvai Event of the Matuyama Reversed Epoch (Pleistocene)[6]. Negative evidence, that is, the absence of such forms as *Rhizosolenia praebergonii* var. *robusta* Burckle, *Nitzschia reinholdii* Kanaya and Koizumi, or the silicoflagellate *Mesocena quadrangula* Bukry, suggests that this interval is younger than the Brunhes/Matuyama magnetic boundary. *A. ingens* was not present through this interval nor were there any other pre-Pleistocene forms.

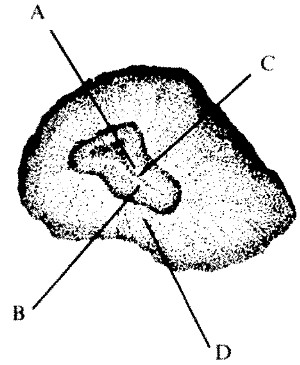

Fig. 2 Schematic diagram of the manganese nodule studied, with sample locations (see text).

Quinterno and Theyer[7] found several per cent of reworked Tertiary forms of radiolarians in surface Quaternary sediment of nearby cores. However, the percentage of reworked material varied markedly from core to core in their study, and in this core, to a depth of 9 cm, less than 1% of any pre-Pleistocene radiolarians were found. The complete absence of pre-Pleistocene diatoms in this interval is therefore not surprising, as diatoms are much more susceptible to corrosion than are radiolaria.

Mud within the nodule was also analysed for ^{230}Th. Figure 2 shows the sample locations of the mud taken from the nodule. The sample marked 'D' was 1 cm from the nodule bottom and had a ^{230}Th concentration of 150 d.p.m. per g. This corresponds to surface sediment and clearly shows that recent mud has leaked in through bottom cracks, and accounts for the presence of the few recent diatoms found in the nodule. Sample 'A', taken from the nodule centre, had only 44 d.p.m. per g, which indicates a mixture of older material with the surface sediment.

The ^{230}Th analysis and diatom data suggest that surface sediment with high ^{230}Th (but no Miocene fossils) reached the nodule's interior. The crusty nodule bottom, immersed in sediment, did have cracks where this material could have leaked in. However, material much older than surface sediment is at the nodule centre, and fossil diatoms there can indicate the approximate age of the nodule. This age should not be affected by contamination from recent sediment that probably leaked in through cracks at the nodule bottom.

Deacidification in a plant with crassulacean acid metabolism associated with anion–cation balance

R. Phillips

Department of Biology, University of Stirling, Stirling FK9 4LA, UK

In plant tissues using crassulacean acid metabolism (CAM), malate accumulates during the dark and declines in the subsequent light period. The malate is an intermediate store of CO_2 which is fixed photosynthetically during the subsequent day and for CAM plants the amplitude of the fluctuation is significant for plant carbon assimilation[1]. Because they are so considerable, the maximum values for acid content aroused early comment[2]. The maximum seems to be related not just to the rate of acidification but also to internal factors which may include the water and cation content of tissues[3]. Changes in the distribution of cations have recently been linked to the diel fluctuation in malate[4]. I report here that the malate measured in leaves at the end of the day can be correlated with an imbalance between total cations and the organic acids other than malate in the leaves of *Kalanchoe daigremontiana*. There occurs a greater imbalance in leaves of plants grown in a long compared with a short day and this may explain the finding that leaves contain considerably more malate at the end of a long photoperiod.

K. daigremontiana was grown in Long Ashton culture solution until the plants were 9–12 weeks old as described previously[3]. The macronutrient composition of the solution was 4 mM KNO_3, 4 mM $Ca(NO_3)_2$, 1.5 mM $MgSO_4$ and 1.33 mM NaH_2PO_4. Although this supplied nitrogen largely as nitrate, the solution contained 1.86 mM ammonium added as hydroxide to bring its initial *p*H to 6.2. Plants were grown at 25 °C with either 16 h dark, 8 h light (short day); 8 h dark, 16 h light (long day); or 8 h dark, 8 h low light, 8 h light (pseudolong day). Light was provided by fluorescent and incandescent sources giving an intensity of 0.2 mE m^{-2} s^{-1} at midplant height, except during the period of low light in pseudolong days when the intensity was reduced to <0.02 mE m^{-2} s^{-1}. Leaves were removed at the end of the light period, divided in half and the midrib discarded. From one half organic acids were extracted and measured by gas chromatography[5]. The adjacent half was homogenized and centrifuged at 4,000*g* for 5 min. The *p*H of the supernatant was measured. The supernatant and pellet were separated and the pellet rinsed once with 25 cm^3 distilled water. After centrifugation at 40,000*g* for 20 min the supernatant was combined with the original supernatant and assayed for calcium, magnesium, potassium and sodium by atomic absorption spectrophotometry. This extraction consistently removed 99% of the monovalent and 90% of the divalent cations and allowance was made for this loss in calculations of the total cation concentrations.

The photoperiod markedly affected whether malate or isocitrate was the major component of the acid fraction of leaves at the end of the day (Table 1). In long days malate exceeded the sum of isocitrate and citrate whereas in pseudolong and short days the reverse was true. These differences occurred mainly because of large differences in the amount of malate. At the end of a long day leaves contained nine times more malate than after a short day. Several reports show that malate is at or close to its minimum during the diel fluctuation at the end of the photoperiod[6,7]. Clearly long days do not necessarily lead to low levels of malate in leaves by the end of the day.

Figure 1 shows that increasing amounts of malate occurred together with an increased excess of cations over the anions citrate and isocitrate. The slope of Fig. 1 is very close to unity. It is likely that virtually all the cations have been measured but the organic acids will represent only a component of the total anions in leaves. The intercept in Fig. 1 may provide an estimate of these unmeasured anions in which case this fraction is similar in all leaves at 64.1 μequiv. g^{-1}. A correlation like that shown in Fig. 1 would occur if *K. daigremontiana* deacidified to a limit determined by a particular balance between total anions and cations in the leaves.

Table 1 Amounts (μequiv. per g leaf water) of malate, citrate and isocitrate and the *p*H of extracts of leaves from node 7 (upper) and node 5 (lower) of *K. daigremontiana* analysed at the end of the photoperiod

	Malate	Citrate	Isocitrate	*p*H
Long day				
Upper	88.2±2.7	18.5±3.8	36.3±4.9	5.1±0.05
Lower	87.2±1.9	23.7±4.9	43.8±8.1	5.0±0.05
Pseudolong day				
Upper	46.2±6.0	26.0±1.5	53.1±5.3	5.9±0.01
Lower	26.4±0.8	32.0±3.0	95.0±8.8	6.0±0.05
Short day				
Upper	9.4±2.8	18.5±0.8	70.1±4.3	5.9±0.01
Lower	7.8±1.8	20.5±1.0	68.1±4.5	5.8±0.02

Results are shown as mean ±s.e. of at least three replicates.

The *p*H values recorded for leaf extracts were at least 5.0 and in most cases nearly 6.0 (Table 1). The published *pK* values for malate, citrate and isocitrate indicate that complete dissociation of these acids occurs at about *p*H 6.0 (ref. 8). The addition of small amounts of alkali to the extracts resulted in a rapid increase in their *p*H. Thus, by the end of the photoperiod, leaves have deacidified such that there is just sufficient malate to maintain electroneutrality in the leaves by organic acids anions rather than hydroxyl anions. This is very similar to the observation that higher plants generally redress any imbalance between inorganic cations and anions with organic acid, particularly malic acid[9].

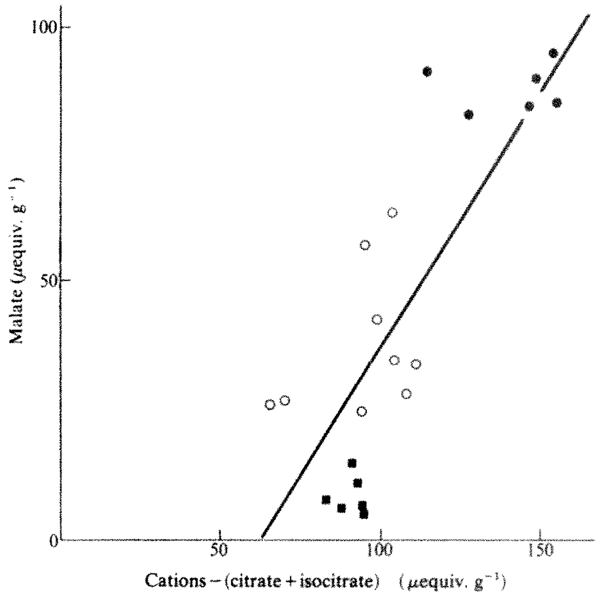

Fig. 1 The amount by which equivalents of cations exceeded citrate and isocitrate in leaves of *K. daigremontiana* and the equivalents of malate in the same leaves measured at the end of three different photoperiods. ●, Long day; ○, pseudolong day; ■, short day. $r = 0.81$, $P > 0.001$; $y = 1.02x - 65.4$.

0028–0836/80/430727—02$01.00

The results presented here suggest that the malate which fluctuates in CAM plants includes a component which is involved in charge balance and this fraction is not available for CAM.

Haplodiploid sex ratios and the mutation rate

R. H. Smith & M. R. Shaw*

Department of Zoology, University of Reading, Reading RG6 2AJ, UK

Deviations from a 1:1 sex ratio in species with haplodiploid genetics are well known and sociobiologists have produced various explanations[1–8], all of which ignore the effect of mutations on haploid viability. Lethal recessive mutations can significantly increase male (haploid) mortality and their effect should be estimated to provide the appropriate null hypothesis with which to compare observed sex ratios before considering any more complex, sociobiological hypothesis. Prospective maternal care[4] and local mate competition[1,2] will also affect sex ratio, but increased haploid mortality due to mutation rate is the only effect common to all haplodiploid species. Using emergence data for some parasitoid species, the rate of mutation to lethal recessives is estimated to be about 0.035 per genome per generation giving a differential haploid mortality of 10%.

The selective forces affecting sex ratio were first considered in detail by Fisher[9] who concluded that an equal investment by a parent in male and female offspring would be evolutionarily stable in a randomly mating population. In arrhenotokous (haplodiploid) species, the primary sex ratio is determined by mated females laying both fertilized (female) and unfertilized (male) eggs. Biased adult sex ratios are well known in groups such as the Hymenoptera and the Acarina; possible evolutionary explanations have included local mate competition[1,2], inbreeding with stochastic effects[3], and a variety of approaches based on asymmetrical relationships[4–8].

All of these explanations ignore a fundamental genetical feature of arrhenotoky which must always contribute to differential survival and hence to a biased sex ratio. A haploid male cannot survive if he carries a lethal recessive mutation and his viability will be severely reduced by non-lethal but deleterious recessive alleles. Mutation seems to have been ignored because the mutation rate per locus per generation is very small, but the mutation rate per genome per generation (m) is vastly greater. For instance, although there are difficulties in estimating m because of large amounts of redundant DNA, it is estimated that the total number of gene loci in man is about 3×10^4 with a mutation rate per locus of 10^{-5}, giving a rate per genome of around 0.3 per generation[10]. Data from consanguineous marriages give a comparable estimate of the mutation rate to lethals and lethal equivalents of 0.06–0.15 per gamete per generation[11]. An estimate of m which may be more relevant to haplodiploid arthropods than data from diplodiploid vertebrates has been obtained for sex-linked lethals in *Drosophila melanogaster*[12]. The mutation rate for recessive lethals is approximately 0.006 per X chromosome per generation or about 0.030 per haploid genome per generation, and the estimate of m is increased to 0.058 lethal equivalents per haploid genome per generation when deleterious recessives are taken into account. In the following discussion, m will be treated as though it refers entirely to lethal recessives.

If mutations occur randomly and independently of one another, the distribution per gamete will be Poisson and the probability that a haploid genome receives no new mutations will be $\exp(-m)$; thus the probability that a haploid male dies as a result of one or more new mutations is $1-\exp(-m)$. An unfertilized egg might also receive with probability 1/2 a lethal recessive present in the heterozygous state in the mother's genome. The probability that a female will not have received any new lethal mutation via either the maternal or the paternal gamete is $\exp(-2m)$. Summing over all previous maternal generations, the probability that a male receives one or more lethal mutations heterozygous in his mother's genome is:

$$(1-\exp(-2m))(\tfrac{1}{2}+\tfrac{1}{4}+\tfrac{1}{8}\ldots) = 1-\exp(-2m)$$

Thus, ignoring dominant lethal mutations which are assumed to be very rare, the probability that a male dies because of either a new mutation or the mutational load in the female genome is:

$$\begin{aligned} P &= (1-\exp(-m)) + (1-\exp(-2m)) \\ &\quad -(1-\exp(-m))(1-\exp(-2m)) \\ &= 1-\exp(-3m) \qquad (1) \end{aligned}$$

Equation (1) can be derived from more than one approach and represents a special case of the balance of selection and mutation for sex-linked recessives[13].

Maynard Smith (personal communication) has suggested that an intuitive interpretation of equation (1) is that the parents of a mixed brood suffer $3m$ new mutations per generation, on average, and all must be eliminated in males. Hence the survival rate of haploids relative to diploids is $\exp(-3m)$ simply as a consequence of the mutation rate, and an initially equal number of fertilized and unfertilized eggs will always lead to an average bias towards females in emergent adults. Numbers seem to be the appropriate measure of investment in the absence of maternal care[5] as there is no reason why fertilized and unfertilized eggs should represent different costs to the mother. Figure 1 shows the expected female : male ratio given an equal initial numerical investment in the sexes plotted against mutation rate per haploid genome m. The female bias obviously increases with m, and the logarithm of the sex ratio is linear in m. Note that the calculations assume that lethal recessive alleles cause no loss of viability in heterozygotes, and that the probability of homozygosity of a lethal allele is negligible (of the order of the mutation rate per locus per generation).

The importance of equation (1) is that it provides the correct null hypothesis against which any sociobiological explanation of a haplodiploid sex ratio should be tested; clearly a 1 : 1 ratio is not the expected consequence of an initially equal numerical investment. The difficulty which arises is that the appropriate

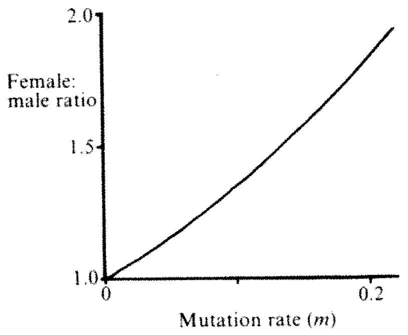

Fig. 1 Expected female : male ratio of adults, given an equal numerical investment in eggs, in relation to mutation rate per haploid genome per generation.

---

Table 1 Differential haploid mortality and estimation of mutation rate (m) in gregarious *Apanteles* species

Species		*A. chares*	*A. ruficrus*	*A. abjectus*	*A. zygaenarum*	Total
All-male broods	Larvae	11	35	11	19	76
	Adults	7	33	8	8	56
Mixed broods	Larvae	6	51	169	335	561
	Adult males	1	4	43	124	172
	Adult females	3	46	103	117	269
Maximum likelihood estimate of haploid : diploid survival:			0.900			
95% confidence interval:			0.838 to 0.957			
Estimated mutation rate per genome per generation:			0.035			
95% confidence interval:			0.015 to 0.059			

Mortality of males and females is estimated using the total emergence data. The mortality considered here relates only to the time between parasite larvae leaving the hosts and emerging as adult parasites from their cocoons. Because mortality in earlier developmental stages has been ignored, m may well have been underestimated. Other mortality factors such as hyperparasitism or starvation have been assumed not to be differential. The maximum likelihood estimate was found by numerical exploration of the likelihood surface. The distribution of twice the log likelihood ratio is chi-squared, allowing the determination of a 95% confidence interval.

null hypothesis cannot be quantified without knowledge of the parameter m in any particular case. An approximate estimate of P can be obtained from the egg to emergent adult mortality in haploid broods of unmated females, but P would be overestimated if there were any mortality factors affecting both haploids and diploids. An unbiased estimate could, in principle, be obtained by cytological examination of eggs in mixed broods, giving a primary sex ratio for comparison with that of emergent adults. In either case it would be necessary to use sufficiently large numbers to obtain a reasonably precise estimate of P because differential mortality of haploids due to mutation is by nature stochastic and sex ratios will be very variable[8].

There seem to be no published data which allow estimation of P by comparing emergence in all-male and in mixed broods because entomologists generally eliminate data from broods where emergence is not close to 100%. However, one of us (M.R.S.) has collected data over a number of years on the emergence of broods of gregarious parasitoid species of the genus *Apanteles* (Hymenoptera: Braconidae) from hosts collected in the field and reared individually in the laboratory. Four out of 22 species produced large all-male broods as well as mixed broods and the data are given in Table 1, along with the consequent estimate of differential haploid mortality P and the mutation rate m. The 95% confidence interval for P shows clearly that haploids suffered significantly greater mortality than diploids. The maximum likelihood estimate $m = 0.035$ is remarkably close to Mukai's value[12] of 0.030–0.058 for *D. melanogaster*, which suggests that these figures are of the correct order of magnitude for haplodiploid arthropods. The consequent differential mortality of haploids relative to diploids is too large to be ignored and therefore the mutation rate is of some significance when formulating the correct null hypothesis associated with a primary sex ratio of 1:1.

It could be argued that factors other than the mutation rate might cause differential mortality in the two sexes (compare with ref. 14), but in haplodiploid species it is difficult to see how differential pre-emergent mortality in identical rearing conditions could be explained other than by lethal or strongly deleterious recessive alleles. Extreme female-biased ratios which cannot be explained by mutation alone are seen where inbreeding is combined with arrhenotoky[1], and any consequent local mate competition between brothers seems to be reduced by producing often only one or two males in a brood. In these circumstances a haploid male is effectively no more than his mother's gamete and fitness is defined as number of female offspring[1,3]. A full theoretical treatment of optimum sex ratios in inbred arrhenotokous species should include not only stochastic survival[3] but also differential haploid mortality as predicted by equation (1). It is interesting that inbreeding in haplodiploids will not increase female mortality through increasing homozygosity of lethal recessives because these are always eliminated in males. Similarly, because every female has a male parent and every male has a female parent, the increase in homozygosity of non-lethal but deleterious recessives will affect both sexes equally at equilibrium. Sex ratio arguments based on parental care[5] are unaffected by the effect discussed here only if differential mutational mortality occurs before the stage at which care is invested. Thus it is clear that mutations can have a significant effect and should therefore be taken into account by sociobiologists considering haplodiploid sex ratios.

We thank John Maynard Smith for noting an error in an earlier version of equation (1), and Roger Mead for advice on exploring messy likelihood functions.

Eyes and classification of malacostracan crustaceans

A. A. Fincham

British Museum (Natural History), Cromwell Road,
London SW7 5BD, UK

During the past 100 yr various methods of classifying mysids, krill, prawns, shrimps, crabs and lobsters have been proposed, including the use of behaviour, gill type and the relationship of the carapace with the head and the thoracic segments. At least two factors have been ignored in all these schemes—larval characters and optical mechanisms. A survey of malacostracan crustaceans reveals three types of optical mechanism. The simplest uses apposition optics, often with hexagonal facets, and is found in all decapod larvae and most adult brachyuran crabs. Refracting, superposition eyes with hexagonal facets occur in mysids and euphausids, and reflecting, superposition eyes with square facets using mirror optics are found in adult prawns, shrimps, macrurans such as lobsters, and dromiid 'crabs'. Artificial relationships have been imposed on malacostracan crustaceans by a failure to incorporate eye structure in schemes of classification. Once evolved, eye structure is a stable character and provides evidence for the continued grouping together of penaeid, caridean and stenopid prawns and shrimps; it demonstrates their affinity with lobsters and other Macrura, and confirms the unity of a re-defined Brachyura and the weakness of the Anomura as a coherent taxon. •

0028–0836/80/430729—03$01.00

The classification of decapods has been based on adult characters. Boas[1] and Borradaile[2] used behaviour, Bate[4] and Burkenroad[3] gills, Laurent[5] structure of the head and its relationship with the carapace together with the degree of development before eclosion, and Guinot[6] the position of genital openings. It is difficult to frame diagnoses for larval groups using such frameworks of higher taxa based solely on characters of the adult. Larval characters have not been included in these schemes, yet ideally a natural classification should encompass both adult and larval stages[7].

Recent work on decapod development and larval adaptation[8–11] and optical mechanism in crustacean eyes[12–14] has led to a re-examination of decapod relationships. It was assumed that the compound eyes of crustaceans used the same refracting, superposition optical mechanism described by Exner[15] for nocturnal insects. Kuiper[16] pointed out that the peripheral optical elements in crustaceans did not have a sufficiently high refractive index and that they were too uniform to provide the continuous bending necessary. Vogt[17] and Land[12] independently discovered that superposition optics in certain Crustacea were achieved not by lenses but by mirrors and reflection. Grenacher[18] reported that individual facets were square in the compound eyes of prawns and shrimps and certain other groups of Macrura, but did not suggest that this was linked with a special optical mechanism. Square facets are, in fact, essential to the mirror mechanism[19,20]. Compound eyes in most malacostracans, including all decapod larvae and adult Brachyura, have hexagonal facets and the optical mechanism is one of apposition with no clear zone, a mosaic image being built up from indivdual ommatidia[21]. Syncarida, Hoplocarida and most Peracarida with well-developed compound eyes such as amphipods and isopods use apposition optics, but loose packing of the surface elements results in circular or irregularly shaped facets rather than closely packed hexagonal facets.

There are at least two exceptions to this usual apposition condition. The first includes mysids and euphausids, once classified together as the Schizopoda on the basis of biramous limbs retained throughout life. These groups are now placed respectively in the Peracarida (free posterior carapace when present and oostegites forming a marsupium) and Eucarida (carapace fused to all thoracic segments and often with a long planktonic development). However, Land[13] reported that mysids and euphausids both have refracting, superposition eyes in which the essential clear zone is present together with crystalline refractive cones and hexagonal facets. This may be a case simply of convergence by mysids and euphausids, but optical mechanism needs to be taken into account in future phylogenetic studies of these shrimp-like groups, especially in view of the suggestion[22] that mysid-like types may have given rise to euphausids and to decapods. The presence of a marsupium seems inadequate as evidence for the retention of such disparate orders as amphipods, isopods, cumaceans, tanaids and mysids together in the Peracarida.

Table 1. Eye structure and classification of selected recent Malacostraca

Taxon	Adult eye type
Subclass Malacostraca	
Series Eumalacostraca	
Superorder Peracarida	
Order Mysidacea	2
Superorder Eucarida	
Order Euphausiacea	2
Order Decapoda	
(Suborder Natantia)	
Section Penaeidea	3
Section Caridea	3
Section Stenopodidea	3
(Suborder Reptantia)	
Section Macrura	
Superfamily Eryonoidea	? (eyes reduced or absent)
Superfamily Scyllaroidea	3
Superfamily Nephropoidea	3
Superfamily Thalassinoidea	1 (eyes poorly developed or reduced)
(Section Anomura)	
Superfamily Galatheoidea	3
Superfamily Dromioidea	3
Superfamily Homoloidea	3 (see text for discussion)
Superfamily Paguroidea	1
Superfamily Hippoidea	1
Section Brachyura	
Subsection Gymnopleura	1
Subsection Oxystomata	1
Subsection Brachygnatha	
Superfamily Brachyrhynchoidea	1
Superfamily Oxyrhynchoidea	1

1, Apposition optics, hexagonal facets; 2, superposition refracting optics, hexagonal facets; 3, superposition reflecting optics, square facets. Taxa of dubious validity are given in parentheses.

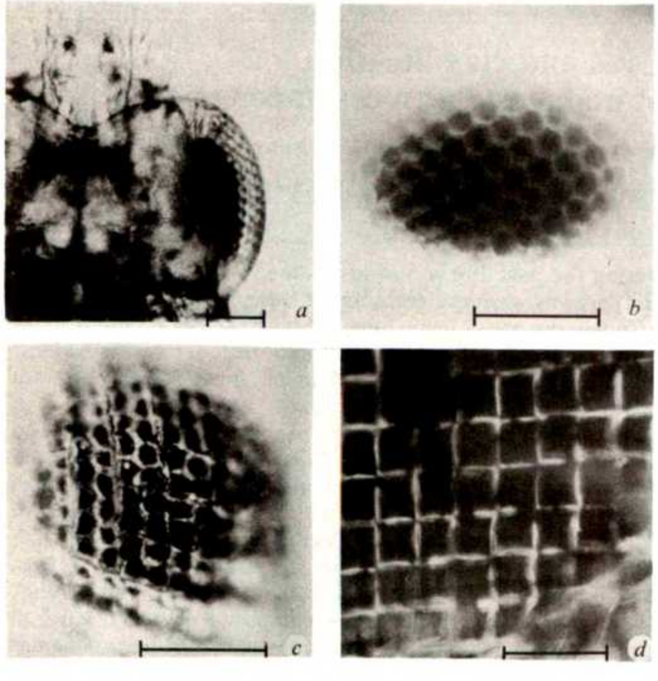

Fig. 1 *Palaemonetes* (*Palaemonetes*) *varians* (Leach, 1814). Stage 1 larva: *a*, dorsal view of compound apposition eye; *b*, surface view of hexagonal eye facets. Stage 5 post-larva: *c*, eye facets 'squaring off'. Adult: *d*, square facets of superposition reflecting eye. Bar scales represent 0.1 mm. (Photographs: Peter York BM(NH).)

The second exception to the usual apposition form of crustacean compound eye is superposition, represented by reflecting eyes with square facets which are found only in adult prawns and shrimps, Macrura and certain Anomura. The larvae of these groups begin their planktonic existence with hexagonal-faceted apposition eyes. There is such a great change in life style and morphology at metamorphosis that this would seem to be the most likely time to convert hexagonal facets to square facets on the surface of the compound eye in those groups which have this form in the adult. However, in the ditch shrimp *Palaemonetes* (*Palaemonetes*) *varians* (Leach, 1814) and other palaemonids[9–11], there is an hexagonal array in all larval stages (Fig. 1*a*, *b*) and the facets remain hexagonal until the fifth post-larval moult when the carapace is about 2.8 mm long. There is then a gradual 'squaring off' (Fig. 1*c*) of the hexagons until the juveniles reach a carapace length of about 5.8 mm. The facets are then perfectly square and arranged in an orthogonal matrix (Fig. 1*d*). The square-faceted eyes of the adult may still function as apposition eyes in well-lit conditions by migration of proximal and distal pigment cells across the clear zone (M. F. Land, personal communication).

Not all decapods develop mirror optics. Adult crabs retain hexagonal-faceted apposition eyes, in common with many other groups of crustaceans with compound eyes. An analysis of adult eye type of selected malacostracan groups held in the Crustacea collection at the British Museum (Natural History) is presented in Table 1. Natantia and Macrura with well-developed eyes have at least part of the compound eye composed of square facets. Those burrowing macrurans that have small or poorly developed eyes, such as members of the superfamily Thalassinoidea, have hexagonal facets. Section Anomura lies uneasily between the Macrura and Brachyura and contains a wide variety of forms. This is shown clearly by eye structure with square facets in superfamily Galatheoidea and hexagonal facets in superfamilies Paguroidea and Hippoidea. All Brachyura have hexagonal facets with the exception of the Dromiacea in which there are square facets distally with hexagons in the lateral field. This transference of Dromiacea from the Brachyura is strongly supported by larval evidence for the superfamily Dromioidea[7]. However, Rice[23] suggests, again on the evidence of larvae, that the Dromiacea are polyphyletic and that the homolid Dromiacea and raninids of the subsection Gymnopleura are closely related and near to the stem from which the higher Brachyura evolved. Homoloidea would therefore be alone among the Brachyura in having evolved independently square-faceted eyes.

The oldest decapod fossil material[24] comes from the Permo-Trias and includes *Antrimpos* Munster, 1839 of the natant family Penaeidae and *Protoclytiopsis* Birshteyn, 1958 of the astacid family Erymidae (Brachyura are not recorded until the Jurassic). Fossil evidence is equivocal about the structure of eyes as preservation is generally poor, but recent penaeids and lobsters have square-faceted eyes in the adult. Reflecting superposition eyes are found only in prawns, shrimps, long-bodied macrurans and some anomurans. Such an unusual eye type suggests a strong phylogenetic relationship and not simply convergence. As it is likely that this optical mechanism arose early in decapod evolution, eye structure will be useful as an indicator of affinity. This is turn provides a strong case for maintaining penaeid, caridean and stenopid prawns as a group, in contrast to recent proposals[5] for their division, and also emphasizes their link with the Macrura. Suborder Reptantia becomes an untenable taxon containing a mixture of eye types. Anomura has long been recognized as a taxon of convenience[7] rather than a natural grouping and its constituent groups should be redistributed (Table 1). On the basis of eye design the Decapoda should be divided into only two groups—Natantia, Macrura, Galatheoidea, Dromioidea and Homoloidea which have the unique reflecting superposition eye mechanism and the true Brachyura in which, together with the Paguroidea and the Hippoidea, the apposition eye present in the larva is retained throughout life.

Modulation of lateral geniculate neurone excitability by noradrenaline microiontophoresis or locus coeruleus stimulation

Michael A. Rogawski & George K. Aghajanian

Departments of Pharmacology and Psychiatry,
Yale University School of Medicine and the Connecticut Health Center,
New Haven, Connecticut 06510

The dorsal lateral geniculate nucleus (LGNd) receives afferents from the brainstem which regulate its capacity to transmit visual information from the retina to the striate cortex[1]. One such pathway consists of noradrenaline (NA)-containing fibres originating in the locus coeruleus (LC). These provide a dense, uniform, noradrenergic innervation of the LGNd[2]. Electrical stimulation in the LC region has been reported to enhance the responsiveness of LGNd neurones to afferent excitation[3]. Although this effect was abolished when brain NA stores were pharmacologically depleted, it was not established as a direct action of NA on LGNd neurones because of the widespread distribution of LC fibres to many parts of the brain and the long latency of the response. Recently, we observed that NA, applied locally by microiontophoresis with low ejection currents, produced a delayed increase in the firing rate of most spontaneously active LGNd neurones, an effect selectively blocked by α-adrenoceptor antagonists[4]. We show here that microiontophoretic NA can mimic the ability of LC stimulation to enhance the synaptic excitation of LGNd neurones. As neither NA nor LC stimulation activated LGNd neurones in the absence of synaptic or glutamate-induced excitation, both appear to act through a neuromodulatory mechanism. The postsynaptic α-adrenoceptor antagonist WB-4101[5] blocks the facilitation produced by locally applied NA and by coeruleo-geniculate pathway stimulation, providing evidence for pharmacological identity of the two effects.

Extracellular recordings were obtained from single neurones in the LGNd of male albino rats anaesthetized with chloral hydrate. Microiontophoresis was carried out with blunt five-barrel micropipettes to which a fine glass recording pipette was cemented. The electrode assembly was positioned 4.0 mm anterior to lambda and 3.5–4.0 mm lateral to the midline and lowered approximately 4.0 mm below the cortical surface until the LGNd was recognized by cellular responses to movement of a light beam across the visual field. To activate LGNd neurones orthodromically, some animals had a stimulating electrode implanted in the optic chiasm. Further experimental details are given in Fig. 1 legend.

First we examined the effects of iontophoretically applied NA on the response of LGNd neurones to stimulation of the optic chiasm. Suprathreshold shocks usually evoked a single discharge with latency 2–4 ms followed by a period of inhibition typically lasting 70–230 ms. Late activity, consisting of bursts of up to four or five spikes at regular intervals following the inhibitory pause, was exhibited by most cells. This response pattern is characteristic of geniculocortical relay neurones (P-cells)[6].

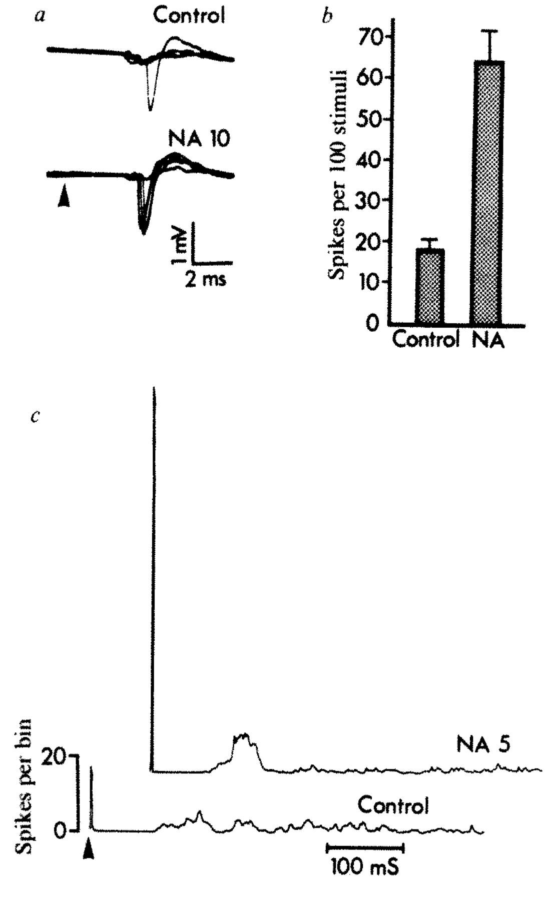

Fig. 1 NA facilitation of unitary action potentials in the LGNd evoked by optic chiasm stimulation. In *a*, subthreshold shocks were applied to the optic chiasm with a concentric bipolar stimulating electrode (SNE-100, Rhodes Medical Instruments) at a frequency of 1 Hz. The stimulus strength was adjusted so that approximately one out of five stimuli produced a short latency spike discharge (upper trace). For the cell shown, 0.5 mA peak to peak, 0.1 ms duration biphasic rectangular pulses satisfied this condition. The position of the stimulus is indicated on the storage oscilloscope record by an arrowhead. Shock artefacts were electronically blanked in these traces. During NA iontophoresis (10 nA, 60 s), four out of five stimuli produce spikes in identical stimulation conditions (lower trace). Five superimposed sweeps. Positivity is upward. *b*, Summary of data from five cells in four animals. The experimental procedure was as in *a* except that each unit was tested with 100 shocks before and during the iontophoresis of NA at 5–20 nA for 2–5 min and this was repeated 2–8 times per cell. Data are the mean ±s.e.m. of averages for each cell. *c*, Post-stimulus time histogram demonstrating the effect of NA on the early and late responses to optic chiasm stimulation. As well as facilitating the initial spike response (vertical line at left of each histogram), NA (5 nA, 50 s) causes a shift in the late activity to a peak of high probability firing immediately following the inhibitory pause (upper histogram). Histograms were generated with a Nicolet 1072 signal averager. Each histogram represents the summed responses to 100 stimuli delivered at 1 Hz. Stimulation parameters: 1 mA, 0.15 ms. Bin width: 2 ms. In this and subsequent experiments, Sprague–Dawley rats weighing 240–300 g were used. The animals were anaesthetized with chloral hydrate (400 mg kg^{-1}, intraperitoneally); additional anaesthetic injections were given as necessary. Core temperature (monitored with a rectal probe) was maintained above 36° C with a heating pad. Extracellular unitary action potentials were recorded using microelectrode assemblies consisting of a five-barrel micropipette array (15–25 μm in diameter) to which a fine single-barrel recording electrode (~1 μm tip diameter) was affixed with dental acrylic. The tip of the recording electrode extended 20–40 μm beyond the iontophoresis barrels. The recording electrode contained 2% pontamine sky blue in 2 M NaCl and typically had an impedance of 6–12 MΩ. Solutions used for microiontophoresis were: L-noradrenaline D-bitartrate (Regis), 0.1 M, *p*H 4; serotonin creatinine sulphate (Regis), 0.04 M, *p*H 4; L-glutamic acid monosodium salt (Sigma), 0.5 M, *p*H 8; picrotoxin (Sigma), saturated solution in 0.15 M NaCl, *p*H 4; and WB-4101 (2-([2′,6′-dimethoxy]phenoxyethylamino)methylbenzodioxan HCl; WB Pharmaceuticals), 0.1 M, *p*H 4. A retaining current of −10 nA was applied to the iontophoresis barrels between periods of ejection except when glutamate was used in which case the backing current was +10 nA. To minimize polarization artefacts, a balancing current was continuously passed through an electrode barrel containing 4 M NaCl. Electrode placement was verified by ejecting dye iontophoretically from the recording pipette and identifying the spot thus produced in brain sections prepared by routine histological procedures.

Local application of NA by microiontophoresis caused an increase in the probability of spike generation during the early phase of the response to chiasmatic stimulation (Fig. 1*a–c*). In addition, late spikes tended to occur at earlier times following the stimulus and frequently a peak of high probability late firing was observed immediately after the inhibitory pause (Fig. 1*c*). To obtain these effects, NA was applied with iontophoretic currents of 5–20 nA for periods of 1–5 min. (Low iontophoretic currents were exclusively used because recently[4] we found that higher currents may produce a loss of responsiveness or have weak depressant effects. This may, in part, account for the variable effects of NA noted by previous investigators[7–9].) In some cases the stimulus intensity was adjusted so that approximately 20% of the stimuli produced initial spikes. In these conditions, iontophoresis of NA resulted in a 255% increase in the frequency of spike generation (Fig. 1*a*, *b*). In contrast, in paired comparisons with NA, serotonin, another monoamine present within axon terminals in the LGNd[10,11], always depressed responses to optic chiasm stimulation (5–10 nA; six cells), as has been reported by others[7,8].

These results suggested that NA could facilitate the responsiveness of LGNd relay neurones to retinal ganglion cell excitation and ultimately enhance signal transfer from retina to visual cortex. To determine whether this was due to a direct excitatory action of NA or to an interaction of the amine with afferent synaptic activation, ongoing tonic excitation of the relay cells was suppressed by section of the optic nerve behind the globe of each eye[12,13]. Following this, NA generally failed to excite silent LGNd units although the same cells could be activated easily by iontophoresis of the excitatory amino acid glutamate. Thus NA, in contrast to glutamate, did not seem to be a direct excitant. However, low currents of NA (2–15 nA) were able to facilitate the excitatory action of the amino acid dramatically. Iontophoresis of glutamate at currents which produced little or no excitation before application of NA, resulted, with concurrent ejection of NA, in marked activation of firing (22 cells in 14 rats) (Fig. 2*a*). The effect of NA took 30–90 s to develop and lasted up to 6 min following cessation of the ejection.

The ability of NA to produce enhanced responsiveness to glutamate suggested that NA could facilitate the general excitability of relay neurones, presumably through a postsynaptic mechanism. However, it has been speculated that the facilitatory effects of conditioning LC stimulation are due to suppression of inhibitory interneurones[3] and it is possible that locally applied NA acts indirectly as well. Two populations of local inhibitory elements seem to synapse on P-cells: perigeniculate reticular (PGR) neurones located in the thalamic reticular nucleus[14] and intrinsic interneurones (I-cells)[15]. Arguments against the participation of PGR neurones in the facilitatory action of iontophoretic NA are: first, NA generally produced only a small decrease in the postexcitation inhibitory period believed to be mediated by PGR cells, yet the responsiveness, especially of the short latency spike, was markedly facilitated. Second, the activity of NA was independent of the proximity of the iontophoretic pipette to the reticular nucleus which is situated rostral to the geniculate, as much as 1.5 mm anterior to the caudal extent of the LGNd[14].

However, it is conceivable that I-cells could mediate the action of iontophoretic NA. Recent evidence suggests that γ-aminobutyric acid (GABA) is the neurotransmitter utilized by these cells[16]. Therefore, if the facilitatory action of NA on relay neurones was due to depression of I-cell firing or suppression of GABA release from presynaptic I-cell dendrites[17], blockade of GABA-mediated neurotransmission should produce a similar effect. In preliminary experiments, we found that the GABA antagonist picrotoxin was able to block GABA-induced depression of spontaneously active LGNd neurones when iontophoresed with currents of 15–20 nA for 1–5 min. Picrotoxin was then applied to 'silent' neurones in optic nerve-sectioned animals. Even with prolonged administration (up to 25 min), the GABA antagonist (15–50 nA) did not produce a facilitation of the response to glutamate (five cells) (Fig. 2*b*).

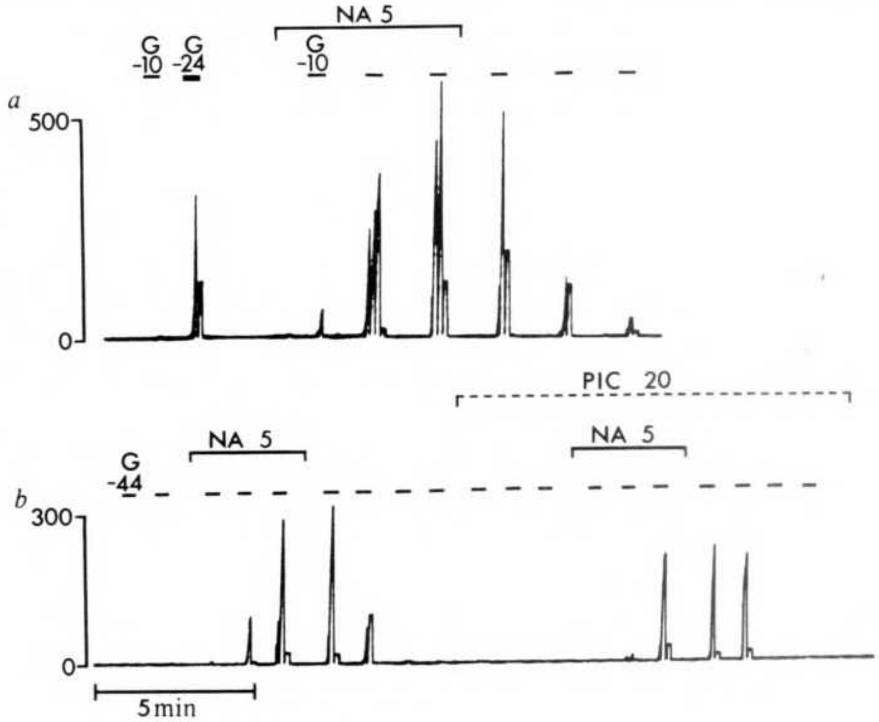

Fig. 2 NA facilitation of glutamate (G)-induced excitation in conditions of suppressed spontaneous activity. *a*, Constant current, 30-s pulses of G were applied to a 'silent' neurone in an acutely optic nerve-sectioned rat. NA causes a reversible potentiation of the response to subthreshold G. In this and subsequent examples, silent neurones were identified by optic chiasm stimulation or iontophoresis of G. Unit activity is expressed as an average rate histogram where the ordinate indicates the number of spikes per 10-s epoch. Duration of iontophoretic ejections are indicated by bars above each record. Numbers refer to iontophoretic currents in nA. *b*, Response of another cell demonstrating that NA but not picrotoxin (PIC) facilitates the action of G (20-s pulses). Note that during the PIC ejection the response to NA is slightly diminished rather than enhanced as would be predicted if the cell were under tonic GABA inhibition.

These observations suggest that the facilitatory action of NA is not mediated transynaptically via adjacent interneurones, although suppression of either class of inhibitory neurone could play a role in the overall physiological action of the coeruleo-geniculate pathway.

To confirm that activity in the coeruleo-geniculate pathway can produce similar effects on cellular excitability as iontophoretically applied NA, we examined the response of LGNd neurones to electrical stimulation in the region of the LC. Concentric bipolar stimulating electrodes were implanted in or

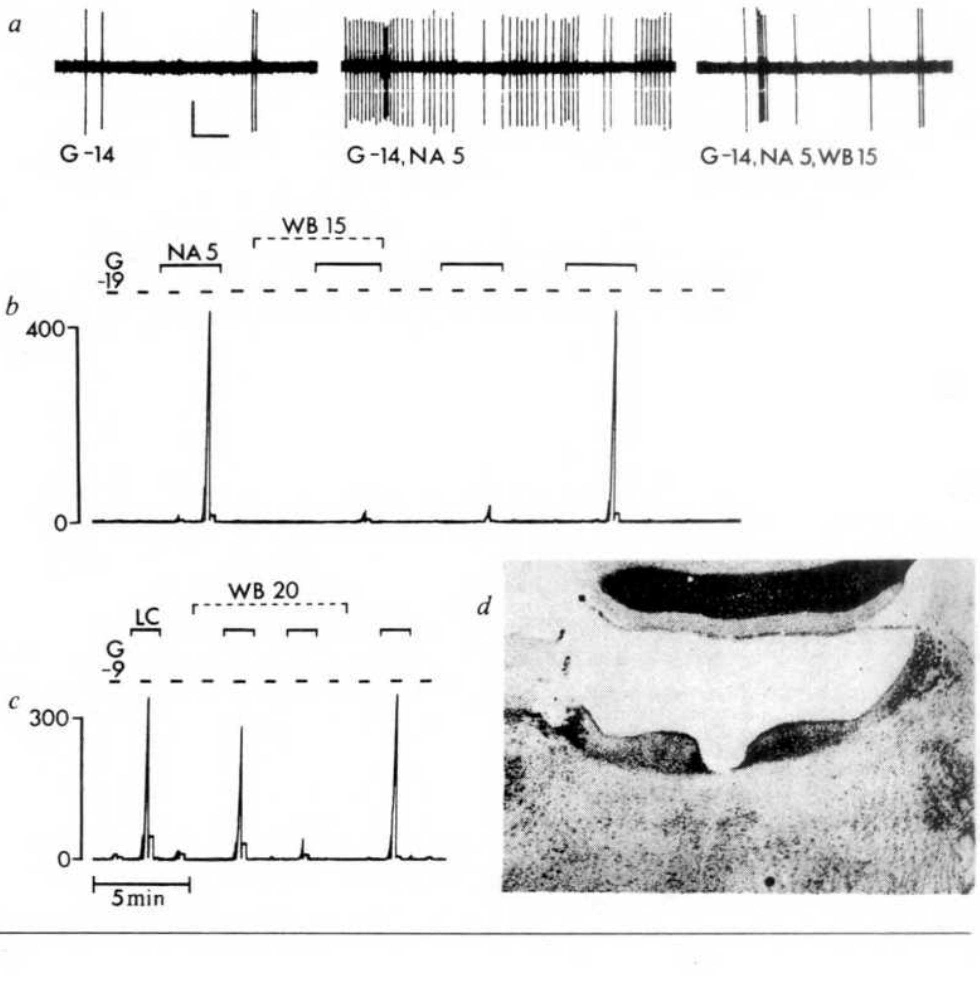

Fig. 3 Blockade by WB-4101 (WB) of the facilitatory actions of NA (*a*, *b*) and LC stimulation (*c*). *a*, Storage oscilloscope tracings of the extracellular spike records of a 'silent' unit in an acutely optic nerve-sectioned rat. The cell was activated by glutamate (G) (left panel) and this response was enhanced by NA (middle panel). WB applied for 16 min antagonized the effect of NA (right panel). Note that the spike amplitude is unaltered during prolonged application of WB. *b*, Rate histogram demonstrating the effect of WB on another cell. *c*, Blockade by WB of LC stimulation-induced facilitation of G in a third cell. LC stimulation does not activate the cell in the absence of G. Stimulation parameters: 0.5 mA, 1 ms, 10 Hz (NE-100 electrode, Rhodes Medical Instruments). *d*, Electrolytic lesion produced at tip of stimulating electrode (20 μA for 20 s) indicating typical placement in LC. Cresyl violet stained, 50-μm thick coronal section of formalin-fixed tissue. Position of the electrode tract is marked with an arrow. The arrowhead points to the contralateral LC. V, IVth ventricle. Calibration bar, 1 mm.

alongside the ipsilateral LC (Fig. 3*d*). Spontaneously active cells in normal animals invariably responded to trains of stimuli applied to the LC (1 ms duration, 10 Hz, 0.3–0.8 mA) with a dramatic increase in firing rate. As with NA iontophoresis, the effect of LC stimulation was delayed in onset (requiring 1–30 s to attain a peak response) and sustained beyond the duration of the stimulus (up to 20 s). In contrast to the effects on spontaneously active cells, 'silent' cells in optic nerve-sectioned animals were not activated directly by LC stimulation. However, as with iontophoretic NA, LC stimulation markedly enhanced the excitatory action of glutamate (five cells) (Fig. 3*c*).

For further evidence that LC stimulation and iontophoretic NA evoke identical postsynaptic actions, we examined whether the enhanced excitability each produced was sensitive to the α-adrenoceptor antagonist WB-4101. In four cells, WB-4101 at currents of 15–30 nA produced a blockade of the facilitatory action of NA (5 nA) (Fig. 3*b*). Spike amplitude was unaffected by WB-4101 (Fig. 3*a*) suggesting that local anaesthetic effects do not occur at the doses used. Similar iontophoretic currents also markedly attenuated the facilitatory action of LC stimulation (three cells) (Fig. 3*c*). As both the responses to LC stimulation and iontophoretic NA are antagonized by WB-4101, we conclude that the effects of stimulation of the LC are mediated by NA released from the terminals of noradrenergic fibres located in the vicinity of LGNd neurones.

These results support the concept that brain noradrenergic neurones act primarily to modify the responsiveness of their target cells to convergent inputs carried by other afferent channels[18]. This phenomenon has been termed 'neuromodulation' to distinguish it from the action of the conventional neurotransmitters which produce direct excitation or inhibition[19,20]. Modulatory transmitters typically have little effect on cellular activity in themselves and the changes in excitability they produce are usually slow to develop and prolonged in duration. The properties of NA action in the LGNd are those of neuromodulation and exemplify a common neuromodulatory role of monoaminergic neurotransmitters in invertebrate[21–25] and vertebrate[18,26–30] nervous systems. However, an understanding of the detailed cellular mechanisms mediating the facilitatory actions of NA on LGNd neurones requires analysis with intracellular recording techniques.

ATP mediates rapid reversal of cyclic GMP phosphodiesterase activation in visual receptor membranes

P. A. Liebman* & E. N. Pugh Jr†

* Department of Anatomy and †Department of Psychology,
University of Pennsylvania, Philadelphia, Pennsylvania 19104

Weak or strong lights will activate visual receptor rod disk membrane (RDM) cyclic GMP phosphodiesterase (PDE) in the presence of GTP cofactor[1,2]. A similarly activated GTPase can exhaust small amounts of initially present GTP to deactivate the PDE. However, further additions of GTP reactivate PDE without more light, and deactivation by simple GTP depletion takes minutes or more, even at GTP concentrations 100 to 1,000 times lower than physiological levels[1,2]. A more rapid deactivation mechanism must exist if modulation of cytoplasmic cyclic GMP by light is to play a role on the time scale (seconds) of events in vision[3,4]. We report here that ATP is essential to such rapid control and that its presence permits multiple cycles of activation–deactivation. The complete control mechanism seems to involve gamma phosphate transfer from both ATP and GTP.

Bovine RDM suspensions were prepared from fresh or frozen retinas in IR light using standard procedures[5]. Cyclic GMP PDE activity was measured continuously using a fast recording *p*H meter to assay the stoichiometric production of protons[6], in the reaction

$$H_2O + cGMP^{-1} \rightleftharpoons 5'GMP^{-2} + H^+$$

A xenon photoflash equipped with calibrated attenuator filters was used to activate PDE. Light titration of the hydrolytic velocity with GTP cofactor showed saturation kinetics with half-maximal activation at bleaches of 1 part in 10,000–20,000. For all experiments reported here, the activating bleach was kept at 1 part per 50,000, within the linear range of the hydrolytic velocity response to the bleaching stimulus[3].

Figure 1, curve *a*, shows the formation of protons associated with cyclic GMP hydrolysis on flash activation in the presence of 60 μM GTP. Given sufficient substrate, cyclic GMP, the hydrolysis seen in curve *a* continues for more than 2 min while curves *b* and *c* show that a pulse of 8 μM ATP can arrest or 'quench' the activity within a few seconds anytime after the light activation. If this quenching effect were due to ATP competitive inhibition at the GTP binding site, one might expect ATP to be even more effective if added before the flash. This is not the case as seen in curve *d*. Activation takes place just as in the previous curves and is quenched with the same delay. Curve *e* shows that 8 μM ATP alone cannot support activation but that quenching has still occurred, as subsequent addition of GTP at times exceeding the characteristic quench delay shown in *b*, *c* and *d* can no longer produce activation. Yet after the GTP is available, a flash again produces a normal activation–quench cycle. Curve *f* and its derivative, *g*, show that this cycle can be repeated indefinitely.

In previous work, it was shown that the GTP analogues, GMP-PNP and GMP-PCP, are efficient cofactors of activation[1,2]. However, Fig. 2*A* shows that activation with GMP-PNP is not efficiently quenched by ATP (compare curves *a* and *e*). Nor is it possible to quench GTP-mediated activation using the ATP analogue, AMP-PNP (curve *b*). Instead, AMP-PNP competitively blocks the action of ATP (curve *d*).

Figure 2*B* shows that the efficiency of quench increases with ATP concentration. We find (Fig. 2*C*) that GTP alone can quench PDE activity, though both required concentration and maximum effectiveness show it to be a poor substitute for ATP. The quench process has a K_m of about 4 μM for ATP and about

0028–0836/80/430734—03$01.00

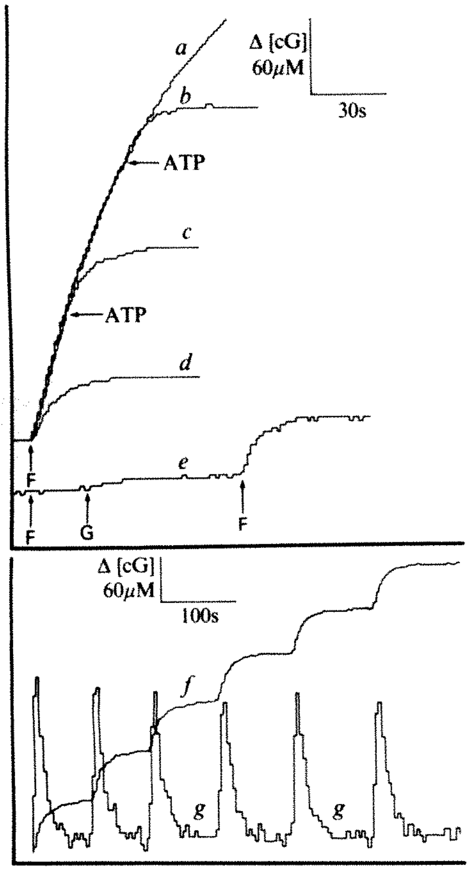

Fig. 1 Stoichiometric proton release with cyclic GMP hydrolysis following a flash, F, of 1-ms duration that bleaches 2.4×10^{-5} rhodopsin in presence of 60 µM GTP cofactor (*a–d*). Curves *b–d*, 8 µM ATP was injected at 25 s, 15 s or −5 s. Curve *e*, no GTP present until G, 23 s after flash, but ATP present at −5 s before flash. Curve *f*, cyclic GMP hydrolytic response to series of flashes in presence of 1 mM GTP/3 mM Mg-ATP. Curve *g*, derivative of trace *f* showing rise and fall of light-activated enzyme velocity. All traces from separate disk membrane samples containing 5 µM rhodopsin, 4 mM cyclic GMP, 2 mM $MgCl_2$, 150 mM KCl, 20 mM HEPES, 1 mM dithiothreitol, *p*H 7.9, $T = 32.4$ °C. Buffer limited *p*H change to 0.1 unit per 1 mmol H^+ added. 100 µM HCl or cyclic GMP gave equal deflections after hydrolysis of the latter in activated preparations. Membranes were from frozen retinas for this and subsequent figures. Fresh material gave nearly identical results.

1,400 µM for GTP. In addition, the V_{max} ratio of ATP to GTP in this process is about 2. Thus, the specificity V_{max}/K_m for quenching is about 700 times greater for ATP than for GTP.

It has been shown previously that rhodopsin is phosphorylated on bleaching in the presence of a membrane-bound kinase and ATP[7,8]. The K_m and specificity of this kinase for both ATP and GTP are close to those of the quenching process reported here[9]. No other protein is known to be phosphorylated on RDMs. We propose that the quenching process reported here, which terminates the potency of bleached rhodopsin to activate PDE, is opsin phosphorylation. A function for opsin phosphorylation has not been previously established.

The results of this and earlier work[2,3] suggest that light initiates a cycle of activation and deactivation of PDE according to the following scheme:

$$\text{Activation}\begin{cases}(1)\quad h\nu + \text{R} \rightarrow \text{R}^* \\ (2)\quad \text{R}^* + \text{D} \rightleftharpoons \text{R}^*\text{D} \\ (3)\quad \text{R}^*\text{D} + \text{GTP} \rightleftharpoons \text{R}^*\text{DGTP} \rightleftharpoons \text{R}^* + \text{D}^*\text{GTP}\end{cases}$$

$$\text{D}^*\text{GTP}\ \begin{matrix}\text{cyclic GMP}^{-1}\\ \searrow 5'\text{GMP}^{-2} + \text{H}^+\end{matrix}$$

$$\text{Deactivation}\begin{cases}(4)\quad \text{R}^* + n\text{ATP} \xrightarrow[\text{kinase}]{} \text{RP}_n + n\text{ADP} \\ (5)\quad \text{D}^*\text{GTP} \xrightarrow[\text{G'ase}]{} \text{D} + \text{GDP} + \text{P}\end{cases}$$

R* is the long-lived activator formed by the bleaching of rhodopsin, R. It can be quickly made inactive by phosphorylation [reaction (4)] as suggested by this report. While active, it can bind an inactive PDE molecule, D, and catalyse the binding of GTP to it or to a separate GTP-binding protein which in turn activates D by complexing with it to yield D*GTP (ref. 10). The active diesterase, D*GTP, then hydrolyses cyclic GMP until it also is deactivated by action of a GTPase that is specific for the bound form of GTP.

In this scheme, it is apparent why GTPase alone is not capable of deactivating D*, for the trigger molecule, R*, is still present and able to mediate activation again and again until it is deactivated by the kinase reaction. The gamma-phosphate lability of both GTP and ATP is required for fully reversible PDE activity: AMP-PNP does not permit R* to be phosphorylated and GMP-PNP does not permit GTPase to release the bound cofactor to terminate D* activity. After the activator, R*, is quenched, a GTPase specific for the bound GTP of the complex D*GTP

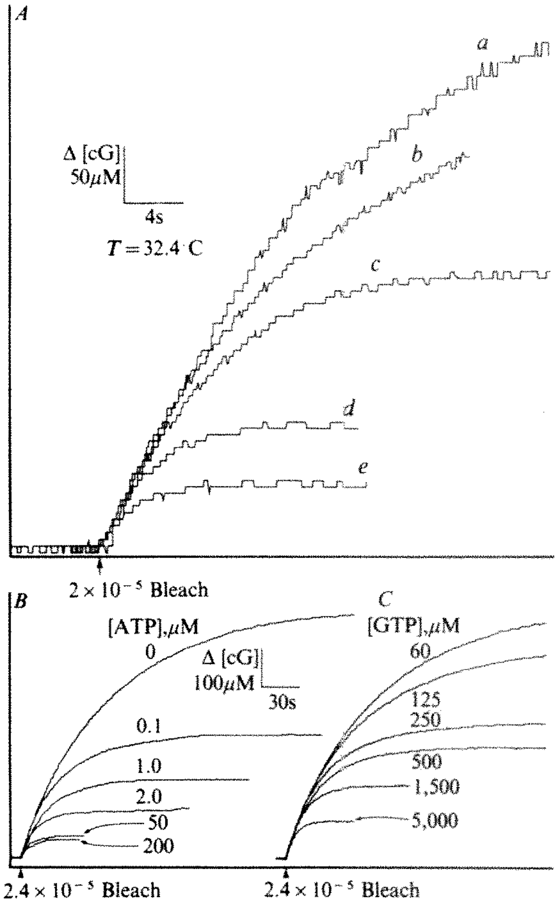

Fig. 2 *A*, Effect of ATP and GTP analogues on quench. Curve *a*, 500 µM GMP-PNP + 5 µM ATP; curve *b*, 50 µM GTP + 100 µM AMP-PNP; curve *c*, 50 µM GTP; curve *d*, 50 µM GTP + 5 µM ATP + 100 µM AMP-PNP; curve *e*, 50 µM GTP + 5 µM ATP. *B*, ATP titration of quench effect. The parameter labelling the curve is the concentration of ATP, in µM. 60 µM GTP present for all curves and ATP added 2 s before flash. *C*, GTP titration of quench effect (no ATP present). Flash F, as described in Fig. 1 legend.

could terminate activity even in the presence of large amounts of ambient but unbound GTP. Thus, the deactivator role of GTPase is not mediated via the cytoplasmic GTP depletion implied by previous work[1,2].

It is worthwhile to compare the mechanism proposed here with that of hormonally activated adenylate cyclase, also known to require GTP cofactor[11]. Both systems activate effectively in GMP-PNP[12] and neither can deactivate without the action of a membrane-bound GTPase[13]. As in RDM, however, it should not be possible for GTPase to deactivate the cyclase mechanism alone. The hormone–receptor complex needs to be deactivated as well. Reduction of blood hormone concentration alone might in some cases lead to adequate dissociation of the hormone–receptor complex to complete the deactivation on a time scale appropriate to needs for control. However, to achieve more rapid regulation, a hormone–receptor might be quenched by phosphorylation in a process similar to that which quenches the capacity of rhodopsin to activate RDM phosphodiesterase.

High-resolution phosphorous (^{31}P)-NMR spectra of biological molecules provide detailed information about the metabolism of living systems[1–4]. Although the NMR method is non-destructive, all studies so far, with two exceptions[5,6], have been carried out on excised, perfused organs and tissues or have required some form of surgery[2] for *in situ* measurements. The use of 'surface' radiofrequency coils[5] does not require surgery but is best suited for tissues close to the surface of the animals. We describe here 'topical magnetic resonance'—a new, non-surgical method for acquiring ^{31}P-NMR spectra from a selected, localized place deep within an animal by modifying the main magnetic field, B_0, using only static-field gradients. The method is conceptually similar to one spin-imaging method[7] but primarily provides biochemical rather than spatial information. This new technique can be used in fundamental investigations into living systems, clinical diagnosis and the estimation of the efficacy of drug therapy.

To limit the volume from which the high-resolution ^{31}P-NMR signals are received, the effective homogeneous volume of B_0 must be reduced and centred on the region of interest. The topical magnetic resonance (TMR) technique consists of superimposing high-order, static magnetic field gradients on to B_0 via room-temperature magnetic field profiling coils mounted coaxially inside the bore of the magnet.

The magnetic field, $\beta(r, \theta)$, generated by a profile-coil system with azimuthal symmetry, can be described in terms of a Taylor expansion about the origin[8],

$$\beta(r, \theta) = \sum_{n=0}^{\infty} \beta_n r^n P_n(\cos\theta) \qquad (1)$$

where $\beta(r, \theta)$ is the magnetic field at (r, θ), $P_n(\cos\theta)$ are the Legendre polynomials of order n, and the field derivatives, β_n, are defined by the coil geometry and the d.c. current flowing through the coil system. A sensitive volume of homogeneous field can be delineated, centred on the origin and surrounded by inhomogeneous field gradients. A detailed discussion of the rationale of coil design will be given elsewhere.

The description of the magnetic field profile is simplified if only fields along the z-axis ($r = z$, $\theta = 0$) are considered. In a coil system of maximum order $n = 4$ where $\beta_0 = 0$ and β_4 is negative, the resultant profile along the z-axis produced by the sum of B_0 and $\beta(z)$ is shown in Fig. 1.

The inhomogeneity, ΔB, across the central region of axial extent, $2a$, is given by:

$$\Delta B = \frac{\beta_2^2}{2\beta_4} \qquad (2)$$

where

$$2a = 3.1\left(\frac{\beta_2}{\beta_4}\right)^{1/2} \qquad (3)$$

By varying β_2 and β_4 the sensitive volume can be adjusted to match that of the centrally placed region within any given object.

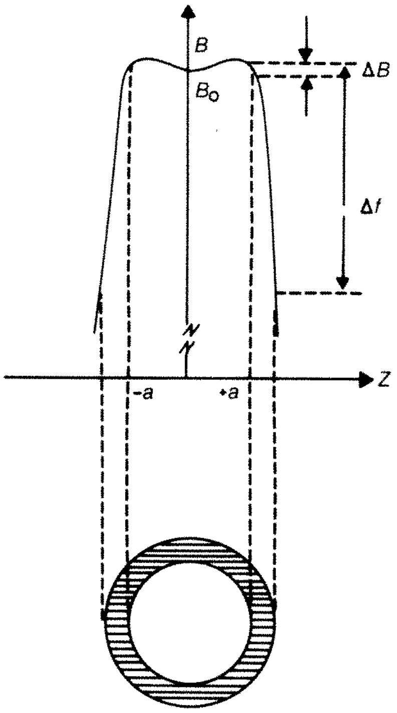

Fig. 1 The profile of the magnetic field along the z-axis in TMR. The inhomogeneity, ΔB, within the central region shown schematically in the projection below, is constrained to remain less than the typical ^{31}P linewidths. In the shaded region the ^{31}P lines will be broadened by the field gradients.

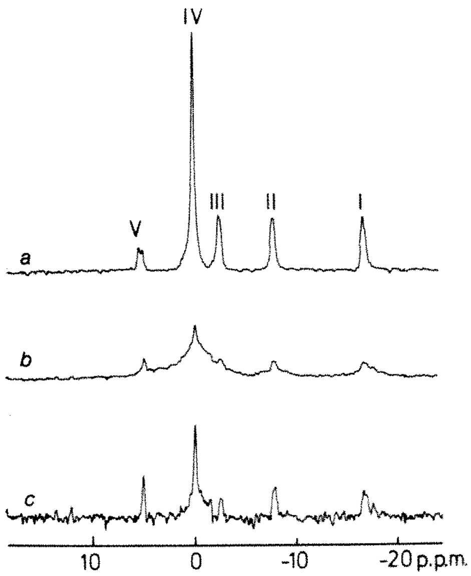

Fig. 2 ^{31}P-NMR spectrum of a two-compartment phantom containing ATP (signals I, II and III), phosphocreatine (IV) and inorganic phosphate (V). A single-turn saddle-shaped radiofrequency coil operating at 73.8 MHz was used in a standard wide-bore (89 mm) superconducting magnet. Profiling was obtained with a coil system designed to provide spatial localization across an internal volume ($2a \sim 15$–45 mm) whilst maintaining a homogeneity of ~ 0.1 p.p.m. at an operating B_0 field of 4.3T. The working bore of the system was 45 mm. The spherical compartment contained 4.65 mM ATP, 9.30 mM PCr and 3.72 mM P_i, and the cylindrical compartment contained 4.65 mM ATP, 18.60 mM PCr and 1.86 mM P_i. *a*, Spectrum (300 scans) in the absence of localizing fields. A 6-Hz line broadening exponential multiplication was used to enhance the signal-to-noise ratio. *b*, Spectrum (600 scans) with the axial extent reduced to 20 mm. The same line broadening was used as in *a*. *c*, Spectrum obtained on removing the broad component of spectrum *b* by convolution difference[9]. Line broadenings of 6 and 60 Hz were used and the vertical scale in the spectrum was multiplied by 4 for clarity of presentation. Chemical shifts are defined as positive in the high-frequency direction with phosphocreatine taken as an internal reference.

Adjacent to the sensitive volume lie regions where the magnetic field changes vary rapidly with position, causing broadening of the spectral lines. The radiofrequency coil will receive signals from the whole sample so the total signal will contain both the narrow, high-resolution lines and the inhomogeneously broadened lines which must be separated out to recover the high-resolution spectrum of the sensitive volume.

Experiments were carried out on a two-compartment test phantom consisting of a cylindrical compartment of diameter 30 mm surrounding a spherical compartment of diameter 20 mm, each containing ATP, phosphocreatine (PCr) and inorganic phosphate (P_i) (for concentrations, see Fig. 2 legend), dissolved in 150 mm KCl to simulate the electrical conductivity of tissue. The internal *p*H was adjusted to be 0.35 units less than that of the external *p*H, thereby producing a chemical shift difference between the P_i resonant frequencies of the two samples.

The spectrum of the sample was obtained with the axial extent set to 45 mm (Fig. 2*a*). The three ATP peaks and the PCr peak are unaffected by the difference in *p*H, whereas two clearly distinguishable P_i peaks appear. Using the PCr peak as a reference, the internal and external P_i peaks correspond to *p*H values of 7.10 and 7.45 respectively. The P_i concentration ratio measured from the peak areas is in good agreement with the expected value.

When the axial extent is reduced to 20 mm, a broad component at the base of each peak arises from the metabolites in the external compartment, which now lie in a region of inhomogeneous magnetic field (Fig. 2*b*). This broad signal is eliminated using the convolution difference technique[9] (Fig. 2*c*). The narrow peaks correspond to the metabolites present only in the spherical compartment, and the *p*H of the P_i peak in this spectrum is 7.10, in agreement with the position measured previously.

To demonstrate the potential of the method in animal experiments, we have studied the liver of a live rat. In the spectrum obtained from the rat in the absence of any localizing fields, the ATP and PCr peaks are readily identifiable, but the P_i and the sugar-phosphate region of the spectrum is less readily assigned because the 2,3-diphosphoglycerate from blood contributes two signals at ~ 5.0 and 6.5 p.p.m. and the first of these overlaps with the P_i signal (Fig. 3*a*). Blood contributes a negligible amount to the ATP peaks. Therefore the ATP signals arise primarily from liver and muscle tissue, the PCr arises exclusively from muscle, whereas the signals in the P_i and sugar-phosphate region may have contributions from liver, muscle and blood.

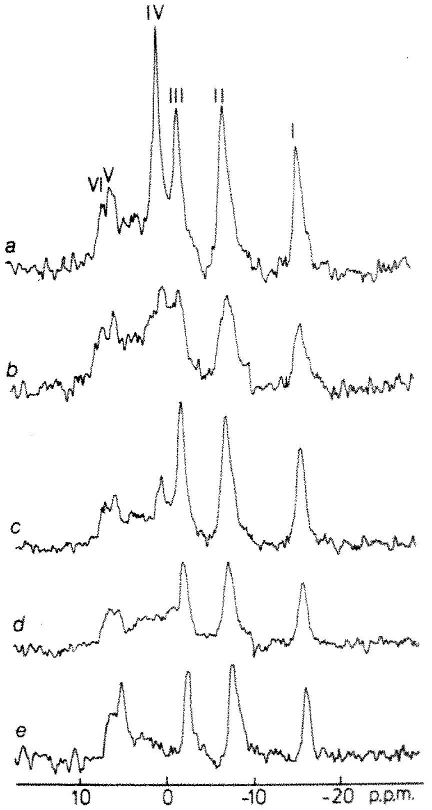

Fig. 3 Spectra *a–d* were obtained from an intact rat anaesthetized with pentabarbitol. 150-g male Wistar rats, starved for 24 h, were used for all experiments. Signal assignments are: I, II and III, the β-, α- and γ-phosphate, respectively, of ATP; IV, phosphocreatine; V, inorganic phosphate; VI, sugar phosphate, AMP and IMP. Peaks V and VI may also contain contributions from 2,3-diphosphoglycerate in the blood. Peak II contains a small contribution from ADP and peak III has contributions from ADP, NAD and NADH. *a*, Spectrum in the absence of localizing fields ($128 \times 90°$ pulses at 2-s intervals). *b*, The same as *a* with localization (axial extent 20 mm). *c*, Spectrum in the absence of localizing fields ($1{,}024 \times 90°$ pulses at 220-ms intervals). *d*, The same as *c* with localization (axial extent 20 mm). *e*, Spectrum of a perfused rat liver ($480 \times 90°$ pulses at 220-ms intervals). For clarity of presentation the spectra in *c* and *d* were divided by 4. The broad components were eliminated using the convolution difference technique[9] with line broadenings of 16 and 233 Hz. Chemical shifts are defined as positive in the high-frequency direction, and phosphocreatine is taken as an internal reference. Measurement of T_1, using progressive saturation technique[11], on the β-phosphate resonance of ATP gave a value of 0.14 s in the presence of localizing fields. This is characteristic of ATP in liver. The remaining small PCr signal in *b* is likely to arise from the diaphragm.

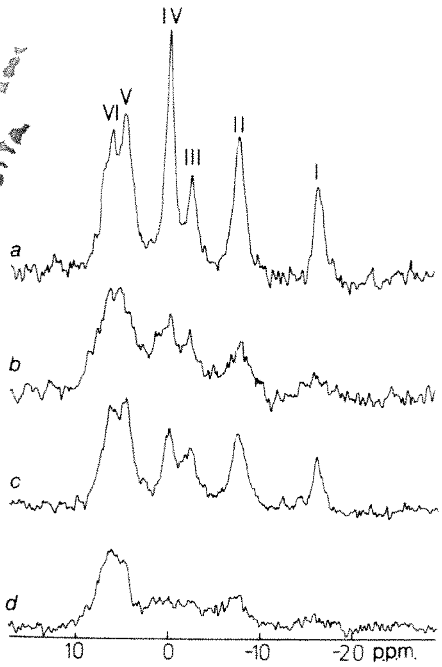

Fig. 4 ^{31}P-NMR spectra of a rat after surgery to cut off the hepatic blood supply. The spectrometer conditions were the same as in Fig. 3 legend. Spectra *a–d* are analogous to spectra *a–d* of Fig. 3.

The sensitive volume was reduced ($2a = 20$ mm) and the resulting TMR spectrum is shown in Fig. 3*b*. The smaller peak intensities indicate that now high-resolution signal is being acquired from a smaller volume, and as the spectra of Fig. 3*a* and *b* were obtained with the same spectrometer conditions, there will be an inevitable reduction in signal-to-noise ratio. Nevertheless, a change in the relative proportions of the metabolite resonances is apparent.

The spectra of Fig. 3*a* and *b* were obtained using a radiofrequency pulse interval of 2 s, which is typical for ^{31}P-NMR studies of whole tissue. Figure 3*c* shows a spectrum obtained with a pulse interval of 220 ms, in the absence of localizing fields. The PCr peak intensity is now significantly reduced in comparison with its intensity in Fig. 3*a*, because its spin–lattice relaxation time, T_1, is long (~ 3 s). The reduction in the ATP peak intensities is far less, as the ATP in tissues such as muscle has a rather shorter relaxation time (~ 1–2 s), and also because a significant percentage of the ATP is in the liver, and liver ATP has very short T_1 values (~ 100 ms)[10]. Figure 3*d* shows the spectrum obtained using the short pulse interval with the reduced sensitive volume ($2a = 20$ mm). This spectrum contains no PCr signal and is very similar to the spectrum of perfused liver shown in Fig. 3*e*, which was obtained using the same pulse interval of 220 ms. This suggests that the signals of Fig. 3*d* are predominantly from the liver. The improvement shown in Fig. 3*d* can only obtained using the localizing fields.

The P_i/ATP ratio is lower in the liver of the whole animal (Fig. 3*d*) than in the perfused liver (Fig. 3*e*). Previous NMR studies of the brain and skeletal muscle of whole rats also show remarkably low P_i levels[6].

By cutting off the hepatic blood supply of the animal using surgery, similar measurements were made on the same animal (Fig. 4). The marked reduction of ATP and increased levels of P_i after ligation (Fig. 4*b* and *d*) indicate unhealthy ischaemic liver, verifying the origin and interpretation of the previous TMR spectra. In contrast, the PCr signal intensity in Fig. 4*a* is very similar to that in Fig. 3*a* indicating that the metabolic state of the muscle is little affected by the operation.

Thus, we have identified *in vivo* liver tissue by the ^{31}P spectral characteristics and the relaxation time of the β-ATP resonance. Global liver ischaemia has been diagnosed in a non-invasive manner. The method is easily extended for the investigation of other organs of laboratory animals.

The work in the Department of Biochemistry was supported by the SRC and the British Heart Foundation. We gratefully acknowledge the work of J. R. Griffiths, R. A. Iles, R. Porteous and A. N. Stevens on perfused liver. Dr J. R. Griffiths provided the perfused rat liver spectrum.

The regular occurrence of a peak due to an unidentified substance (X) in the gas chromatographic traces obtained from phenolic extracts of urine from human pregnant and non-pregnant females has been reported[1]. The biphasic excretion of X with maxima in the luteal phase of the ovulatory cycle and relatively high levels in the first trimester of pregnancy were noteworthy and suggested that the substance may have a biological significance. Close similarities between the excretory pattern, the chemical and chromatographic properties of X and of those of the known phenolic steroids suggested initially that this compound was steroidal in nature. The same, or a similar, substance seems to be excreted in the vervet monkey (*Cercopithecus aethiops pygerythrus*)[2]. We now report the excretory pattern of X in more detail, the isolation of the pure compound from pooled pregnancy urine and the chemical structure. The structure determined by mass spectrometry, IR spectroscopy and NMR spectrometry is: *trans*-(±)-3,4-bis[(3-hydroxy phenyl)methyl]dihydro-2-(3H)-furanone (HPMF) and was confirmed by synthesis.

Sequential analyses were carried out on urine collected daily: (1) by volunteers throughout the normal ovulatory cycle; (2) when monitoring oestrogen excretion in patients who were being treated for anovulatory infertility following treatment with postmenopausal gonadotropin; and (3) when following the urinary excretion of oestrogens and of X from conception to term[3]. After acid hydrolysis of the urinary steroid and other conjugates, phenolic fractions were prepared, the extracts acetylated and analysed by gas liquid chromatography (GLC) using a Pye 104 gas chromatographic system[3]. Figure 1 shows

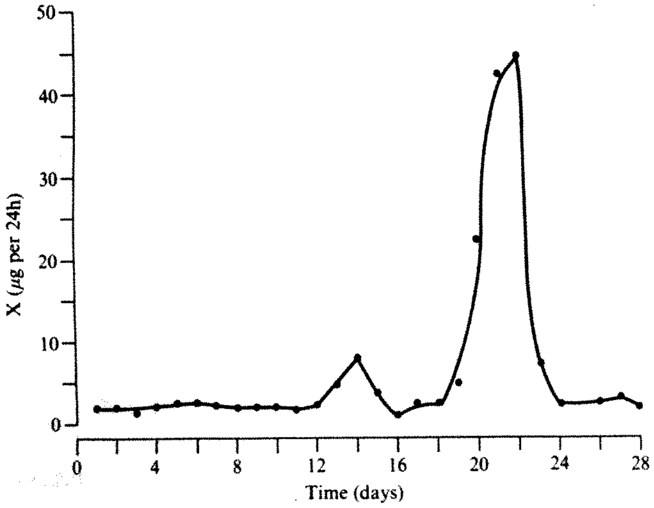

Fig. 1 Cyclic excretion of HPMF in a volunteer with normal ovulatory cycles. 24-h urine specimens were collected daily throughout the cycle and HPMF was extracted from each specimen as described in the text. The phenolic fraction was acetylated and subjected to GLC[3] on a Pye 104 gas chromatograph using a 1-m glass column packed with OVI on Gas Chrom Q Support (100–200 mesh). The oven temperature was maintained at 230 °C and the nitrogen carrier gas flow rate was 40 ml min^{-1}. Values obtained are uncorrected for losses which occurred during the chemical extraction and gas chromatography (~40%).

the biphasic excretion of X in a normal ovulatory cycle, maximum excretion being apparent in the luteal phase. In early pregnancy (Fig. 2) excretion of X exceeds that of oestrone, oestradiol or oestriol, but as pregnancy proceeds to term both the absolute excretion of X and the excretion of X relative to the steroidal oestrogens declines.

A purified sample of compound X (10 mg) was isolated for structural analysis from pooled urine (100 l) collected during the first trimester of normal pregnancies. The urine was processed in 2-l batches by passing through a column of XAD2 resin (BDH chemicals) and eluting first with distilled water and then with ethanol to give a fraction containing conjugates of the steroids and of compound X. The ethanol solution was evaporated to dryness under reduced pressure in a rotary evaporator, and the residue was heated on a steam bath for 1 h with aqueous hydrochloric acid (*p*H 1) to hydrolyse the conjugates. Saturated ammonium chloride was added, and the hydrolysed products were extracted into ether and washed with 8% sodium bicarbonate solution. The phenolic constituents were then extracted with 1 M NaOH solution which was acidified immediately with sulphuric acid. The crude phenolic product was extracted with diethyl ether and purified by chromatography on a column of Sephadex LH20 resin (Pharmacia) and elution with toluene : methanol (9 : 1, v/v). The fraction containing compound X was purified further by thin-layer chromatography on Kieselgel G (type 60, Merck) for 1.5 h with ethyl acetate : cyclohexane (1 : 1, v/v). Compound X (R_F 0.53) was located by spraying a test strip with Turnbull's blue solution (1% ferric chloride with 1% potassium ferricyanide [aqueous]), scraped from the plate, transferred to a small glass column and eluted with chloroform : methanol (1 : 1, v/v). The purity of the product was determined by GLC of a small sample after acetylation. From the IR, mass spectrometry and NMR spectra the structure of compound X was determined to be *trans*-(±)-3,4-bis[(3-hydroxyphenyl)methyl]dihydro-2-(3H)-furanone (HPMF, Fig. 3) on the following evidence.

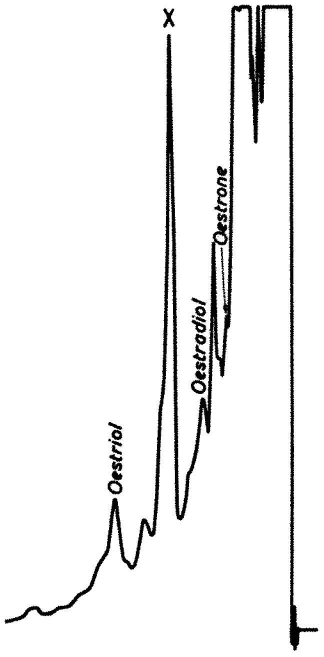

Fig. 2 HPMF was extracted from a 24-h urine specimen, obtained from a patient in the ninth week of pregnancy, as described in the text. The purified phenolic fraction was acetylated and subjected to GLC in the conditions described in Fig. 1 legend.

The formula $C_{18}H_{18}O_4$ was established from the mass spectrum by the parent peak at $m/e = 298.1193$ (calculated, 298.1205) and prominent peaks at $m/e = 107.0503$ (calculated for C_7H_7O, 107.0497) and 108.0583 (calculated for C_7H_8O, 108.0575) were indicative of $-CH_2C_6H_5OH$ groups. The presence of a γ-lactone (ν_{max} 1,770 cm^{-1}, C=O stretch) was evident from the IR spectrum. ^{13}C-NMR revealed signals characteristic of two similar but non-equivalent disubstituted aromatic rings (δ 113.9, 114.0, 115.7, 116.3, 121.1, 121.7, 130.0 and 130.0, aromatic =CH—). In the ^1H-NMR (200 mHz) spectrum, the aromatic region showed the presence of two non-equivalent *m*-hydroxyphenyl groups. In addition, the AB-parts of two ABX-systems centred at δ 4.0 ($J_{AB} = 9, J_{AX} \simeq J_{BX} \simeq 7$) and δ 2.96 ($J_{AB} = 14$, $J_{AX} = 5$, $J_{BX} = 6$) could be detected, arising from the partial structures $-OCH_2-CH\ R-$ and Ar CH_2CH-.

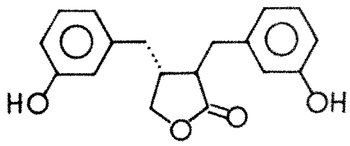

Fig. 3 Compound X; *trans*-(±)-3,4-bis[(3-hydroxyphenyl) methyl]dihydro-2-(3H)-furanone (HPMF).

The proposed structure (Fig. 3) is supported by ^1H-NMR data reported for closely related compounds and has been confirmed by synthesis (to be reported elsewhere)[4]. The racemic product (melting point 141–143 °C) was identical in all respects with the compound of natural origin. The absolute configuration and optical purity of the natural substance were determined by resolution of an intermediate (I) (Fig. 4) in the synthesis. The resolved compound (I) (Fig. 4) had $[\alpha]_D^{20} + 6.4°$ (1% in chloroform) and optically active HPMF prepared from it had a melting point of 125–129 °C and $[\alpha]_D^{20} - 38.4°$ (1% in chloroform). These values for the optical rotations compare favourably with reported values of +4.8° (ref. 5) and −34° (ref. 6) for the closely related compounds (II) and (III), respectively (Fig. 4). The specific optical rotations of samples of natural HPMF isolated from urine varied between 0° and −4° indicating an optical purity of ≤10%.

We have not detected HPMF in normal male urine and this, with the regularity of its cyclic excretion in women, leads to the conclusion that it is not of dietary origin. However, excretion of HPMF increases when anovulatory patients are treated with human menopausal gonadotropin. This and the pattern of its excretion during the menstrual cycle and in pregnancy suggest

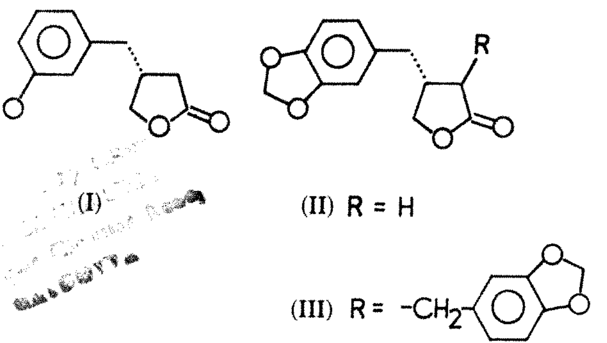

Fig. 4 Intermediate (I) and related compounds (II) and (III) in the synthesis of HPMF.

that there may be an ovarian source or stimulus for the production of HPMF. Investigations are now underway to establish the function and source of HPMF in the body and the biological properties of the synthetic substance. In this respect it is interesting that the same or a similar compound, and a substance with similar chemical and chromatographic properties seem to be excreted in the vervet monkey (*Cercopithecus aethiops pygerythrus*) during the reproductive cycle and in pregnancy[2].

In our laboratories, for several years, two phenolic compounds have been detected during gas chromatographic–mass spectrometric analysis of urinary steroid extracts from human and animal species. Although features of the mass spectra of their trimethylsilyl (TMS) ether derivatives resembled those of oestrogens, they were atypical of steroids. The possibility that they were artefacts of the isolation procedures was discounted after careful studies with blanks, by varying the extraction method and because they were present almost exclusively as conjugates of glucuronic acid. Several of the general characteristics of the unknown compounds were reported[1,2] after one (referred to as compound 180/442) was found to have a cyclic pattern of excretion during the menstrual cycle of an adult vervet monkey (Fig. 1). An investigation of the nature and distribution of the compounds has shown them to be urinary constituents in humans, baboons, vervet monkeys and rats, and further related compounds have been detected, so far only in vervet monkey urine. We now report spectroscopic and chemical studies that show the two original compounds to be lignans, which have a 2,3-dibenzylbutane skeleton as their basic structure. Unlike all previously known natural lignans, invariably of plant origin, the two mammalian compounds carry phenolic hydroxy groups only in the *meta* position of the aromatic rings.

The two compounds are:

(I) 2,3-bis-(3′-hydroxybenzyl)-butyrolactone (referred to in previous reports[1,2] as compound 180/442).
(II) 2,3-bis-(3′-hydroxybenzyl)-butane-1,4-diol (referred to previously as compound 180/410).

Some related compounds subsequently found in the urine of the vervet monkey correspond to I and II but have additional methoxy substituents in one or both of the phenolic rings:

(III) 2-(3′-hydroxy-methoxybenzyl)-3-(3′-hydroxybenzyl)-butyrolactone.
(IV) 2-(3′-hydroxy-methoxybenzyl)-3-(3′-hydroxybenzyl)-butane-1,4-diol.
(V) 2,3-bis-(3′-hydroxy-methoxybenzyl)-butyrolactone.
(VI) 2,3-bis-(3′-hydroxy-methoxybenzyl)-butane-1,4-diol.

Several other compounds found in the urine of the vervet monkey appear from their physicochemical properties to be of related structure, but they have not been characterized.

The locations of the methoxyl groups in the phenolic rings of the relatively minor constituents (III–IV) remain to be established finally. In compound III the non-equivalence of the benzylic groups introduces uncertainty as to which aromatic ring contains the methoxyl function. Figure 2 illustrates the structural formulae of compounds I–VI. The evidence which led to the identification of I and II and the chemical synthesis which confirmed their structures are summarized here and will be described in detail elsewhere.

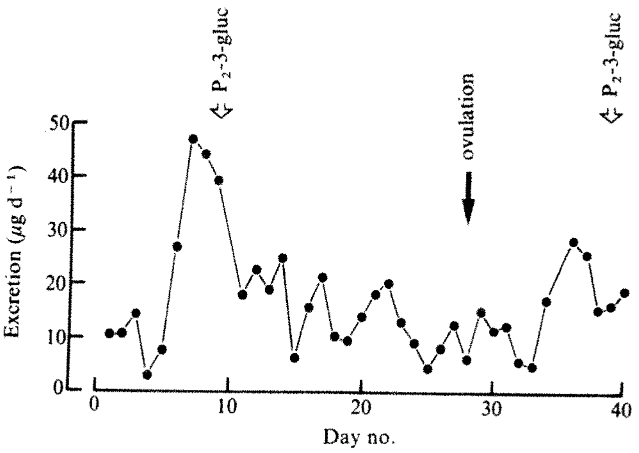

Fig. 1 Urinary excretion ($\mu g\ d^{-1}$) of 2,3-bis-(3′-hydroxybenzyl)-butyrolactone in a mature adult female vervet monkey (*Cercopithecus aethiops pygerythrus*) and its relationship to the time of ovulation and maximum corpus luteal activity determined from measurements of oestrone glucuronide and pregnanediol-3α-glucuronide (P_2-gluc), respectively[1].

Mass spectra of the TMS ether derivatives of compounds I and II isolated from human urine and those of chemically synthesized 2,3-bis-(3′-hydroxybenzyl)-butyrolactone and 2,3-bis-(3′-hydroxybenzyl)-butane-1,4-diol are illustrated in Fig. 3; they are identical. Some aspects of the fragmentation pattern of these spectra have been discussed previously[1]. The presence of the phenolic hydroxy group in the *meta* position is substantiated by the intense rearrangement ion at *m/z* 180. This ion is insignificant in TMS ether derivatives of *ortho* or *para* substituted lignan analogues and model compounds (work in preparation). The gas chromatographic (GC) characteristics of the TMS ether derivatives of the natural and synthetic compounds I and II on open-tubular glass capillary columns coated with silicone OV-1 were identical (retention times: (I, 27.50 methylene units (MU) and II, 27.70 MU). Accurate mass measurement of the molecular ions of the isolated compounds I and II showed their elemental composition to be $C_{18}H_{18}O_4$ and $C_{18}H_{22}O_4$ respectively in agreement with the structures shown in Fig. 2.

Nuclear magnetic resonance (NMR) spectra of the natural compounds I and II were compared with those of authentic

0028-0836/80/430740—03$01.00

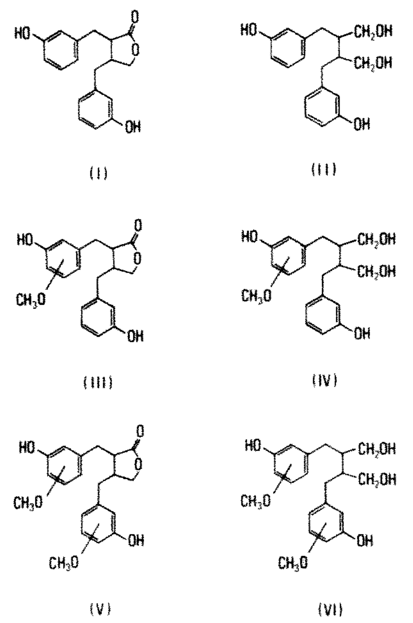

Fig. 2 Chemical formulae of newly identified lignans. Compounds I and II have been identified in the urine of humans, baboons, vervet monkeys and rats while III–VI have so far only been identified in vervet monkey urine[3]. All of these lignans have been identified in urine as glucuronide conjugates.

samples, respectively, of matairesinol dimethyl ether and dihydrocubebin (Fig. 4). The virtual identities of the high field regions of the pairs of spectra indicated the structures of the non-aromatic parts of the molecules I and II (Table 1). The aromatic regions of the spectra of I and II comprised complex multiplets split into two regions: a multiplet integrating for two protons, centred near 7.1 p.p.m., and a multiplet integrating for six protons, mainly between 6.6 and 6.8 p.p.m. A similar pattern found for some model *meta*-alkylated phenols indicated the location of the phenolic hydroxy groups in compounds I and II. The γ-lactone ring in compound I was further indicated by the infrared (IR) spectrum, with carbonyl absorption at 1,750 cm^{-1}.

Compounds I and II were synthesized by an adaptation of the traditional route to lignans of the 2,3-dibenzylbutane type[3,4]. A Stobbe condensation of 3-benzyloxybenzaldehyde (2 mol) with diethyl succinate (1 mol) gave bis-(3-benzyloxybenzylidene)-succinic acid. Catalytic hydrogenation, with simultaneous hydrogenolysis of the protecting benzyloxy groups, followed by reduction of the resulting 2,3-bis-(3'-hydroxybenzyl)-succinic acid with lithium aluminium hydride, and acidification, gave a mixture of products. Preparative thin layer chromatography (TLC) afforded samples which consisted essentially of 2,3-bis-(3'-hydroxybenzyl)-butyrolactone (I) and 2,3-bis-(3'-hydroxybenzyl)-butane-1,4-diol (II). The latter product appeared on the basis of GC and NMR data, to comprise a mixture of the *dl* and *meso* forms.

The TLC behaviour, and the IR spectra of the synthetic and natural compounds I and II, and the NMR spectra of the two samples of the dibenzylbutyrolactone (I), were indistinguishable. The NMR spectrum of the synthetic dibenzylbutanediol (II) contained all the features in the spectrum of the natural material, and some additional signals attributed to the presence of the *meso* isomer.

Compound I is of greatest interest at present because it is quantitatively the most important in human urine, plasma and bile and its daily urinary excretion is comparable to that of many steroid metabolites[2,5]. It is the most likely precursor of most of the other compounds in the series and can be reduced chemically to II. As indicated earlier it is present principally as a glucuronide conjugate[22], as are the other lignans identified in the series.

We found that the urinary excretion of the dibenzylbutyrolactone (I) increased significantly during the mid-luteal phase of the menstrual cycle and showed a marked surge in early pregnancy in humans[2,5] as well as the vervet monkey[1]. In four women the urinary excretion of I was at its minimum at the time of ovulation and then increased, reaching a maximum during the mid-luteal phase (Fig. 5). Furthermore, during pregnancy maximum excretion of dibenzylbutyrolactone occurs between weeks 14 and 22 of gestation[2,5]. A non-steroidal compound has been reported[6] to show similar urinary excretion patterns during the human menstrual cycle and in pregnancy.

The biosynthetic pathway of the lignans is not yet known, although their aromatic nature might suggest a dietary origin or formation by intestinal bacteria. Preliminary results, however, indicate that they may be ovarian in origin or that their production is influenced by ovarian function. For instance, in addition to the cyclic behaviour of compounds I and II[5], their excretion in a limited number of postmenopausal women studied was lower than in normally ovulating women, while in three ovariectomized/postmenopausal women excretion was approximately 5–10% of that in normal ovulating women. Because the compounds are barely detectable in the urine of newborn infants it seems that in pregnancy they are essentially maternal in origin.

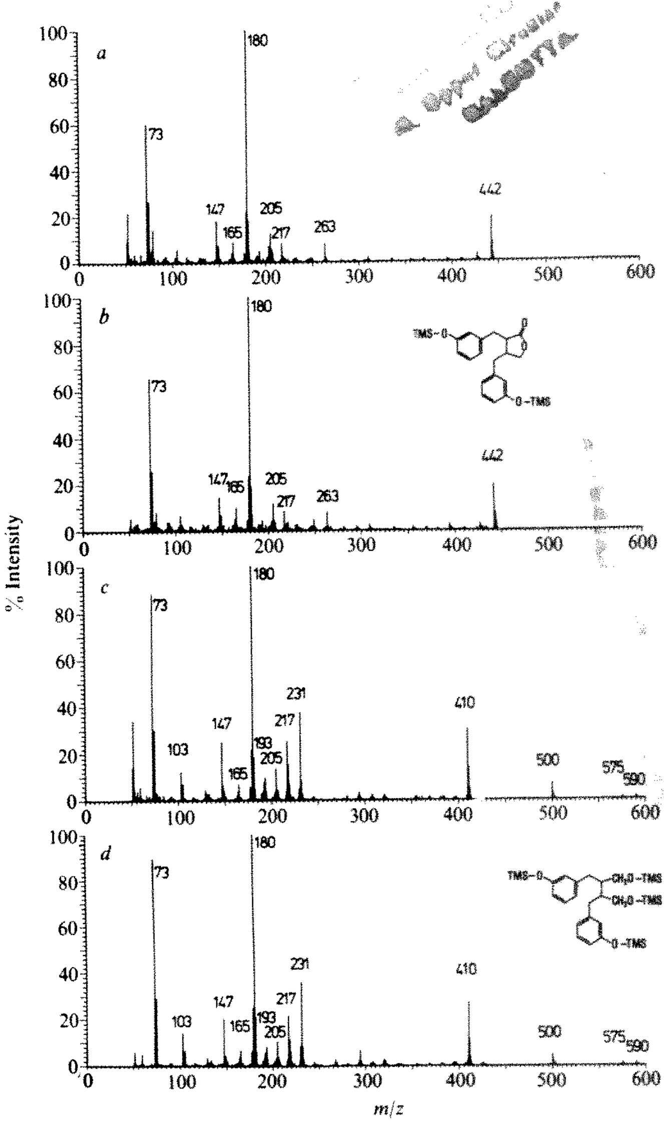

Fig. 3 Mass spectra of the TMS derivatives of: *a*, natural compound I; *b*, synthetic 2,3-bis-(3'-hydroxybenzyl)-butyrolactone; *c*, natural compound II and *d*, synthetic 2,3-bis-(3'-hydroxybenzyl)-butane-1,4-diol.

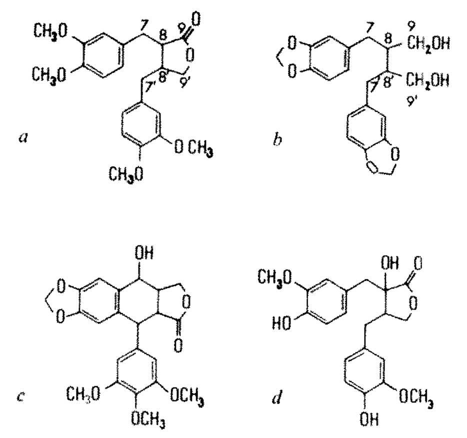

Fig. 4 Chemical structure of the lignans: *a*, matairesinol dimethyl ether; *b*, dihydrocubebin; *c*, podophyllotoxin; *d*, wikstromol.

Table 1 ^{1}H NMR spectra at 100 MHz in $CDCl_3$

Compound	H-7,7'*	H-8,8'*	H-9' or H-9,9'*
2,3-bis-(3'-hydroxybenzyl)-butyrolactone(I)	2.56 (8)	2.94 (9)	4.0 (about 34)
Matairesinol dimethyl ether	2.55 (8)	2.94 (9)	4.0 (about 30)
2,3-bis-(3'-hydroxybenzyl) butane-1,4-diol (II)	2.68 (10)	2.02 (about 10)	3.6–3.7 (br.m.)
Dihydrocubebin	2.66 (12)	1.82 (about 14)	3.63 (br.m.)

Δ Values are given in p.p.m. relative to the Me_4Si; $W_{1/2}$ is given in parentheses. The assignments of spectra are tentative: a detailed analysis of NMR spectra is in progress and will be published elsewhere. br.m., Broad multiplet.

* Numbering system in accordance with that used in ref. 7 (see also Fig. 4).

Compounds I and II were also found in adult males where their urinary excretion is quantitatively similar to that in the follicular phase of normal ovulating women. Although we have no information on the site of their production in men, the fact that they are almost undetectable in the urine of newborn infants[2,5] and in extremely low concentrations in children of both sexes suggests that their production is related to gonadal development.

The existence of lignans in humans, and preliminary observations on their disposition, pose questions as to their physiological and biological significance. The lignans are uncommon plant constituents which have been found so far only in higher plants of the orders Gymnospermophytina and Angiospermophytina. They have been investigated extensively by natural product chemists and various types of dibenzylbutane and related structures have been catalogued[7,8]. As far as we know, however, compounds with the substitution pattern reported here have not been identified in any plant species, presumably reflecting different pathways of biosynthesis or metabolism.

Lignans have been classified by the US National Cancer Institute[9,10] to be of 'high interest' as potential anticancer agents and several have been used in clinical trials to treat tumours[11–14]. Podophyllotoxin[15] (Fig. 4) is probably the best known lignan; it is derived from the roots of the Mayapple plant of the central USA. This lignan and a number of other less complex natural (for example, wikstromol, Fig. 4) and synthetic lignans, exhibits anti-mitotic activity and has been effective in treating several types of tumour in animals[16–20]. Whether or not the lignans of humans have similar activity remains to be determined although it is interesting that to be biologically active the plant compounds require a *trans* configuration of the benzyl substituents on the C_2-C_3 of the butane.

The diphenolic nature of compounds I–VI resemble many of the substances known either to exert oestrogenic action or to block oestrogen receptor sites[21]. The increased urinary excretion of the dibenzylbutyrolactone (I) in the luteal phase, a conspicuous feature of the menstrual cycles studied so far, suggests that this lignan, or a related compound, may be associated with luteolytic activity and the regulation of the length of the luteal phase of the cycle.

We thank Dr D. C. Ayres for matairesinol dimethyl ether, and Professors L. Crombie and R. Row for dihydrocubebin.

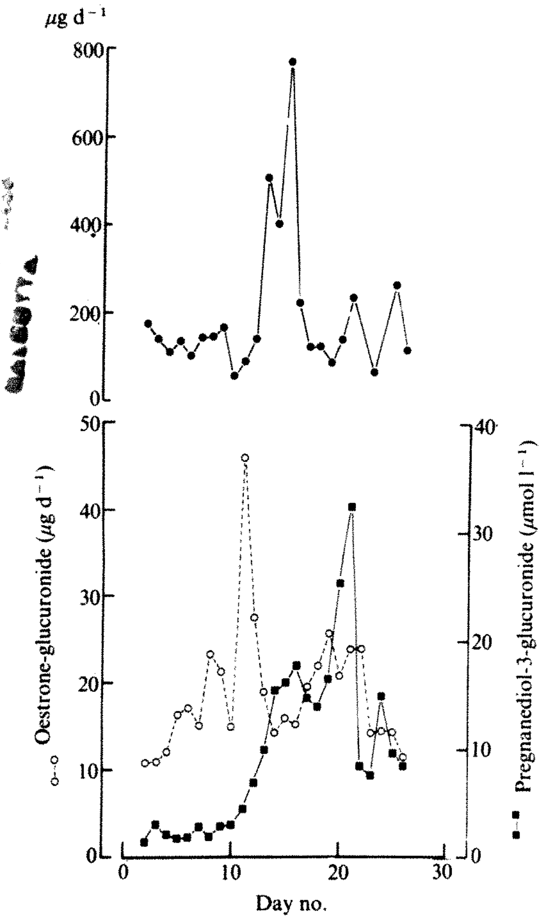

Fig. 5 Urinary excretion ($\mu g\ d^{-1}$) of 2,3-bis-(3'-hydroxybenzyl)-butyrolactone (upper) during the menstrual cycle of a normal ovulating woman. Oestrone–glucuronide and pregnanediol-3α-glucuronide were measured by radioimmunoassay and indicate the ovulatory and luteal phases of the cycle.

Endogenous digitalis-like substance in plasma of volume-expanded dogs

Kenneth A. Gruber, Janice M. Whitaker & Vardaman M. Buckalew Jr

Departments of Physiology and Pharmacology, Medicine and Microbiology and Immunology, Bowman Gray School of Medicine, Winston-Salem, North Carolina 27103

Considerable evidence supports the hypothesis that renal sodium excretion is partly regulated by a humoral agent released or activated by extracellular fluid volume (ECFV) expansion[1], including the demonstration of biological activities in extracts of plasma and urine which support the natriuretic hormone (NH) hypothesis[2–4]. NH is a low molecular weight peptide formed from a precursor in plasma[5], which inhibits sodium transport (anti-natriferic activity) in isolated toad bladder, an analogue of the distal renal tubule and collecting duct. Other evidence indicates that NH can inhibit renal $(\mathrm{Na^+ + K^+})$ATPase[6], which suggests that it might be an endogenous digitalis-like substance. Although an immunoreactive ouabain-like substance has been demonstrated in amphibian plasma[7], none has been reported in mammals. To identify an endogenous digitalis-like substance, we used an approach suggested by the work of Spector and his collaborators, who demonstrated that biological substances which bind to the same receptors as drugs, such as endogenous opioids[8] and benzodiazepines[9], may compete with antibodies specific for the drugs. Hough and Edwardson[10] showed that antibodies to thaumatin, a sweet-tasting plant protein, also bind non-protein sweet substances in a linearly related fashion to the sweetness of the compound, suggesting that the antibody binding site may be similar to the sweet taste receptor. Based on these observations, we postulated that if NH were an endogenous digitalis-like substance, it might bind to antibodies specific for digitalis glycosides. We report here the preliminary isolation of a substance in plasma of dogs which competes with digoxin for two specific digoxin antibodies and is an inhibitor of $(\mathrm{Na^+ + K^+})$ATPase activity. Increased amounts of this factor are found in plasma of volume-expanded dogs, suggesting it is the putative NH.

Blood was obtained from pentobarbital-anaesthetized, saline-expanded and hydropenic dogs. The procedures for acute saline expansion and the protocol for plasma processing have been published previously[5]. Deproteinized plasma extracts, representing an original plasma volume of 10 ml, were eluted by Diafiltration through Amicon UM-10 membranes (exclusion limit <10,000 molecular weight) with 0.05 M acetic acid. Four volumes per sample were eluted, freeze-dried and further purified by HPLC.

Figure 1*a* shows the chromatographic pattern obtained when a deproteinized plasma diafiltrate from a volume-expanded dog was chromatographed on a Partisil SCX (strong cation exchange) column (Whatman). Because we had previously shown that the anti-natriferic factor believed to be the active principle of NH eluted in the void volume on SCX[5], this fraction was tested for immunoreactivity with anti-digoxin antibodies. A substance showing binding to two anti-digoxin antibodies was demonstrated (Fig. 2). The dilution curve of the endogenous immunoreactive substance was similar to that of unlabelled digoxin standard. The two antibodies used were produced in different species to digoxin conjugated to either bovine serum albumin or human serum albumin. The apparent concentration of the endogenous substance in the SCX I sample shown in Fig. 2 was 355 pg digoxin equivalents per ml of plasma.

The SCX void volume fraction was further purified on reverse-phase chromatography (Lichrosorb-ODS; Fig. 1*b*). Salts emerged in the void volume followed by several, distinct fluorescamine-positive peaks. Each tube after the salt peak was assayed for immunoreactivity to the goat anti-digoxin antibody, and for $(\mathrm{Na^+ + K^+})$ATPase inhibitory activity with a purified hog brain ATPase preparation (Fig. 3). Immunoreactivity and ATPase-inhibitory activity eluted in two distinct peaks, the first coming immediately after the salt. These peaks of biological activity and immunoreactivity eluted at similar times, and corresponded to two distinct fluorescamine-positive peaks on ODS chromatography (Fig. 1*b*). Similar elution patterns were obtained with plasma extracts from both hydropenic and saline-expanded dogs. Most importantly, however, activity was higher in saline-expanded plasma samples. ATPase-inhibitory activity at the maximum of peak 1 from four saline-expanded plasma extracts was 185±46 pmol ouabain equivalents (equiv.) per tube compared with 66±25 pmol ouabain equiv. per tube at the maximum of peak 1 from four hydropenic dog samples ($P<0.03$). Similarly, at the maximum of peak 2, ATPase-inhibitory activity was 148±43 pmol ouabain equiv. per tube in four samples from saline-expanded dogs and 43±26 pmol ouabain equiv. per tube in four samples from hydropenic dogs ($P<0.03$). Comparison of peak heights indicates that saline-expanded samples are three times more active than hydropenic samples, but total differences are actually greater. Because the total amount of biological activity in the original samples is equal to the area under the curve for each peak, and because each sample has two approximately equal peaks, the total difference between the two groups would be the sum of the differences for each peak.

The quantitative difference in digitalis-like activity obtained between the radioimmunassay (RIA) and the ATPase activity is of interest (Fig. 3). In the sample shown in Fig. 3, immunoreactivity of peak 1 was 480 fmol digoxin equiv. per tube, whereas the ATPase inhibitory activity was 163 pmol ouabain equiv. per tube. As RIA is a function of numbers of molecules, it probably reflects the actual concentration of the endogenous digitalis-like substance more accurately. This indicates that the endogenous

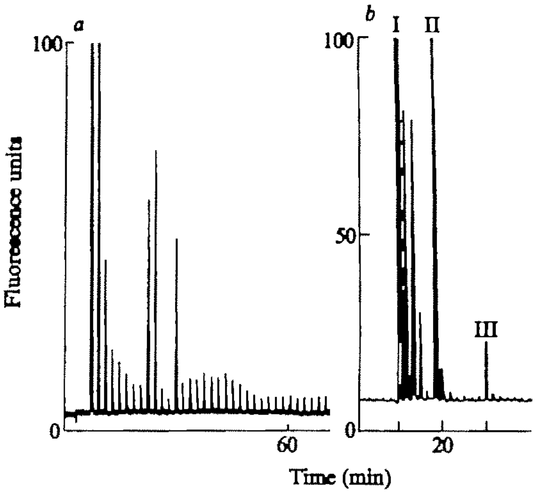

Fig. 1 *a*, Freeze-dried diafiltrate representing 10 ml of plasma was suspended in 400 μl of 10% formic acid and separated on Partisil SCX with a pyridine–acetate gradient[11]. The column flow rate was 400 μl $\mathrm{min^{-1}}$. The column effluent was monitored by a preparative fluorescamine monitoring system[12] which allows detection of primary amines (including peptides and amino acids) by automated, discontinuous sampling of the column effluent. Approximately 1–2% of the effluent was used for detection while the remainder was collected in a fraction collector at 4-min intervals. The discontinuous appearance of the chromatogram is a result of the monitoring system with each line representing one sampling period (2-min interval). The void volume peak (12–20 min), which contains all the plasma salts, was tested for immunoreactivity (Fig. 2) and purified further by reverse phase chromatography. *b*, Reverse-phase chromatography was performed on Lichrosorb ODS. The sample was eluted isocratically in 0.5 M pyridine titrated to *p*H 3 with formic acid, with a column flow rate of approximately 200 μl $\mathrm{min^{-1}}$. Fractions were monitored and collected every 2 min. The salt emerged in the void volume (ODS-I) and the next two fractions (ODS-II and ODS-III) were tested for immunoreactivity and $(\mathrm{Na^+ + K^+})$ATPase inhibitory activity.

0028-0836/80/430743—03$01 00

substance is about three orders of magnitude more potent an inhibitor of purified brain $(Na^+ + K^+)$ATPase than ouabain. This finding is in accord with our observation that 10^{-5} M ouabain is necessary to produce the same degree of antinatriferic activity (25% inhibition of short-circuit current) in toad bladder as that produced by an extract of 5 ml of plasma from volume-expanded dogs (W. C. Plunkett *et al.*, in preparation).

As a further demonstration that the digitalis-like immunoreactive substance is identical to the ATPase inhibitor, preliminary studies have shown that immunoprecipitation of plasma diafiltrates with the goat anti-digoxin antibody yields two peaks on ODS chromatography which are similar to those shown in Fig. 1*b*. Assay for ATPase inhibitory activity of these two peaks showed a similar difference between samples from volume-expanded and hydropenic dogs as shown in Fig. 3.

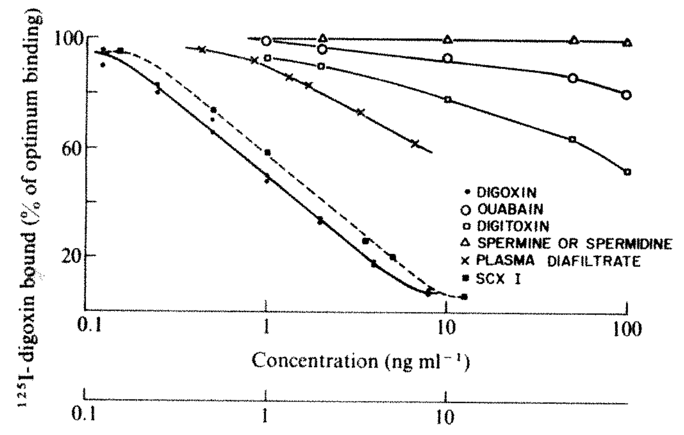

Fig. 2 Radioimmunoassay was performed on SCX fraction I and diafiltrates reconstituted in 500 μl of distilled water, adjusted to *p*H 7.6 with NaOH. Duplicate dilutions of these samples were assayed for cross-reactivity to either an ^{125}I-digoxin clinical radioimmunoassay kit (NEN) or an RIA for digoxin developed in our laboratories using a goat anti-digoxin antibody. The NEN antibody is produced in rabbits by immunization with a digoxin–human serum albumin conjugate, and shows less than 5% cross-reactivity with digitoxin, and essentially none with ouabain or any other steroid glycoside. For assay with the NEN kits, the antibody was incubated with samples or standards in the presence of ^{125}I-digoxin according to procedures provided. Separation of bound antigen from free antigen was accomplished either by charcoal adsorption, or by precipitation with a second antibody (sheep anti-rabbit γ-globulin). Although both separation techniques provided similar results, the double antibody precipitation technique was used routinely. A second, more sensitive RIA developed in our laboratories using an antibody produced in goats immunized with a digoxin–bovine serum albumin conjugate is demonstrated. The degree of cross-reactivity of this antibody with digitoxin, ouabain, spermine or spermidine (known ATPase inhibitors) is shown. Thyrotropin-releasing hormone and various amino acids including phenylalanine and proline were also tested and showed no cross-reactivity. For this RIA the anti-digoxin antibody was incubated for 2 h at 37 °C, *p*H 7.6 (phosphate-buffered saline) in the presence of ^{125}I-digoxin (Burroughs Wellcome) and duplicates of either samples or standards. Rabbit anti-goat γ-globulin was then added to the reaction mixture and incubated for an additional hour. Samples were then centrifuged at 3,000 r.p.m. for 30 min, the supernatant decanted and the pellet counted in a γ counter. Per cent bound was calculated by subtracting nonspecific background and comparing the results with 100% for optimum binding (tubes containing reaction mixture but no unlabelled standard or unknown sample). This immunoassay technique yielded a 10-fold increase in sensitivity over that of the clinical assay kits. Further details on this method will be presented elsewhere. The effect of various glycosides and polyamines on binding of ^{125}I-digoxin to its specific antibody is also shown. Aliquots (100 μl) of standard solutions of glycosides or polyamines were added to the reaction mixture containing buffer, ^{125}I-digoxin and antibody for a total volume of 400 μl. Concentrations of standards are calculated as ng ml^{-1} solution and plotted according to the concentration of the original stock solution. Aliquots (100 μl) of plasma extract from SCX I (void volume lyophilized, reconstituted in H_2O, *p*H 7.6 with NaOH) corresponding to plasma volumes ranging from 0.15 to 12.0 ml were also tested for their ability to compete with ^{125}I-digoxin for its antibody. The binding curve for SCX I is more nearly parallel to the digoxin standard than is the binding curve from the diafiltrate. Apparently, this is due to the removal of interfering substances during the purification procedure. Spermine or spermidine at 100 ng ml^{-1} show no cross-reaction with the antibody whereas similar concentrations of ouabain and digitoxin each show cross-reactivity of less than 1%. Points represent the mean of duplicates which show a variance of less than 5%. The data for plasma diafiltrates and SCX I samples are plotted as a function of original plasma volume; all other substances shown are ● plotted by concentration.

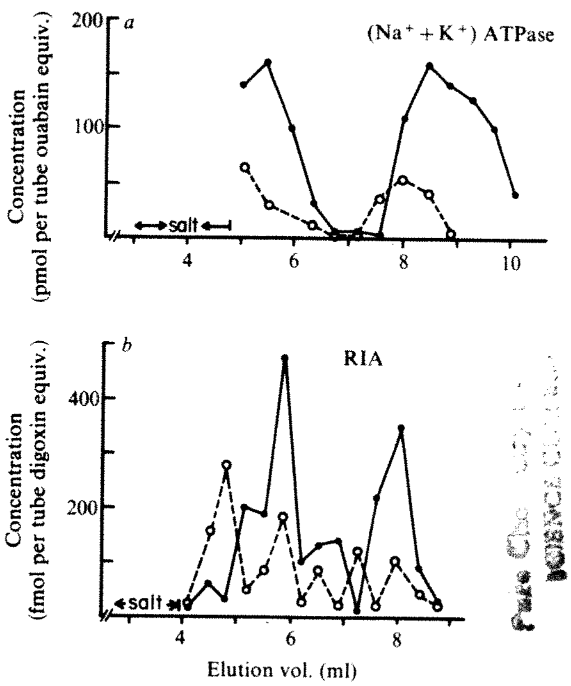

Fig. 3 Assays for $(Na^+ + K^+)$ATPase inhibitory activity (*a*) and digoxin immunoreactivity (*b*) were performed on each 2-min fraction (400 μl) of ODS column effluent. The solid line represents volume-expanded samples, while the dotted line represents hydropenic samples. ATPase inhibition was assayed using a purified $(Na^+ + K^+)$ATPase enzyme derived from hog cerebral cortex (Sigma). This enzyme was originally used in clinical assays for digoxin and digitoxin[13], and has also been used to assay for NH[14]. Ouabain or lyophilized HPLC samples were dissolved in an imidazole–HCl buffer (10 mM, *p*H 7.2) containing sodium (100 mM), potassium (5 mM), magnesium (1 mM) and EGTA (0.5 mM). After addition of enzyme solution the samples were incubated for 10 min in a shaking water bath at 37 °C. ATP was added to a final concentration of 1 mM. The total volume of each incubation tube was 1 ml. Blank tubes contained only ATP and the buffered ion solution, while control ATPase activity was determined in the absence of ouabain. After 15 min of incubation in the presence of ATP the reaction was stopped by the addition of 0.7 ml of cold 13% TCA. ATPase activity was determined as the amount of inorganic phosphate liberated by the method of Eibl and Lands[15]. The minimum sensitivity of this assay is approximately 10 pmol per ml of ouabain, while 100 nmol causes 100% inhibition of enzyme activity. The assay system was standardized with ouabain rather than digoxin because solubilization of digoxin requires an organic solvent which interferes with the assay. Although it is possible to aliquot and steam-dry digoxin[13], we preferred to avoid this rather cumbersome procedure. A dose–response curve for ouabain was generated for each set of unknowns and values for each unknown were calculated from the standard curve by computer program, and expressed as ouabain equivalents.

It is not clear from these studies why two peaks are recovered. However, we have previously reported two fluorescamine-positive peaks on ODS chromatography of the SCX void volume, both of which showed a high degree of correlation with anti-natriferic activity[5]. Thus, there appear to be two molecular species with similar biological activity that differ somewhat in their basic structure.

The evidence presented here suggests that the digitalis-like factors are peptides, as they can be separated by chromatographic protocols for small peptides, and elute in fluorescamine-positive peaks. In addition, we have found that treatment with concentrated HCl at room temperature for 30 min destroys all activity. This susceptibility to acid hydrolysis indicates that the ATPase inhibitory activity is not due to known endogenous ATPase inhibitors such as polyamines[16], vanadium[17] or bufotoxin-like steroids[18]. The initial studies on the use of Partisil SCX with biological samples[11] also demonstrated longer retention times for polyamines than is seen for SCX I.

Interestingly several investigators have reported data which in retrospect support our observations. Early attempts to measure

[illegible] Upper Circular Road
CALCUTTA

cardiac glycosides in plasma by the red blood cell ^{86}Rb uptake assay noted an endogenous interfering substance in patients with congestive heart failure or renal failure[19], which could be separated from cardiac glycosides by its water solubility[20]. The same enzyme preparation used in these studies was originally developed as an assay for digoxin by Burnett and Conklin[13], who also noted endogenous digoxin-like activity in normal non-digitalized controls, and in patients with fluid balance problems[13]. More recently, it has been reported[21] that RIAs for digoxin in patients with renal failure tend to overestimate plasma levels when compared with an HPLC method for the drug. If the factor demonstrated in our studies is the endogenous substance which interferes with clinical assays for digoxin, then its plasma level seems to be elevated in some pathological conditions.

We should mention that the observed plasma levels of endogenous digoxin-like factor would be toxic to an intact animal. This apparent discrepancy could be explained if NH circulated as an inactive precursor, as suggested previously by us[5]. As noted, the plasma isolation protocol used in this study includes a period of incubation to allow precursor breakdown. Alternatively, *in vivo* receptor binding of the endogenous substance for $(Na^+ + K^+)$ATPase could be much lower for all organs other than the target organ (presumably the kidney).

Thus, for the first time we have demonstrated and partially purified a circulating factor in mammals which is an inhibitor of $(Na^+ + K^+)$ATPase and possesses a structure which is recognized by antibodies to the cardiac glycoside digoxin. We have suggested that an appropriate name for this factor would be 'endoxin'[22]. Endoxin has a similar HPLC retention time as the previously demonstrated anti-natriferic factor[5], and both endoxin and the anti-natriferic factor are present in higher concentrations in volume-expanded than in hydropenic subjects. These data support the hypothesis that these several biological and immunoreactive activities are due to the same factor, that this substance is the putative NH, and that anti-digoxin antibodies can be used as an RIA for NH. Confirmation of this hypothesis will require the biochemical characterization of endoxin, which is now in progress.

Portions of this work were presented at the Conference of the Council for High Blood Pressure Research, American Heart Association Cleveland, Ohio (October 1979).

Unusual levels of $(ADP\text{-}ribose)_n$ and DNA synthesis in ataxia telangiectasia cells following γ-ray irradiation

Malcolm J. Edwards & A. M. R. Taylor

Department of Cancer Studies, The Medical School,
University of Birmingham, Birmingham B15 2TJ, UK

Poly (ADP-ribose) polymerase is a eukaryotic chromosomal enzyme which utilizes the ADP-ribose moiety of NAD to synthesize the nucleic acid homopolymer $(ADP\text{-}ribose)_n$ (ref. 1). The precise function of $(ADP\text{-}ribose)_n$ has not been fully established although it does covalently modify chromosomal proteins by ADP-ribosylation[2,3]. Here we demonstrate that γ-ray irradiation of lymphoblastoid cells from normal subjects results in depressed DNA synthesis and increased $(ADP\text{-}ribose)_n$ synthesis. Irradiation of lymphoblastoid cells from patients with the autosomal recessive disease ataxia telangiectasia (AT), however, failed to depress DNA synthesis and did not elevate $(ADP\text{-}ribose)_n$ levels. We have confirmed that $(ADP\text{-}ribose)_n$ is synthesized in response to DNA damage and we propose that this polymer may function in the recovery from DNA damage by suppressing DNA synthesis.

The synthesis of $(ADP\text{-}ribose)_n$ is increased by a variety of agents which cause DNA damage. Radiation[4–7], alkylating agents[8,9] and bleomycin, a radiomimetic antibiotic, increase $(ADP\text{-}ribose)_n$ synthesis and DNA repair synthesis in normal human lymphocytes[10]. The level of $(ADP\text{-}ribose)_n$ increases in normal lymphoblastoid cell lines after UV-irradiation, whereas this response is either absent or delayed in xeroderma pigmentosum (XP) cells[11], which are defective in the removal of UV-induced thymine dimers[12,13]. The synthesis of $(ADP\text{-}ribose)_n$ is increased in proportion to the number of DNA strand breaks induced by exogenous endonucleases[4].

We have investigated the synthesis of $(ADP\text{-}ribose)_n$ in lymphoblastoid cell lines from two ataxia telangiectasia (AT) patients. Patients with this disorder show a predisposition to cancer and enhanced sensitivity to X-ray or γ-ray irradiation as measured by colony survival[14].

Lymphoblastoid cell lines from two normal subjects (LIZ, DEW) and two AT patients (GM1525/AT2BI, GM1526/AT8BI) were irradiated with γ-rays (0–1,000 rad) at 4 °C. The synthesis of $(ADP\text{-}ribose)_n$ from both normal subjects increased in proportion to γ-ray dose. At a dose of 1 krad the synthesis of $(ADP\text{-}ribose)_n$ increased by 54–58% over mock irradiated normal cells. Lymphoblastoid cell lines from both AT patients showed a smaller (8–14%) increase in $(ADP\text{-}ribose)_n$ following the same dose of γ-rays (Fig. 1).

In all experiments the acid-insoluble product synthesized from ^{14}C-NAD was shown to be $(ADP\text{-}ribose)_n$ by the inability of DNase I ($100\ \mu g\ ml^{-1}$) and RNase I ($500\ \mu g\ ml^{-1}$) to hydrolyse the product, whereas 91% was hydrolysed into acid-soluble products by $600\ \mu g\ ml^{-1}$ snake venom phosphodiesterase (Table 1).

To investigate the possibility that poly (ADP-ribose) polymerase was deficient in AT cells, lymphoblastoid cell lines from a normal subject (LIZ) and an AT (GM1526/AT8BI) patient were permeabilized[15] and treated with exogenous DNase I ($100\ \mu g\ ml^{-1}$) and the synthesis of $(ADP\text{-}ribose)_n$ measured. Both the normal and AT cell lines synthesized $(ADP\text{-}ribose)_n$ in similar amounts in response to DNA damage introduced by exogenous DNase I (Table 1). This suggests that the inability of AT cells to synthesis $(ADP\text{-}ribose)_n$ was not due to an intrinsic defect in poly (ADP-ribose) polymerase.

It has been reported that NAD the substrate for $(ADP\text{-}ribose)_n$ synthesis caused decreased ^{3}H-TTP incorporation and template activity of chromatin in isolated rat liver nuclei[16,17] whereas this decrease was not observed in nuclei from

0028-0836/80/430745—03$01.00

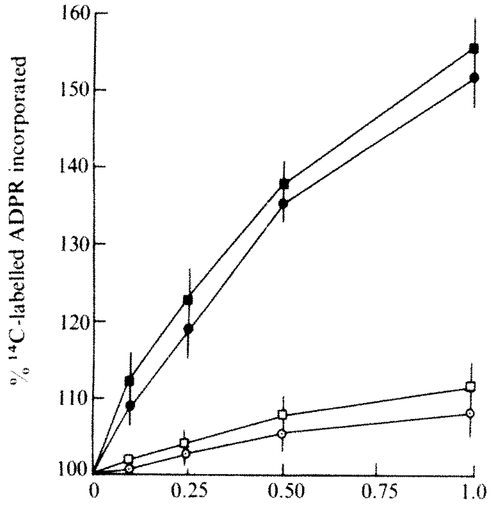

Fig. 1 Effect of increasing γ-ray irradiation dose on (ADP-ribose)$_n$ synthesis in permeable lymphoblastoid cell lines from normal subjects (LIZ ■, DEW ●) and AT patients (GM1525/AT2BI □; GM1526/AT8BI ○). Cell suspensions (7.8×10^5 cells per ml) in exponential growth (72 h) were resuspended in RPMI medium supplemented with 10% (v/v) fetal calf serum (FCS) and irradiated at 4 °C using a ^{60}Co γ-ray source at a dose rate of 200 rad min^{-1}. Irradiated and nonirradiated cell suspensions were centrifuged at 2,000g for 5 min, washed twice in Dulbecco A phosphate-buffered saline (containing 1.15 g l^{-1} Na_2HPO_4, 0.2 g l^{-1} KH_2PO_4, 0.2 g l^{-1} KCl and 8 g l^{-1} NaCl at pH 7.3), resuspended in permeabilizing buffer pH 7.8 (containing 10 mM Tris, 1 mM EDTA, 4 mM $MgCl_2$, 1 mM dithiothreitol and 0.05% (v/v) Triton X-100) for 15 min at 4 °C. 100 μl of cell suspensions were incubated at 30 °C with 10 μl of ^{14}C-NAD (final concentration 5 μl ml^{-1}, 100 μM) in the presence of 50 μl of assay buffer pH 7.8 (containing 50 mM Tris, 15 mM $MgCl_2$, 15 mM KCl, 10 mM NaF and 3 mM cyclic AMP). Triplicate samples were incubated for 10 min. The reaction was stopped with 0.2 ml of 20° (w/v) trichloroacetic acid (TCA). The samples were maintained at 4 °C for 2 h, filtered onto glass-filtre disks (Whatman GF/C) and washed with 10% (w/v) TCA containing 2% (w/v) $Na_4P_2O_7$ (5×10 ml). Protein[23] was determined and radioactivity on the filters was measured in Insta-gel (Packard). Enzyme activity (d.p.m. per μg of protein) is expressed as a percentage of the activity in mock-irradiated cells. Results are presented as the mean ±s.e.m. of three experiments each performed in triplicate.

lymphoma[18] and hepatoma[19] cells. Poly (ADP-ribose) polymerase activity is inversely related to DNA synthesis in rat cardiac muscle, and the synthesis of (ADP-ribose) has been implicated in the regulation of DNA synthesis[20]. We therefore measured DNA synthesis in these normal and AT lymphoblastoid cell lines in response to γ-ray irradiation. As previously demonstrated[21] an inhibition of [Me-^{3}H]thymidine incorporation into the DNA of both normal cell lines (LIZ, DEW) after treatment of cells with a γ-ray dose of 500 rad was observed (Fig. 2). However, no inhibition of [Me-^{3}H]thymidine incorporation into the DNA of either AT cell line (GM1525/AT2BI, GM1526/AT8BI) was observed at a γ-ray dose of 500 rad (Fig. 2). Control experiments demonstrated that the amount of [Me-^{3}H]thymidine transported into both normal and AT lymphoblastoid cells decreased by similar amounts after treatment with γ-rays.

These results confirm that γ-ray irradiation produces an inverse relationship between (ADP-ribose)$_n$ and DNA synthesis in normal human lymphoblastoid cells. It has been proposed that suppressed DNA synthesis and stimulation of (ADP-ribose)$_n$ are associated with the development of DNA strand breaks[22]. If this is correct the absence of an inverse relationship between (ADP-ribose)$_n$ and DNA synthesis in the two AT lines suggests one of at least two possible alternatives. First, the AT cells may have a lower number of strand breaks;

Table 1 Characterization of the acid-insoluble product synthesized from ^{14}C-NAD in permeable DNase I-treated lymphoblastoid cells from a normal subject (LIZ) and an AT patient (GM1526/AT8BI)

	Acid-insoluble radioactivity remaining after treatment with nuclease (d.p.m. per mg of protein)	
Treatment	Normal cells	Ataxia telangiectasia (GM1526/AT8BI)
100 °C control	12,922 ± 646 (3)	19,100 ± 947 (3)
Deoxyribonuclease (100 μg ml^{-1})	13,164 ± 661 (3)	19,100 ± 995 (3)
Ribonuclease (500 μg ml^{-1})	12,320 ± 610 (3)	18,038 ± 879 (3)
Snake venom phosphodiesterase (600 μg ml^{-1})	1,246 ± 58 (3)	1,380 ± 67 (3)

Cells (7.8–8.3×10^5 cells per ml) in exponential growth (72 h) were made permeable as described in Fig. 1 legend. Cell suspensions (4 ml) were incubated in the presence of DNase I (100 μg ml^{-1}) for 30 min at 37 °C. Aliquots (50 μl) were removed to measure total (ADP-ribose)$_n$ synthesis in 100 μl of poly (ADP-ribose) polymerase assay buffer, pH 7.8 and 10 μl ^{14}C-NAD added. Reactions were terminated at 100 °C for 5 min. Aliquots (0.3 ml) of the DNase I treated cell suspensions heated at 100 °C for 5 min were incubated at 37 °C for 30 h in the presence of DNase I (100 μg ml^{-1}), RNase I (500 μg ml^{-1}) or snake venom phosphodiesterase (600 μg ml^{-1}). Reactions were terminated with 0.2 ml of 20% (w/v) TCA containing 2% (w/v) $Na_4P_2O_7$. Acid-insoluble product was collected and radioactivity counted as described in the legend to Fig. 1. Results are presented as the mean ±s.e.m. of three experiments each performed in triplicate.

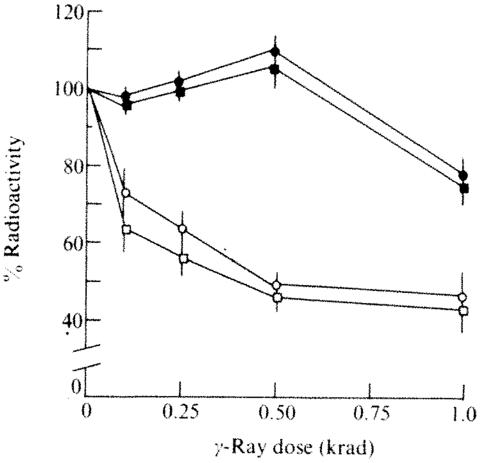

Fig. 2 Effect of increasing γ-ray radiation dose on DNA synthesis in lymphoblastoid cell lines derived from normal subjects (LIZ □, DEW ○) and AT patients (GM1525/AT2BI ■, GM1526/AT8BI ●). Cells in exponential growth (72 h) were resuspended in RPMI medium (7.4–8.3×10^5 cells per ml) supplemented with 10% (v/v) FCS and irradiated at 4 °C at the indicated dose using a ^{60}Co γ-ray source at a dose rate of 200 rad per min. Irradiated and non-irradiated cell suspensions were incubated after irradiation for 30 min at 37 °C and then 10 μl of [Me-^{3}H]thymidine (final concentration 10 μCi ml^{-1}, 10 μM) added. Triplicate tubes were incubated for 30 min at 37 °C. Cells were collected and washed twice in Dulbecco A phosphate-buffered saline, pH 7.3 at 4 °C (2×20 ml). Cells were resuspended in 1 ml of a buffer (containing 50 mM Tris, 4 mM $MgCl_2$ and 0.2 M NaCl at pH 7.4) and 0.2 ml of 20% (w/v) TCA added. The acid-insoluble product was washed in 10% (w/v) TCA (5×10 ml) and dissolved in 1 ml of 0.1 M NaOH. Protein was measured and radioactivity determined by liquid scintillation counting in Insta-gel. DNA synthesis (d.p.m. per μg of protein) in γ-ray irradiated cells is expressed as a percentage of mock irradiated (100%) control cells. Results are presented as the mean ± s.e.m. of four experiments each performed in triplicate.

there is, however, no evidence to support this[24]. Second, it might suggest that the damage produced by γ-rays in these cells is not translated into a signal which stimulates poly (ADP-ribose) polymerase. The synthesis of (ADP-ribose)$_n$ may have a role in the protection of DNA by suppressing DNA synthesis during states of DNA damage, and AT cells are hypersensitive to the effects of ionizing radiation for this reason.

We thank Professor D. G. Harnden and Dr C. Paraskeva of the Department of Cancer Studies for helpful criticism of the manuscript, Dr M. Steel of the Clinical and Population Cytogenetics Unit, Edinburgh, for the normal lymphoblastoid cell lines, the staff of the University of Birmingham Radiation Centre for the use of their facilities, Miss D. Williams for typing the manuscript and Miss Gillian Duckworth for technical assistance. This work was supported by the Cancer Research Campaign.

Defective DNA repair and increased lethality in ataxia telangiectasia cells exposed to 4-nitroquinoline-1-oxide

P. J. Smith & M. C. Paterson

Health Sciences Division, Atomic Energy of Canada Limited, Chalk River Nuclear Laboratories, Chalk River, Ontario, Canada KOJ 1JO

Ataxia telangiectasia (AT) is a rare autosomal recessive disorder in man characterized by progressive loss of muscular coordination (due to neurodegeneration) and permanent dilation of the small blood vessels of the eyes and skin[1,2]. AT patients also have repeated sinopulmonary infections, immune defects associated with thymus underdevelopment, and abnormal endocrine functions[1,2]. Affected patients are at high risk of developing malignancy, particularly lymphomas and lymphatic leukaemias[1], and there are clinical indications[3–5] that AT patients are hypersensitive to conventional radiotherapy administered for treatment of malignancy. Cultured diploid fibroblasts from AT donors are consistently hypersensitive to ionizing radiation[2,6,7], apparently due to defective enzymatic repair of radiogenic DNA damage[2,8]. We have determined the survival responses and DNA repair abilities of AT cells exposed to 4-nitroquinoline-1-oxide (4NQO), a chemical carcinogen whose DNA-damaging properties partially mimic those of ionizing radiation[9]. We report here that certain AT cell strains show hypersensitivity to inactivation by 4NQO and defective repair of 4NQO-induced adducts in DNA.

The mutant strains studied (Table 1) were selected on the basis of their *in vitro* DNA repair characteristics. AT2BE and AT3BI are defective in the excision repair of γ-ray-induced DNA base damage[2,8]; this is manifested in reduced levels of γ-ray-induced repair replication. The repair defects in AT2BE and AT3BI are genetically distinct, since the strains have been assigned to different complementation groups in cell fusion studies[10]. In the strain AT4BI[2,10], no anomalous repair of radiogenic base damage has been detected but it is possible that this strain is defective in the repair of a class of radiogenic DNA lesions that is simply not discernible in the repair assays used[2]. XP9RO was derived from a patient with the sunlight-sensitivity disorder xeroderma pigmentosum (XP). This strain (defective in the repair of UV-induced pyrimidine dimers in DNA[11,12]) is utilized as a sensitive control in repair experiments since XP cells are known to be sensitive to 4NQO[13] due to the defective repair of 4NQO-induced DNA base damage[14].

Figure 1 compares the survival responses of the cell strains to killing by 4NQO. Both AT4B1 and in particular AT2BE are abnormally sensitive to 4NQO, whereas AT3BI demonstrates a response similar to that of strains from two normal donors, GM 38 and GM 498. For example, when survival levels at 0.2 μM 4NQO are compared with those of the normal GM 38 control strain, then AT2BE, AT4BI and AT3BI yield ratios of survival values of 3.2-, 1.7- and 1.0-fold respectively. Compared with ionizing radiation, chemical agents induce a relatively narrow spectrum of lesions in cellular DNA[2]. Thus interstrain differences in the responses of AT cells to 4NQO and other radiomimetic chemicals[2,15,16] probably reflect the different DNA repair pathways in which AT strains are malfunctional.

The principal types of DNA damage induced by the active cellular metabolite of 4NQO are one stable adduct with adenine and two stable and one unstable adduct with guanine[14,17,18]. The

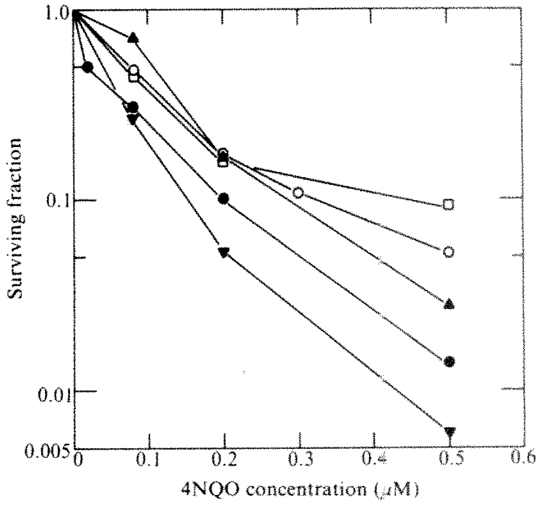

Fig. 1 Cell survival against 4NQO dose for normal and AT fibroblasts. Cells were collected from late logarithmic phase cultures and allowed to attach at 2×10^2–2×10^4 cells per 10-cm diameter plastic dish (Lux Scientific Corporation) containing growth medium at 37 °C for a period of 6 h. Attached cells were then washed with phosphate-buffered saline and incubated for 1 h at 37 °C with the indicated dilution of 4NQO in serum-free growth medium. Following the chemical treatment, the cultures were washed with growth medium and clonogenic potential was measured using the feeder layer technique previously described[7]. Data points represent the means of independent determinations (number in parentheses) for: ○, GM 38 [5; plating efficiency (PE) range, 7–21%]; □, GM 498 [1; PE, 6%]; ▼, AT2BE [3; PE range, 2–6%]; ▲, AT3BI [2; PE, 2% and 5%]; ●, AT4BI [4; PE range, 4–8%]. s.e. for each datum point was routinely ≤10%.

Table 1 General description and *in vitro* DNA repair characteristics of diploid fibroblast strains

Strain	Details of donor			Repair of ionizing radiation damage*		
	Diagnosis	Age (yr)	Sex	Repair replication	Removal of base damage	Strand-break rejoining
GM 38	Normal	9	F	+	+	+
GM 498	Normal	3	M	+	NT	+
AT2BE	AT	7	F	−	−	+
AT3BI	AT	4	M	−	−	+
AT4BI	AT	6	M	+	+	+
XP9RO	XP	9	M	+	NT	+

Monolayer stocks of each fibroblast strain (whose origin was human skin) were cultured in Ham's F12 medium supplemented with 15% (v/v) heat-inactivated fetal bovine serum, 1 mM glutamine, 100 U ml^{-1} penicillin G and 100 μg ml^{-1} streptomycin sulphate (growth medium). All culture procedures have been described previously[7]. Solutions of 4NQO (K & K Laboratories) were prepared immediately before use by dissolving the solid in 100% ethanol at room temperature and diluting to the appropriate concentration in pre-warmed serum-free growth medium.

* Details of DNA repair characteristics for the normal strains (our unpublished data), AT strains[2,6,8] and the XP strain[25]: +, proficient; −, deficient; NT, not tested.

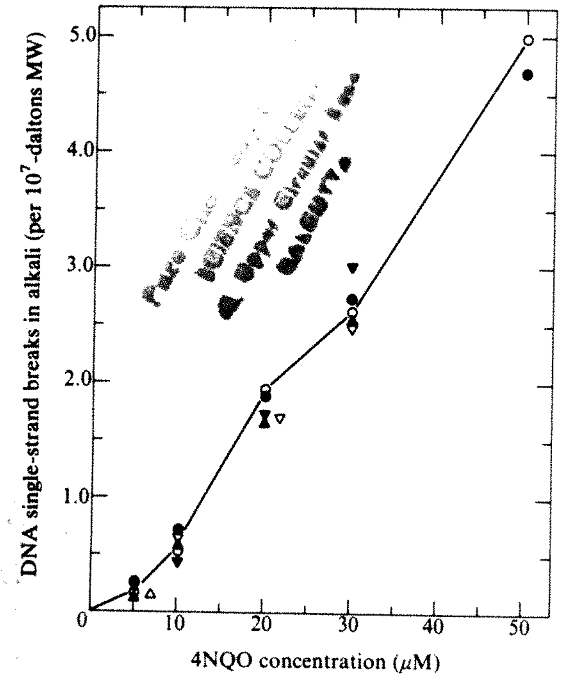

Fig. 2 4NQO dose-dependent induction of alkali-labile lesions in the DNA of normal, AT and XP fibroblasts. Cells were grown for ~48 h at 37 °C in medium containing either (*Me*-^{3}H]thymidine (1 μCi ml^{-1}; stock specific activity, 6.7 Ci/mmol^{-1}; NEN Canada) or [*Me*-^{14}C]thymidine (1 μCi ml^{-1}; 40.8 mCi mmol^{-1}; NEN). Tritium-labelled cultures (4 × 10^5–6 × 10^5 cells per 10-cm diameter dish) were exposed for 1 h to the appropriate concentrations of 4NQO as described in Fig. 1 legend. The ^{14}C-labelled control cultures were handled in a similar manner but not exposed to 4NQO. The parallel cultures were lysed and DNAs from the untreated control (^{14}C) and carcinogen-treated (^{3}H) cells were co-extracted with 0.5 M Tris-HCl (*p*H 8.0)-saturated phenol and dialysed against 0.05 M Na_2PO_4-1 mM EDTA buffer (*p*H 7.0). Co-extracted, radioactively labelled DNAs (100 μl) were incubated with unlabelled, sonicated calf thymus DNA (40 μl; 1 μg ml^{-1} stock; included to compete for any nonspecific nuclease activity) at 37 °C for 30 min followed by the addition of 1 M NaOH (100 μl). The DNAs were analysed by velocity sedimentation (40,000 r.p.m., 20 °C, 120 min in a Spinco SW-56 rotor driven by a Beckman L5-65 ultracentrifuge) in alkaline sucrose gradients (5–20%, w/v); 0.5 M NaCl, 0.2 M NaOH, 10 mM EDTA; *p*H adjusted to 12.5). After gradient fractionation and liquid scintillation counting, computer analysis of the gradient profiles yielded the number of strand breaks in alkali in the 4NQO-treated ^{3}H-DNA compared to the control ^{14}C-DNA. Data points represent arithmetic means of at least two separate determinations. ○, GM 38 (solid line); ▽, XP9RO (5 and 20 μM points offset for clarity); ▼, AT2BE, ▲, AT3BI; ●, AT4BI. s.e. for each datum point was ≤10%. MW, Molecular weight.

unstable guanine adduct appears to give rise to a DNA single-strand break in alkaline conditions[17,19,20]. The unstable 4NQO-guanine adducts are removed by a process(es) which may involve an ionizing radiation-like repair pathway(s)[9] and these defects are therefore candidates for the lethal lesions in the radiosensitive strains AT2BE and AT4BI. There is evidence in both bacterial[21] and mammalian cells[9,14] that the stable purine adducts are repaired by a UV-light-like excision repair pathway which leads to extensive DNA repair synthesis.

Figure 2 shows the 4NQO dose-dependent induction of single-strand breaks, detected in alkaline conditions, for several cell strains. The three AT strains examined all show similar levels of DNA damage to those of normal (GM 38) and XP (XP9RO) strains, despite their different sensitivities to the carcinogen.

Since the survival responses of AT strains to 4NQO could not be explained by differential susceptibility to DNA damage, we examined the repair kinetics of the alkali-labile lesions for the five strains (Fig. 3). In the normal strain (GM 38) and the AT strain of normal 4NQO sensitivity (AT3BI), fewer than 10% of the initial number of lesions remain 6 h after 4NQO treatment. Analysis of samples at incubation times longer than 6 h was sometimes complicated by anomalous sedimentation characteristics of the DNA preparations. For the two AT strains that

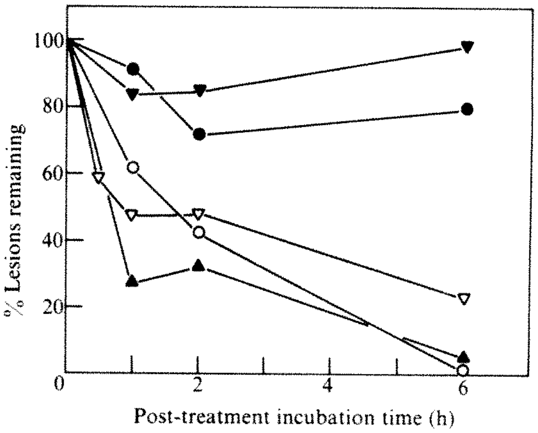

Fig. 3 Disappearance of 4NQO-induced alkali-labile lesions from the DNA of normal, AT and XP fibroblasts. The method is similar to that used to follow the repair of radiogenic single-strand breaks[8], and the protocol is detailed in Fig. 2 legend. Post-treatment incubation was in growth medium at 37 °C. Data points represent arithmetic means of multiple determinations indicated in parentheses: ○, GM 38 (6); ▼, AT2BE (4); ●, AT4BI (4); ▽, XP9RO (3); ▲, AT3BI (2). s.e. for each datum point was ≤15%.

are hypersensitive to 4NQO (AT2BE and AT4BI), more than 75% of the initial number of lesions remain 6 h after chemical treatment. This repair defect is also observed at lower 4NQO concentrations (data not shown). The XP strain displays an essentially normal rate of disappearance of this type of lesion. Thus, the cell survival responses of the three AT strains correlate with their ability to remove the carcinogen-induced alkali-labile DNA lesions.

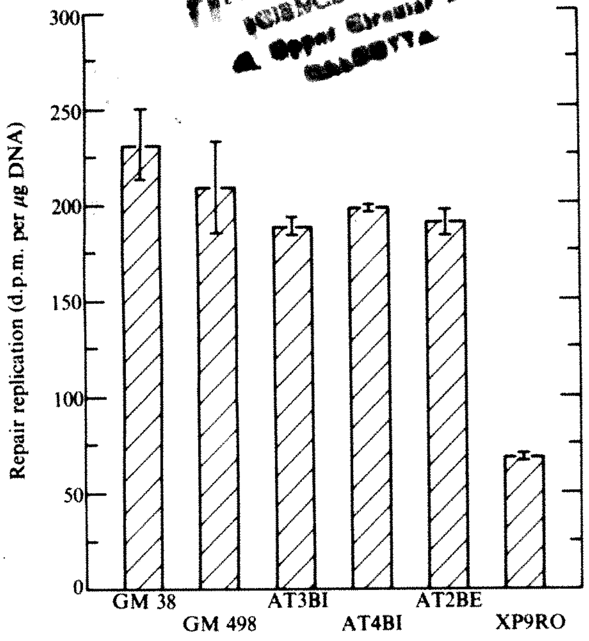

Fig. 4 DNA repair replication in normal, AT and XP fibroblasts exposed to 4NQO. The technique used was essentially that described for the measurement of γ-ray-induced DNA repair replication[8]. Repair replication is a measure of the incorporation of tritiated thymidine into non-replicating DNA during damage site repair. Growth medium was supplemented with 10% (v/v) dialysed calf serum rather than fetal bovine serum. Before 4NQO treatment, cultures (1×10^6–1.5×10^6 cells per 15-cm diameter dish) were incubated for 2 h in growth medium containing 6.5 μM 5-bromodeoxyuridine (BUdR) and 1 μM 5-fluorodeoxyuridine (FUdR). After exposure for 1 h to 30 μM 4NQO, repair was followed in the presence of 6.5 μM BUdR, 1 μM FUdR, 1 mM hydroxyurea and 10 μCi ml^{-1} [*Me*-^{3}H]thymidine (stock specific activity, 41 Ci mmol^{-1}; NEN) for 2 h at 37 °C. The labelling medium was then removed, and the cells were incubated for a further 1 h in medium containing 6.5 μM BUdR and 1 μM FUdR. DNA was then isolated for density gradient centrifugation by lysing the collected cells and extracting in chloroform–isoamyl alcohol. Neutral NaI gradients were prepared (6.2 ml containing 0.22 mM Na_2SO_3, 10–20 μg extracted human DNA, 0.1 mg ethidium bromide, 4.69 g NaI, adjusted to a final density of 1.54 g cm^{-3}) and centrifuged (33,000 r.p.m. at 30 °C; ≥60 h in a Spinco Type 40 rotor). The gradients were each fractionated into 18 tubes for the estimation of DNA concentration in a spectrofluorometer (Mk 1; Farrand Optical Co.). One rebanding of 'light' parental DNA was carried out to reduce contamination by 'heavy' DNA arising from semiconservative *de novo* DNA synthesis. Rebanding involved: (1) pooling six fractions containing light DNA per gradient; (2) dialysis overnight against 10 mM Tris-0.15 M NaCl-10 mM EDTA (*p*H 7.5) buffer; (3) preparation; and (4) centrifugation of NaI gradients as above. The rebanded samples were again fractionated and DNA concentration measured. Gradient fractions were transferred into ice-cold 10% trichloroacetic acid and 10 mM $Na_2P_2O_4$ and the precipitated, radioactive DNA collected on Whatman GF/C filter papers, and counted by liquid scintillation in toluene-Scintiprep 2 (Fisher Scientific). Histograms represent the arithmetic mean (background corrected) of two determinations for each designated strain with the range denoted by error bars.

Repair replication (a measure of repair synthesis) was measured for 2 h following exposure of cultures to 30 μM 4NQO. The results shown in Fig. 4 indicate that the technique clearly detects the defect in repair synthesis expressed by an XP cell strain[22–24]. However, there was no significant difference between the levels of repair in the two normal controls and the levels in the three AT cell strains. Since the expression of repair synthesis is considered to reflect largely the repair, by UV-like pathways, of the stable 4NQO-purine adducts[14], we conclude that such lesions are repaired with normal efficiency in AT strains. This view, that UV-like repair pathways are not defective in AT strains, is consistent with observations that far UV-induced repair synthesis is not reduced in AT strains[8,16] compared with normal cells.

As a DNA damaging chemical, 4NQO shows potential as a screening agent for DNA repair deficiencies in human cells. Its usefulness is facilitated in part by: (1) its dual UV-mimetic and radiomimetic properties, (2) its direct relevancy to carcinogenesis-related studies, and (3) the defined range of induced DNA lesions whose repair can be independently monitored.

Our data point to the presence in some AT cell strains of a defect in the repair of the unstable class of 4NQO–guanine adducts. We propose that the repair defect lies in the initial enzymatic release of the base adduct. Our results provide the first evidence of the nature of the putative DNA repair defect in AT4BI. Genetic heterogeneity in the repair abilities of AT strains following γ-ray or 4NQO treatment may be explained on the basis of deficiencies in either a pathway which handles γ-ray damage (for example, in AT3BI) or a pathway which handles γ-ray and 4NQO damage (for example, in AT2BE and AT4BI). Future research into the cellular and DNA repair properties of AT cells should provide a greater insight into the role of host and environmental factors in the process of neoplastic transformation and neurological degeneration.

P. J. S. was a Postdoctoral Fellow of the Natural Sciences and Engineering Research Council Canada.

GM 38 and GM 498 were from the Human Genetic Mutant Cell Repository, Institute for Medical Research, Camden, New Jersey; AT2BE (CRL 1343) was from the American Type Culture Collection; AT3BI was supplied by Dr A. R. Lehmann, AT4BI by Dr A. M. R. Taylor, and XP9RO (complementation group C[16]) was a gift from Dr D. Bootsma. Cell culture supplies were from Microbiological Associates.

Dimeric tRNA precursors in yeast

Otto Schmidt*, Jen-i Mao*, Richard Ogden†, Jacques Beckmann†, Hitoshi Sakano†, John Abelson† & Dieter Söll*

Two DNA fragments, each containing a tRNA$_3^{Arg}$ and a tRNA^{Asp} gene in close conjunction, have been isolated from different genomic regions of *Saccharomyces cerevisiae*[1]. Nucleotide sequence analysis of the gene regions revealed that in both fragments the tRNA$_3^{Arg}$ coding region is located 5′-proximal to the tRNA^{Asp} coding region. They are separated by an identical spacer of 10 nucleotides. Although the 5′-flanking sequences are different in the two plasmids, some similarities are observed. To test the mode of expression of this gene configuration, we transcribed the DNA fragments in a *Xenopus* oocyte nuclear extract[2,3]. Specific transcription of the yeast tRNA genes took place in an RNA precursor which comprised both tRNA species. We report here that the precursor RNA was processed to the mature-sized tRNA molecules, indicating the presence of an enzyme activity in the *Xenopus* nucleus capable of cutting a dimeric tRNA precursor. This is the first observation of a eukaryotic dimeric tRNA precursor.

The tRNA genes of several eukaryotes have recently been shown to be organized in a variety of ways. In some cases, such as *Drosophila* and *Xenopus*, multiple copies of the same gene or a number of different genes are clustered[4–7]. On the other hand, in nematode[8], silkworm[9,10] and yeast[1], tRNA genes generally seem to be scattered throughout the genome. Pulse-chase experiments of RNA in mammalian cells[11] and UV-light mapping studies of transcription units in yeast[12] have shown that dimeric or multimeric tRNA precursors are very unlikely to exist. In addition, *in vivo* and *in vitro* transcription studies in the *Xenopus* system have determined that eukaryotic tRNA genes are organized as single transcription units[3,6–10,13–15].

The recombinant pBR313 plasmids pJB18u and pJB19f contain *Hin*dIII fragments of *S. cerevisiae* DNA[1]. Hybridization patterns of [5′-^{32}P]tRNA to Southern blots of different DNA fragments from these plasmids suggested that the coding sequences for tRNA$_3^{Arg}$ and tRNA^{Asp} are located in adjacent positions[16] and that they may be co-transcribed. The plasmid pJb18u contains, in addition, a tRNA^{Tyr} gene about 1 kilobase upstream of the tRNA$_3^{Arg}$ and tRNA^{Asp} genes[16]. The DNA around the tRNA$_3^{Arg}$ and tRNA^{Asp} position has been sequenced in both plasmids (Fig. 1). Up to position −12 the 5′ flanking sequences are almost identical, but further out differ considerably in the two plasmids. This confirms the results of restriction enzyme analysis that the *Hin*dIII fragments in pJB18u and pJB19f derive from unique sites in the *S. cerevisiae* genome. In both plasmids the tRNA$_3^{Arg}$ coding sequence is 5′-proximal to the tRNA^{Asp} coding sequence. They are separated by an identical 10-nucleotide spacer in pJB19f and pJB18u. The two plasmids contain the same tRNA coding sequences which are identical to the known tRNA$_3^{Arg}$ (ref. 17) and tRNA^{Asp} (ref. 18) sequences. As in most other eukaryotic tRNA genes, the 3′-flanking sequences in both clones contain an oligothymidylate sequence which is probably a transcription termination signal for RNA polymerase III[9,10,13,19].

The transcription of these tRNA genes was tested in a nuclear extract of *Xenopus* oocytes[2,3]. The radioactive RNA was separated by polyacrylamide gel electrophoresis as shown in Fig. 2. Four major products designated RNA-1, RNA-2, RNA-3 and RNA-4 were observed. Using yeast 5S, yeast 5.8S and tRNA precursors of known length[20] as markers, the length of RNA-1 was determined to be 170 ± 10 nucleotides.

The first evidence that RNA-1 is a precursor to the tRNA-sized transcripts came from a pulse-chase experiment. After incubation with [α-^{32}P]CTP for 1 h, an excess of unlabelled CTP was added and the reaction allowed to proceed for another 2 h (Fig. 2). It is evident that RNA-1 and RNA-2 are less prominent in the chase experiment, indicating a precursor–product relationship to RNA-3 and RNA-4. This result was confirmed by reincubation of isolated radioactive RNA-1 in GV extract, which led to formation of RNA-3 and RNA-4 (not shown).

The nucleotide sequence of these RNA species was established by conventional methods[21] and compared with the DNA sequence. The RNase T$_1$ fingerprint of RNA-1 displayed all the fragments expected for the two tRNAs (Fig. 3*a*, Table 1). In addition, the fragments CUUUG (fragment 4) and UUCUUCCG (in fragment 2) were present indicating that the spacer sequence between the two tRNA coding regions is transcribed. The fact that the mature 5′ end of the tRNA^{Arg} is not found in RNA-1 implicates additional nucleotides in the form of a leader sequence. RNA-4 contained all the RNase T$_1$ fragments of tRNA^{Asp} (Fig. 3*c*). Analysis of a separate [α-^{32}P]CTP-labelled RNA-4 revealed the mature ends to be pUCCG, which apparently co-migrates with CUUG (fragment 6), and CCA$_{OH}$ (Table 1). Additional evidence that the 3′ end contains the CCA$_{OH}$ oligonucleotide derives from the fact that the preceding RNase T$_1$ fragment (AG) is labelled in this RNA (Table 1)

Fig. 1 Nucleotide sequences of the anticoding strand of the tRNA$_3^{Arg}$–tRNA^{Asp} genes from plasmids pJB18u and pJB19f. They are aligned according to the tRNA coding sequences (boxed). The chemical degradation method of Maxam and Gilbert[24] was used for DNA sequencing. The pJB18u sequence was determined from a *Taq*I site at position 55 in opposite directions for ~110 nucleotides. The elucidation of the pJB19f sequence of a *Cla*I–*Hpa*I subfragment (440 base pairs) was done from the *Cla*I (position −235), the *Hpa*I (position 199), the *Hae*III (position −119) and the *Sau*3AI (position 127) site. The identity of each nucleotide was determined at least twice.

although its nearest 3′ neighbour is A in the original transcript. An RNase T$_1$ fingerprint of RNA-3 (Fig. 3*d*) revealed all the oligonucleotides for tRNA$_3^{\mathrm{Arg}}$ (Table I) including the mature 5′ end (pGp). Furthermore, the CCA$_{\mathrm{OH}}$ oligonucleotide was found in a [α-^{32}P]CTP-labelled RNA (Table 1). Preliminary fingerprint analysis indicates that RNA-2 contains a mixture of the tRNA species and probably represents the cleavage product from the dimeric precursor. However, other events, such as transcription termination in the intergenic spacer region, cannot be ruled out.

Thus, the sequence analysis of the transcription products confirms the notion that the two RNA sequences are contained in a large transcription product including the spacer and probably flanking sequences. We suggest that dimeric tRNA precursors do exist in yeast, although they are not abundant. The dimeric transcript is processed in the nuclear extract to yield the

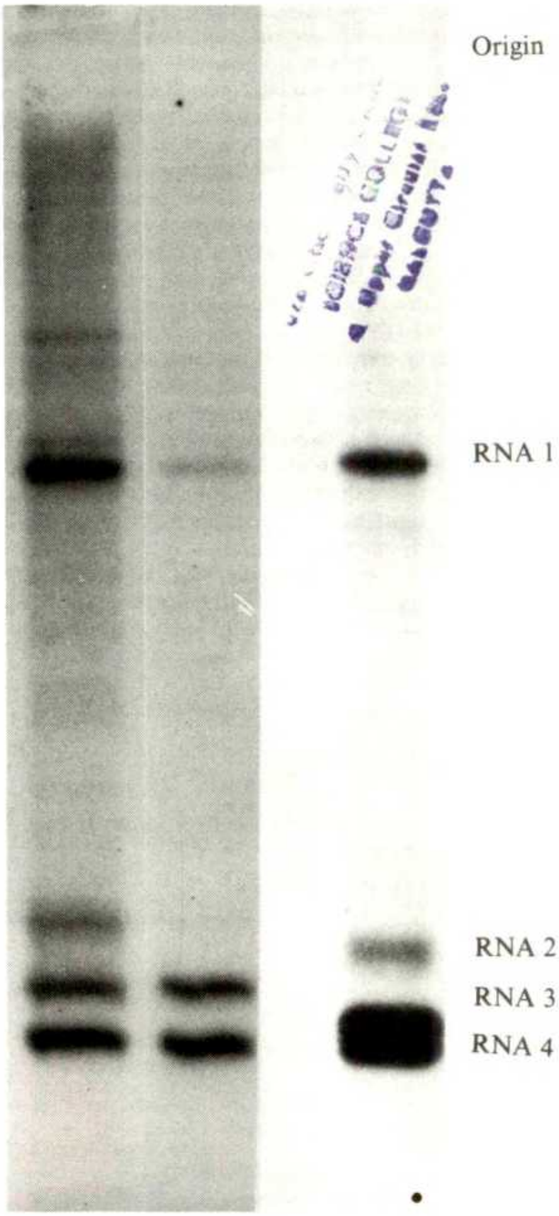

Fig. 2 Transcription and processing in *Xenopus* nuclear extracts. Autoradiograms of RNA transcribed from plasmids pJB18u and pJB19f in a variety of conditions separated on 10% polyacrylamide–4 M urea gels. The transcription reactions (40 µl) contained 30-µl GV extracts, 1 µg DNA, ATP, UTP, and GTP (0.03 mM each) and [α-^{32}P]CTP (0.01 mM, 40 Ci mmol^{-1}) in NH_4Cl (70 mM), $MgCl_2$ (7 mM), EDTA (0.1 mM), HEPES (10 mM, *p*H 7.4), dithiothreitol (2.5 mM) and 1% polyvinylpyrrolidone. After incubation at 22 °C for the specified length of time, the RNA was extracted[14] and separated by electrophoresis. Lane 1, pJB19f transcription for 1 h; lane 2, after 1 h in pJB19f transcription, reaction (lane 1) was supplemented with cold CTP and the incubation continued for a further 2 h; lane 3, pJB18u transcription for 1 h and separated on a different gel without urea.

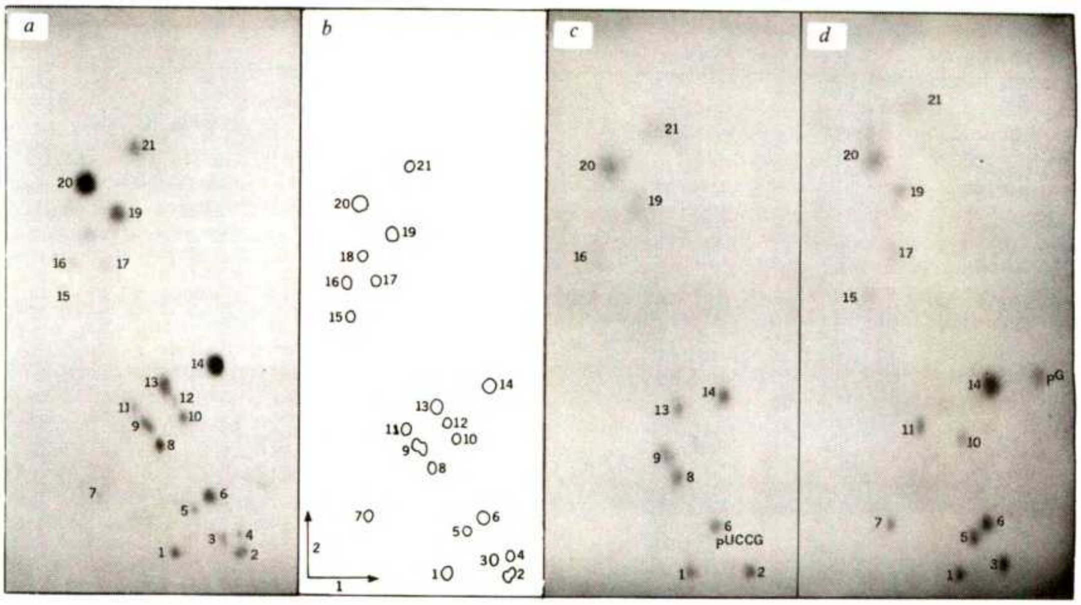

Fig. 3 RNase T_1 fingerprints of: *a*, RNA-1; *c*, RNA-4; *d*, RNA-3 of pJB19f DNA transcripts labelled with [α-^{32}P]GTP. *b* Is a diagram of a fingerprint of RNA-1. The numbering corresponds to that in Table 1. Standard RNA fingerprint separations were by electrophoresis on cellulose acetate at *p*H 3.5 (I) and on DEAE-cellulose at *p*H 1.7 (II).

mature-sized tRNA molecules. A number of nucleotide modifications are also found in these RNA species. Analysis of C-labelled RNA-3 and RNA-4 revealed ψ and m^{1}A residues present in the position expected from the sequence of the mature tRNAs[17,18]. It is not known whether a specific endonuclease activity is required to cleave the dimeric precursor or whether the nucleases processing monomeric transcripts can perform this function. The analysis of a different dimeric tRNA precursor in *Schizosaccharomyces pombe* indicated an endonuclease activity to cleave at the 5′ end of the second tRNA[20]. This activity, together with the activities involved in the processing of the 3′-flanking sequences are present in the nuclear extract[9,10,17]. Therefore, these processing steps are likely to occur in the nucleus, which has also been shown by *in vivo* experiments[22].

As these experiments involved a heterologous system, the results need to be confirmed in a yeast transcription system or by Northern hybridization analysis[23] of yeast RNA. Our results agree with the existence of tRNA-related yeast RNA species of greater than 5S RNA size, which have been shown in short *in vivo* pulse-labelling experiments (R. M. Bock, personal communication).

We thank Frank Horodyski for initial mapping of pJB18u and Beverly Harrell for initial mapping of pJB19f. O.S. was a Postdoctoral Fellow of the Deutsche Forschungsgemeinschaft.

The protein-coding sequence of the bovine ACTH-β-LPH precursor gene is split near the signal peptide region

The pituitary hormones corticotropin (ACTH) and β-lipotropin (β-LPH) are formed from a large common precursor[1–8]. Recently, we have elucidated the whole primary structure of the bovine ACTH-β-LPH precursor (designated alternatively as preproopiocortin) by determining the nucleotide sequence of cloned DNA complementary to the mRNA coding for the precursor protein[9]. The amino acid sequence assigned has disclosed a characteristic repetitive structure of the ACTH-β-LPH precursor. The repetitive units of the precursor protein each contain a melanotropin (MSH) sequence (α-, β- or γ-MSH) as well as other peptide components such as β-endorphin and corticotropin-like intermediate lobe peptide (CLIP). The repetitive units as well as their peptide components are each bounded by paired basic amino acid residues, which apparently represent the sites of proteolytic processing. Several studies[10] have confirmed the translational initiation site and protein structure assigned (see also ref. 11 and refs therein). In view of the recent knowledge about the organization of eukaryotic genes (see refs 12, 13 for reviews), it would be of particular interest to investigate the relationship between the repetitive structure of the ACTH–β-LPH precursor containing different functional components and the arrangement of the protein-coding sequence in its gene. We have now isolated and characterized bovine genomic DNA fragments encoding this precursor protein and have demonstrated that the protein sequence is encoded by two non-consecutive DNA segments. An intron (intervening sequence) of approximately 2.2 kilobase pairs separates the smaller exon (mRNA-coding sequence), which contains the gene sequence encoding the signal peptide, from the larger exon, which contains the gene sequence for most of the protein structure, including the known biologically active component peptides.

Calf thymus DNA was digested with various restriction endonucleases or their combinations and then subjected to agarose gel electrophoresis. DNA fragments containing an ACTH–β-LPH precursor gene sequence were identified by the Southern blotting method[14] with the cloned cDNA (*Pst*I-excised insert of plasmid pSNAC20[8]) as a probe. Three hybridization-positive *Eco*RI fragments of 0.9, 1.5 and 3.5 kilobase pairs were detected. For further characterization of these fragments, we used two additional probes produced by *Eco*RI digestion of the cDNA insert, which has a single *Eco*RI site corresponding to the carboxy-terminal amino acid residues of ACTH[9]. The cDNA segment representing the 5′ side of the mRNA (AL_L) hybridized exclusively to the 0.9 and 3.5-kilobase pair fragments, whereas that representing the 3′ side of the mRNA (AL_R) hybridized exclusively to the 1.5-kilobase pair fragment (for the AL_L and AL_R segments, see Fig. 1*e*). Further restriction patterns obtained with various endonucleases and their combinations enabled us to construct a restriction map of the ACTH–β-LPH precursor gene as shown in Fig. 1*a*. The 0.9- and the 1.5-kilobase pair fragments are adjacent to each other and are located on the left and the right side, respectively, of the unique *Eco*RI site present within the protein-coding sequence. The 3.5-kilobase pair fragment is positioned to the left of the 0.9-kilobase pair fragment.

To characterize the structural organization of the ACTH–β-LPH precursor gene, we isolated DNA clones carrying each of the three *Eco*RI fragments (for the cloning procedure, see Fig. 1 legend). Comparative restriction mapping with the Southern blotting technique confirmed that the cloned DNA fragments retained the sequence organization found in the cellular DNA. In addition, hybridization-positive calf thymus DNA fragments prepared by partial *Eco*RI digestion yielded DNA clones carrying a 5.9-kilobase pair insert which contains the 3.5-, 0.9- and 1.5-kilobase pair fragments oriented consecutively in this order.

Figure 1*c* and *d* compare the restriction patterns of the cloned 0.9- and 1.5-kilobase pair fragments with those of the cDNA segments AL_L and AL_R, respectively. There was a clear one-to-one correspondence between some of the restriction fragments derived from the 1.5-kilobase pair fragment and all restriction fragments derived from the AL_R segment, except the fragment that contains the site corresponding to the 3′ end (poly(A) addition site) of the mRNA (Fig. 1*d*, *e*). A one-to-one

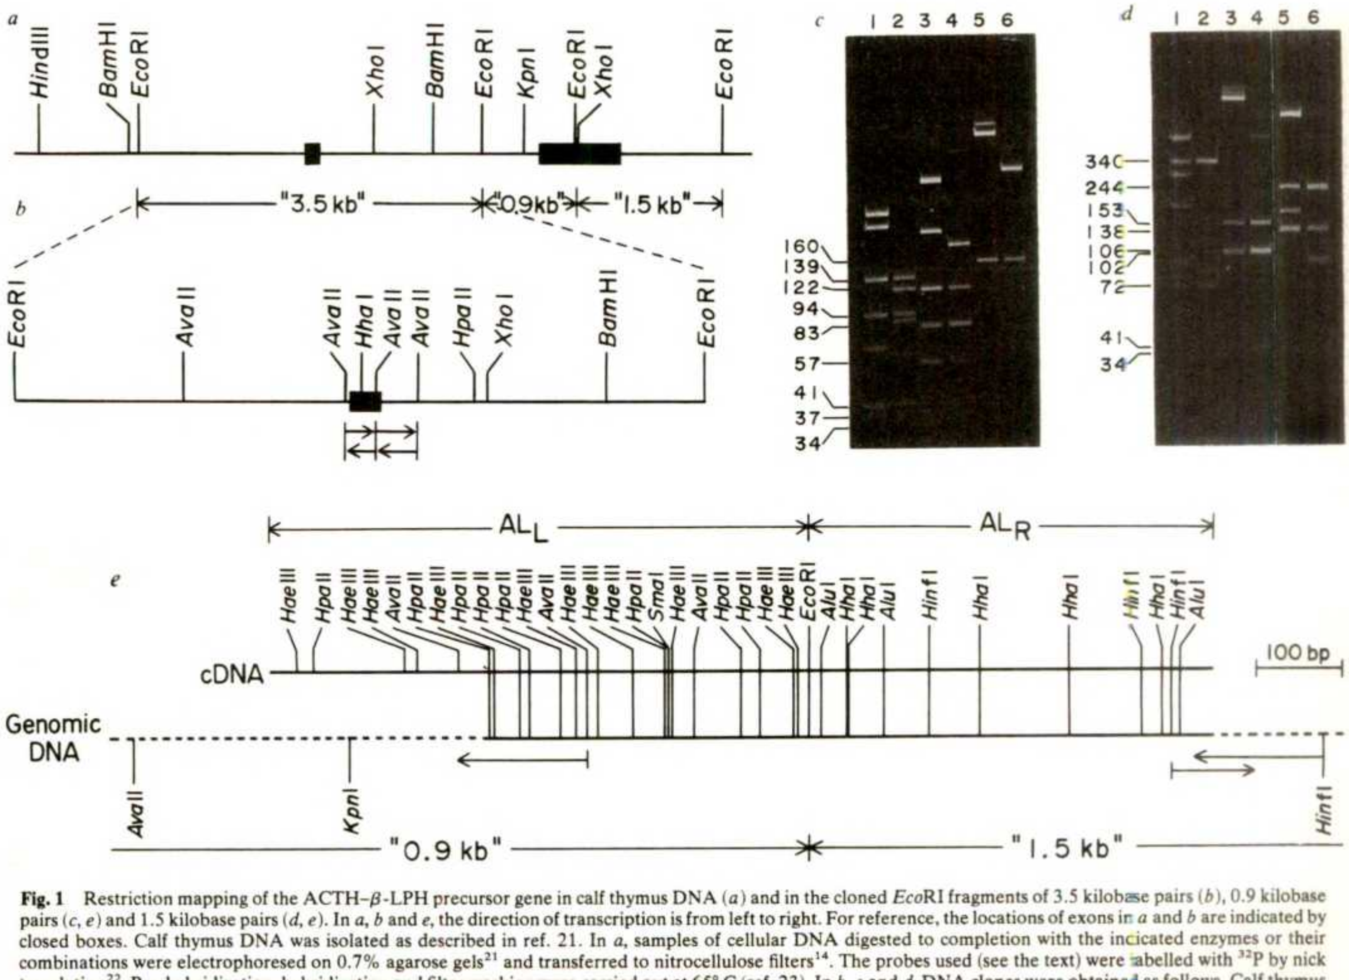

Fig. 1 Restriction mapping of the ACTH–β-LPH precursor gene in calf thymus DNA (*a*) and in the cloned *Eco*RI fragments of 3.5 kilobase pairs (*b*), 0.9 kilobase pairs (*c*, *e*) and 1.5 kilobase pairs (*d*, *e*). In *a*, *b* and *e*, the direction of transcription is from left to right. For reference, the locations of exons in *a* and *b* are indicated by closed boxes. Calf thymus DNA was isolated as described in ref. 21. In *a*, samples of cellular DNA digested to completion with the indicated enzymes or their combinations were electrophoresed on 0.7% agarose gels[21] and transferred to nitrocellulose filters[14]. The probes used (see the text) were labelled with ^{32}P by nick translation[22]. Pre-hybridization, hybridization and filter washing were carried out at 65° C (ref. 23). In *b*, *c* and *d*, DNA clones were obtained as follows. Calf thymus DNA fractions containing the *Eco*RI fragments of 3.5, 0.9 or 1.5 kilobase pairs were isolated by preparative agarose gel electrophoresis[21] and ligated to the purified *Eco*RI arms of bacteriophage λgtWES·λB (ref. 24). The recombinant DNA was packaged *in vitro* into viable phage[25], which were screened by hybridization with ^{32}P-labelled cDNA[26]. Each *Eco*RI fragment was isolated from these recombinant phage and subcloned in pBR322 (ref. 27). In *b*, samples of the 3.5-kilobase pair ("3.5 kb") fragment digested with the indicated enzymes or their combinations were electrophoresed on 5% polyacrylamide gels[9] or on 0.7% agarose gels[21] and were stained with 0.1% ethidium bromide. The *Ava*II sites were located by partial digestion of the *Eco*RI–*Hpa*II fragment on the left side; the *Hpa*II end was 5′-^{32}P-labelled. The horizontal arrows indicate the direction and extent of sequence determinations. In *c*, samples of the 0.9-kilobase pair ("0.9 kb") fragment (lanes 1, 3, 5) and the AL_L segment (lanes 2, 4, 6) were digested with *Hae*III (lanes 1, 2), *Hpa*II (lanes 3, 4) or *Sma*I (lanes 5, 6). The resulting restriction fragments were electrophoresed on 5% polyacrylamide gel[9] and stained as described above. Restriction fragments common between the cloned genomic DNA and cDNA are indicated on the left side of the electropherogram by their sizes in base pairs (bp). Faint bands observed in the upper region of the gel are due to incomplete digestion of the DNA. In *d*, samples of the 1.5-kilobase pair ("1.5 kb") fragment (lanes 1, 3, 5) and the AL_R segment (lanes 2, 4, 6) were digested with *Alu*I (lanes 1, 2), *Hha*I (lanes 3, 4) or *Hin*fI (lanes 5, 6). Other details were as described for *c*. In lane 4, the 3′-end-containing fragment was not separated from the fragments of 106 and 102 base pairs. In *e*, the restriction maps of the 0.9- and 1.5-kilobase pair fragments have been constructed on the basis of the data in *c* and *d* and the results of *Ava*II digestion. The dashed lines represent the regions where no correspondence between the restriction pattern of the cloned genomic DNA fragments and that of the cDNA was observed; in these regions, only the restriction sites used for DNA sequencing are shown. The horizontal arrows just below the line representing the genomic DNA indicate the direction and extent of sequence determinations. The portions of the AL_L and AL_R segments that correspond to the poly(dG)·poly(dC) tails and the poly(A) tail are not shown.

Fig. 2 Nucleotide sequence of the exon and its surrounding regions in the 3.5-kilobase pair fragment, the exon–intron junction in the 0.9-kilobase pair fragment and the region corresponding to the 3′ end of the mRNA in the 1.5-kilobase pair fragment. 5′-End labelling of restriction fragments and DNA sequence analysis were carried out by the procedure of Maxam and Gilbert[28]. The sequencing strategy was as follows: for the 3.5-kilobase pair fragment, the two *Ava*II fragments containing the exon (see Fig. 1*b*) were labelled and denatured, and both strands of each *Ava*II fragment were sequenced (sequence between the two dashed lines); for the 0.9-kilobase pair fragment, the *Ava*II fragment containing the exon–intron junction was labelled and cleaved with *Kpn*I (see Fig. 1*e*), and the *Ava*II–*Kpn*I fragment containing the exon–intron junction was sequenced (sequence between the second dashed line and solid line); for the 1.5-kilobase pair fragment, the 3′-end-containing *Hin*fI fragment (see Fig. 1*e*) was labelled and denatured, and both strands were sequenced (sequence between the solid line and dotted line). The nucleotide sequence of the message strand is shown. Amino acid residues are numbered as in ref. 9. The numbers of nucleotide residues are those of the corresponding residues in the cDNA[9]. The solid line represents the exon sequence encoding the majority of amino acid residues and the 3′-noncoding segment of the mRNA. The dashed lines represent intron sequences, and the dotted line the 3′-flanking sequence. The exon–intron junctions indicated are positioned according to the GT/AG rule[16]. The redundant nucleotide residues at the exon-intron junctions and the residues corresponding to the ambiguous 3′ terminus of the mRNA are boxed. The nucleotide residues representing an inverted repeat are underlined.

correspondence was similarly observed between some of the restriction fragments derived from the 0.9-kilobase pair fragment and all restriction fragments derived from the AL_L segment that are located less than 0.37 kilobase pairs upstream from the unique *Eco*RI site (Fig. 1*c*, *e*). In contrast, the restriction fragments positioned further upstream in the AL_L segment were completely displaced by unidentical restriction fragments derived from the 0.9-kilobase pair fragment. In agreement with these results of restriction mapping, nucleotide sequence analysis located the 3′ end of the mRNA in the expected region of the 1.5-kilobase pair fragment, and an exon–intron boundary 373–374 nucleotide residues upstream from the right end of the 0.9-kilobase pair fragment (Fig. 2). We conclude, therefore, that one of the exons of the ACTH–β-LPH precursor gene is composed of 838–841 base pairs, which represent a major portion of the protein-coding sequence, specifying 221 amino acids from the alanine residue located 87 residues before the amino terminus of ACTH through the carboxyl terminus of the precursor protein, and the 3′-noncoding sequence of the mRNA. The site corresponding to the 3′ terminus of the mRNA cannot be uniquely defined because the first two residues of the poly(A) tail could be transcribed from the genomic DNA. The 10 nucleotide residues immediately preceding the poly(A) tail have 7 residues in common with the model sequence TTTTCACTGC proposed by Benoist *et al.*[15]. Note also the presence of an inverted repeat (a region of two-fold rotational symmetry) surrounding the 3′ end of the mRNA.

On the basis of restriction mapping of the cloned 3.5-kilobase pair fragment (Fig. 1*b*), a possible region containing the protein-coding sequence was located between 1.6 and 1.8 kilobase pairs upstream from the right end of this fragment. In fact, nucleotide sequence analysis of this region demonstrated a 156-base-pair sequence that corresponded precisely to the mRNA sequence starting 23 nucleotide residues upstream from the translational initiation codon (Fig. 2). Because the 3′-border sequence of this exon and the 5′-border sequence of the exon present in the 0.9-kilobase pair fragment form a consecutive sequence on the mature mRNA, we conclude that these two exons are separated by an intron of approximately 2.2 kilobase pairs on the genomic DNA. The border sequences of this intron exhibit a redundancy of two nucleotide residues. By appropriate selection of the splicing point, however, the intron follows the general rule proposed by Breathnach *et al.*[16]: it begins with a GT and ends with an AG dinucleotide.

Further mapping of the 3.5-kilobase pair fragment with restriction endonucleases known to cleave the region corresponding to the 5′-terminal sequence of the mRNA, in conjunction with the failure of the resulting restriction fragments to hybridize to a cDNA sequence in this region, indicated that the mRNA-coding sequence upstream from that of the smaller exon is not included in the 3.5-kilobase pair fragment. Our attempts to identify a DNA fragment(s) containing the 5′-terminal mRNA structure have been unsuccessful. This small mRNA-coding segment may have been missed due to the relative instability of the hybrid formed during the Southern filter analysis.

Our results on the structural organization of the ACTH–β-LPH precursor gene are summarized in Fig. 3. Comparison of the restriction sites and partial DNA sequence of the cloned genomic DNA fragments with the known structure of the cDNA has demonstrated that the protein-coding sequence of this gene is split into two portions by an intron of approximately 2.2 kilobase pairs. This intron is located within the region corresponding to the peptide structure that exhibits some homology to the hormone calcitonin (L. J. Deftos, personal communication and refs 11, 17) and thus separates the gene sequence encoding the signal peptide[18] from that encoding most of the protein sequence which includes different functional components corresponding to several biologically active peptides. A second intron is present within the region corresponding to the 5′-noncoding sequence of the mRNA as is the case for the ovalbumin gene[19]. Very recently, we have learned that Chang *et al.*[20] isolated a human genomic DNA segment containing a continuous sequence equivalent to the larger exon of the bovine ACTH–β-LPH precursor gene we identified.

This investigation was supported in part by research grants from the Ministry of Education, Science and Culture of Japan, the Mitsubishi Foundation and the Japanese Foundation of Metabolism and Diseases.

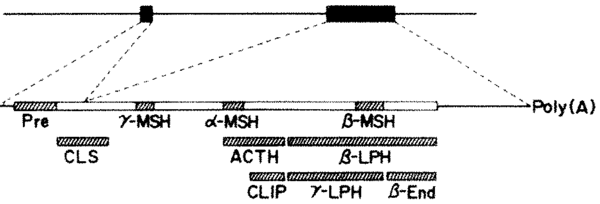

Fig. 3 Arrangement of the protein-coding regions in the bovine ACTH–β-LPH precursor gene. The exons are indicated by closed boxes on the upper line. For comparison, the topology of the mRNA is shown below. The shaded bars on and under the mRNA represent the regions coding for the component peptides of the ACTH–β-LPH precursor. Pre, signal peptide; CLS, calcitonin-like structure; β-End, β-endorphin.

Note added in proof: We have recently identified a third exon of 108 base pairs encoding the whole remaining 5′-terminal sequence of the mRNA by isolating additional bovine genomic DNA fragments and have thus confirmed the assigned position of the 3′ end of the proximal intron, which has a length of approximately 4 kilobase pairs.

Crystal structure analysis of a complete turn of B-DNA

Richard Wing*, Horace Drew, Tsunehiro Takano, Chris Broka, Shoji Tanaka, Keiichi Itakura† & Richard E. Dickerson

Division of Chemistry and Chemical Engineering, California Institute of Technology, Pasadena, California 91125

DNA is probably the most discussed and least observed of all biological macromolecules. Although its role in biology is a central one, with many examples such as operators and restriction sites where specific base sequences have control functions or interact with specific enzymes, the structures that DNA can adopt have been based until now only on sequence-averaged fibre diffraction patterns. Recent improvements in triester synthesis methods have made possible the preparation of sufficient homogeneous DNA of predetermined sequence for crystallization and X-ray structure analysis. We report here the first single-crystal structure analysis of more than a complete turn of right-handed B-DNA, with the self-complementary dodecamer sequence d(CpGpCpGpApApTpTpCpGpCpG) or CGCGAATTCGCG.

Two of the first crystal structure analyses of DNA prepared by the triester method, CGCGCG (ref. 1) and high-salt CGCG (ref. 2), produced variants of a totally unexpected left-handed zigzag or Z helix, of considerable structural interest but uncertain biological significance. The dodecamer sequence reported here was originally chosen to incorporate an *Eco*RI restriction endonuclease site, GAATTC, within ends related to the CGCG tetramer that was already being investigated in our laboratory. The discovery of the Z helix made this sequence potentially even more interesting as an example of two Z-compatible segments, CGCG, bracketing a Z-incompatible AATT. We fully expected the structure to contain left-handed Z ends and a right-handed or melted-out centre. Instead, we found a right-handed B helix with slightly more than 10 base pairs per turn.

Crystals were grown from a *p*H 7.5 solution of DNA with a 2:1 molar excess of magnesium acetate, and one spermine hydrochloride molecule per eight base pairs, by vapour diffusion from 20 to 30% 2-methyl-2,4-pentanediol (MPD). Crystals 3 mm × 0.7 mm × 0.5 mm could be grown in a matter of weeks. These were broken up and used for heavy atom soaking trials; more perfect small crystals were used for data collection.

The dodecamer crystallizes in space group $P2_12_12_1$ with cell dimensions $a = 24.87$ Å, $b = 40.39$ Å and $c = 66.20$ Å. An assumed crystal density of $1.5\ \text{g cm}^{-3}$ leads to one double-stranded dodecamer per asymmetric unit in a cell 47% DNA by weight. Assuming 22 negative backbone phosphate charges per dodecamer, the above unit cell dimensions indicate that the crystals are 2.2 M in negative charge even if no account is taken of possible anions contributed by magnesium acetate. Because all of these must be counterbalanced by spermine or other cations, the dodecamer crystals are fully as 'high-salt' in local DNA environment as are CGCG (2.0 M) or CGCGCG (2.6 M, see ref. 2). If there had been a significant tendency for CGCGAATTCGCG to adopt a partial Z-helical conformation, it should have done so in the crystal. Instead, a right-handed B helix is formed, with not even an indication of local structure irregularity in the CGCG regions.

The distribution of X-ray intensities on survey precession photographs suggests a cross pattern centred on the *c* axis and shows a cluster of very strong reflections at ~3.5 Å along the *c* axis, both implying that this is close to the direction of the DNA helix axis. Intensities remain strong in all directions out to 2.9 Å, and then exhibit a rapid decline until essentially no data can be obtained beyond 1.9 Å. Of the 5,691 possible reflections to 1.9 Å resolution, 2,818 were found to have an intensity greater than 2σ and were used in the analysis. Two isomorphous heavy atom derivatives were used: *cis*-dichlorodiamino platinum (II) obtained by diffusion, and a 3-Br derivative obtained by *de novo* synthesis of the dodecamer with 5-bromocytosine in the third position along each chain. The 1-Br derivative was crystallized but proved not to be isomorphous, and the 9-Br derivative was synthesized but not needed. Isomorphism in the *cis*-Pt derivative began to fail beyond 4-Å resolution, but the 3-Br derivative remains isomorphous to 2.7 Å.

The present report describes the partially refined structure obtained from multiple isomorphous replacement (MIR) analysis at 2.7 Å (mean figure of merit 57%), followed by Jack–Levitt refinement procedures[3] using 2,725 2σ intensities between 8.0 and 1.9 Å. The current residual error or *R* factor is 24.8% for a DNA molecule of 486 atoms and 9 initial water molecules. The structure of the DNA itself is essentially correct and is reported now because of its general interest. Refinement will continue with the addition of more solvent and spermine atoms, and some improvement in local nucleotide conformations.

A skeletal drawing of CGCGAATTCGCG is presented in Fig. 1, and a space-filling version from the same orientation in Fig. 2. The molecule is a Watson–Crick B helix with an average rise per residue of 3.4 Å, and 10.1 base pairs per turn. This is somewhat less than the 10.4 ± 0.1 base pairs per turn as measured in solution by Wang[4] or calculated by Levitt[5] from energy considerations.

The deoxyribose rings in our structure have been fitted to electron density in the MIR map and then allowed to refine; no attempt has been made to impose a uniform C2′-*endo* or C3′-*exo* geometry on them. At this intermediate stage of refinement they are about equally distributed between C2′-*endo* and the O1′-*endo* configuration that is related by rocking about the glycosyl bond, but no conclusions about sugar puckering should be drawn until refinement is completed. No sequence-dependent variations in the uniform B helix have been seen, but these will be watched for as refinement continues.

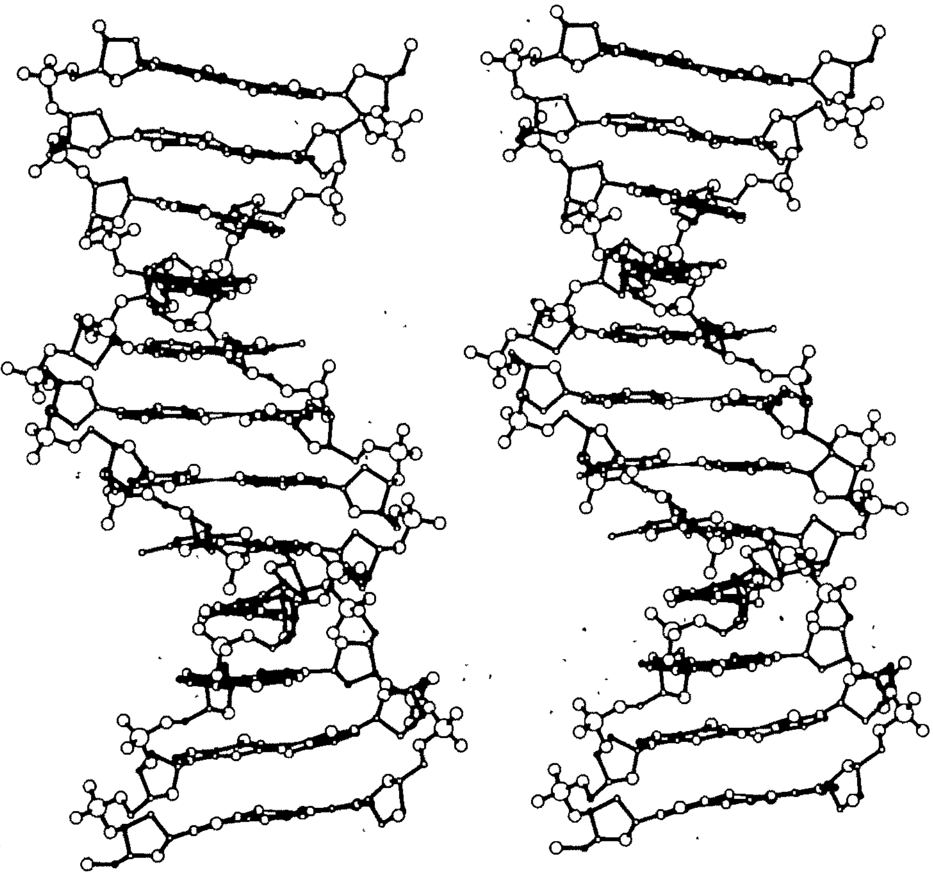

Fig. 1 Skeletal stereo drawing of CGCGAATTCGCG looking into the wide groove of the B double helix. Bases 1 and 24 are at the upper right and left in this view, and 12 and 13 are at the lower right and left. Note the uniform propeller twist in base pairs so as to maximize stacking contact with adjacent bases on the same strand, and the gentle curvature of the helix axis, concave to the right. For comments see text. Atoms in increasing order of size are C, N, O and P.

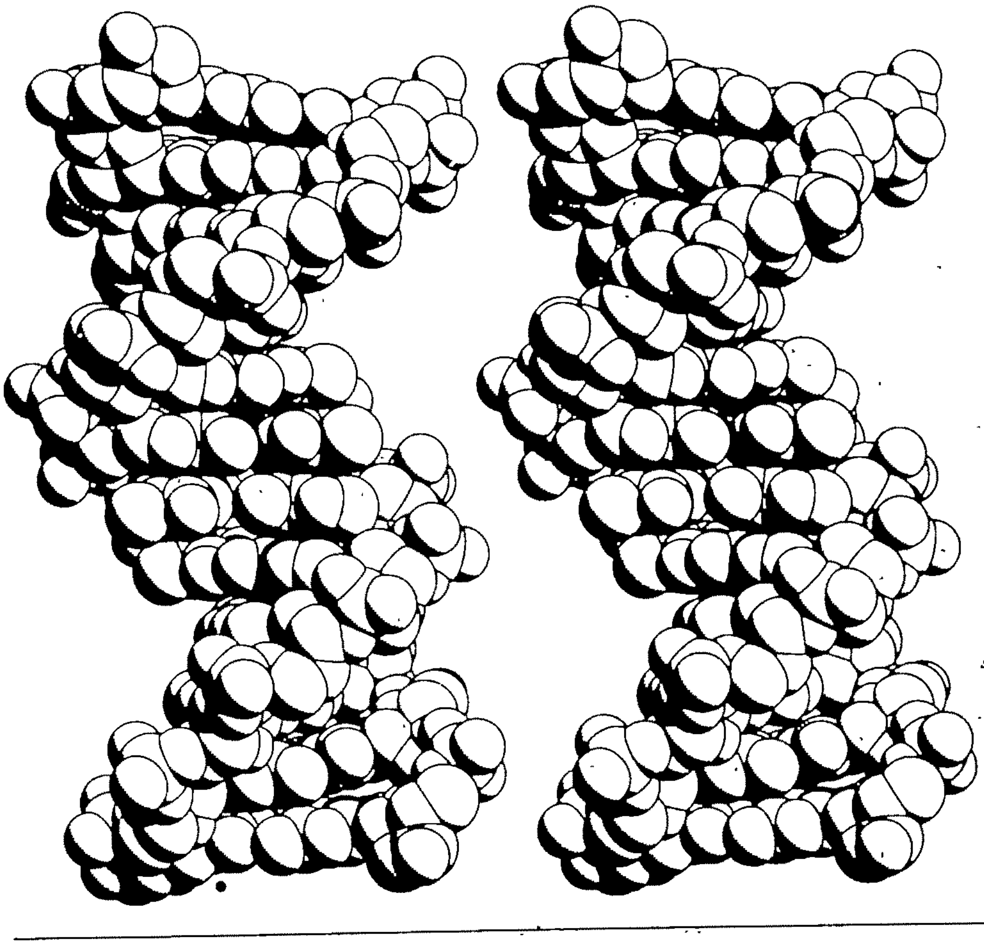

Fig. 2 Space-filling representation of CGCGAATTCGCG from the same viewpoint as Fig. 1. Atomic radii have been set at 85% of their true value for clarity. The advantage of propeller twist in maximizing adjacent base stacking can be seen in this packing drawing.

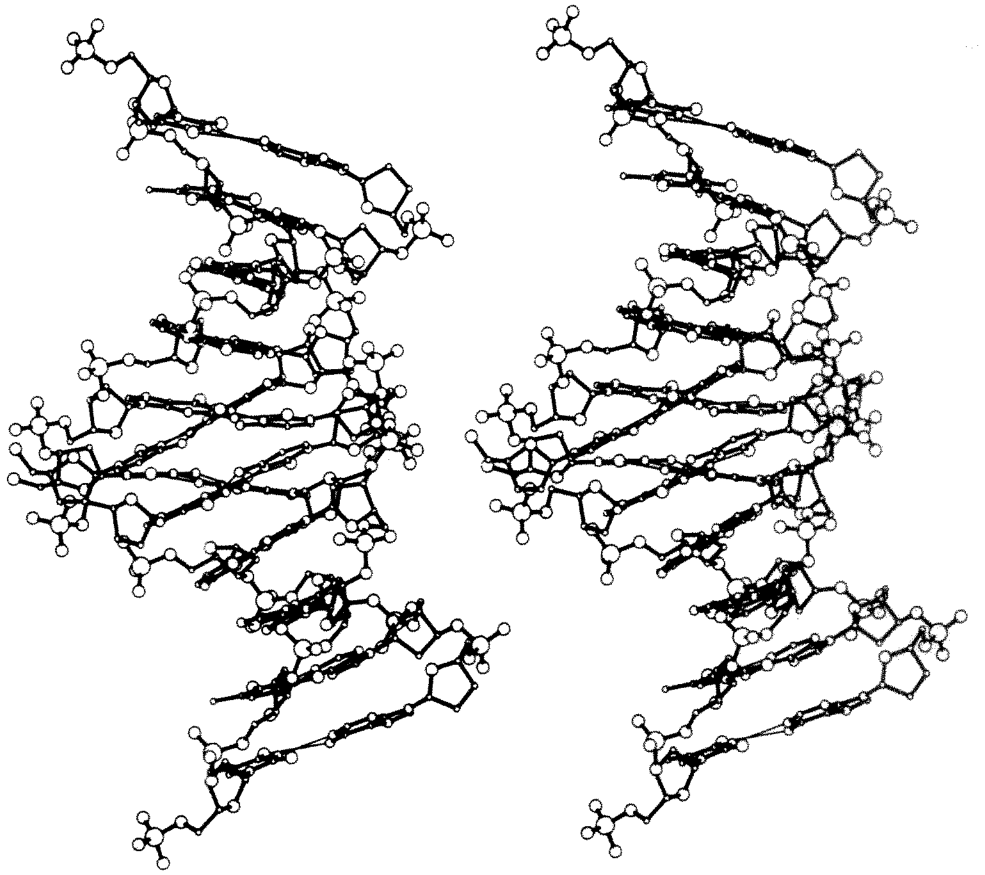

Fig. 3 Overlap of ends of molecules related by 2_1 axis along *c* (vertical). The upper half of one molecule (lower half not shown) sits in front of the lower half of another molecule (upper half omitted), with narrow grooves interlocked but with base planes tilted 35° to one another. The lower molecule shows bases 19–24 in front and 6–1 behind, and the upper molecule has bases 13–18 in front and 12–7 behind. The final base pair in each helix is packed parallel to, and in van der Waals contact with, the sugar–phosphate backbone of its neighbour. The narrow grooves at the ends of the molecules fit against one another like the palms of two cupped hands.

Even at this stage of the analysis, we can be confident about two interesting departures from classical B-helix geometry: each base pair has a propeller twist that increases the overlap between one base and its neighbours up and down the same chain, and the overall helix axis is slightly curved, concave to the right in Fig. 1. Levitt has proposed such a propeller twist in base pairs from energy calculations[5], and has found it to be persistent and not especially sensitive to the particular choice of energy parameters for minimization. Moreover, Hogan *et al.*[6] have found direct experimental evidence for propeller twist in solution from their transient electric dichroism measurements. This agreement gives us confidence that the DNA conformation we observe in the crystal is very close to that which occurs in solution.

The axis of the dodecamer helix bends by 19° over 11 base steps, for a radius of curvature of 112 Å. Moreover, the plane of bending does not contain the internal 2-fold symmetry axis of the base sequence; it is roughly 90° away from it (Fig. 1). This non-use of sequence symmetry means that equivalent positions in the two chains experience different local stresses, and suggests that the curvature is induced by external influences rather than being inherent in the molecule. Little energy would be required to produce such curvature. If the molecule is regarded as an

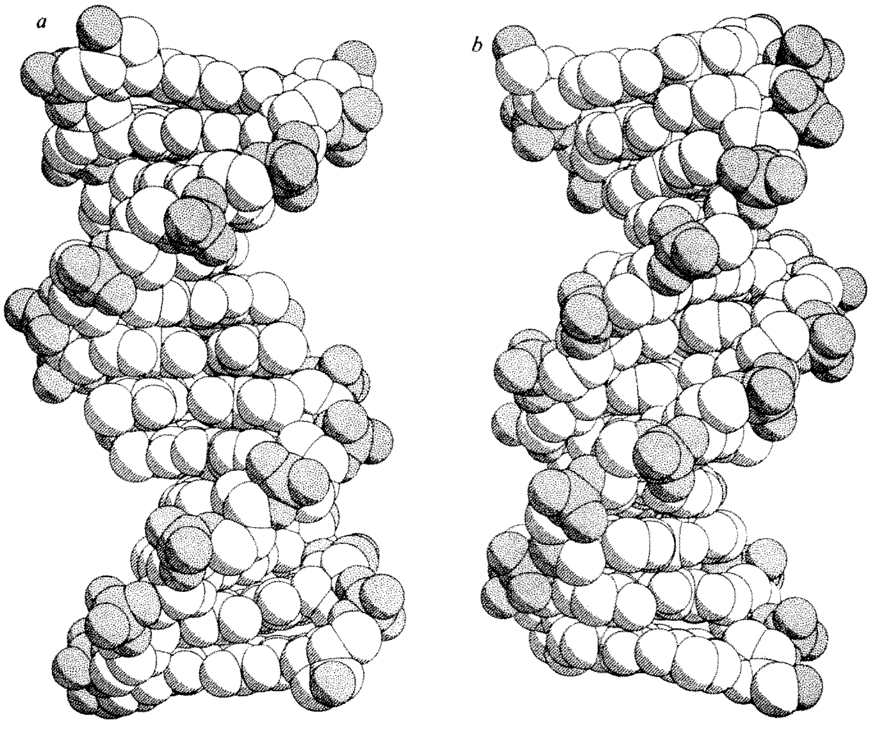

Fig. 4 Comparison of the wide groove (*a*) and narrow groove (*b*) in the B-DNA helix of CGCGAATTCGCG. Phosphate groups are shaded.

elastically deformable rod, the energy required for uniform bending is proportional to the rod length and inversely proportional to the square of the radius of curvature[7,8]. The proportionality constant can be evaluated from the persistence length of DNA in solution, and lies between 85 and 170 kcal Å mol^{-1} (refs 5, 8). This means that only 0.25–0.50 kcal of energy would be required per mol of dodecamer to produce the deformation seen in Fig. 1. As a comparison, the barrier to rotation about a single bond in ethane is nearly an order of magnitude greater, 3 kcal mol^{-1}. As crystal packing forces in proteins do frequently lead to different side-chain conformations in crystals where the asymmetric unit contains two molecules[9,10], such forces would be more than adequate to account for the observed curvature.

The probable origin of the crystal packing forces that produce the curvature is to be found in the association of neighbouring molecules up the 2_1 screw axis parallel to c as shown in Fig. 3. The molecules are not stacked on top of one another like cylindrical drums, instead they are staggered, with each molecule overlapping by three base pairs with its neighbours above and below. The overlap involves contact between minor grooves, with hydrogen bonds connecting ring N3 and amino N2 atoms in adjacent guanines from the two helices. (This pairing of guanines in the minor groove has been encountered in the structure of the complex of 9-ethylguanine and 1-methylcytosine[11], and has been proposed as a possible model for the recognition of guanine by asparagine or glutamine side chains of a protein (Fig. 3 of ref. 12).) Specifically, the N2 and N3 of guanine 14 in the upper molecule are hydrogen bonded to N3 and N2 of guanine 24 in the lower, and N2 and N3 of guanine 12 in the upper molecule are bonded to N3 and N2 of guanine 2 in the lower. However, base pairs in neighbouring molecules are sharply canted or tilted relative to one another by 35°, a tilt that brings the last base pair of one helix parallel to, and in packing contact with, the sugar–phosphate backbone of the other helix. The guanine N2 . . . N3 hydrogen bonds are twisted but not broken, and the tilted structure is locked into place by one more hydrogen bond—from the 3′-terminal OH of the upper helix in fig. 3 to the N2 of guanine 22 in the lower helix. The extra stability provided by these five bonds is more than enough to produce a 19° curvature in the helix axis. This interlocking of helix termini, a function of the CGCG sequences with which the molecule begins and ends, is probably also responsible for the unusual ease and rapidity with which crystals of CGCGAATTCGCG can be grown, in comparison with other DNA molecules whose crystallization has been attempted in our laboratory and elsewhere.

The contrast between major and minor from grooves can be appreciated from Figure 4, in which the molecule is viewed from diametrically opposed directions. The ratio of widths of major and minor grooves along the helix axis is almost exactly 7 : 4, and the minor groove gives, in this space-filling model, the impression of being quite constricted.

The mode of binding of *cis*-dichlorodiamino platinum (II) to DNA is of considerable medical interest because the complex shows promise as a carcinostatic agent in cancer chemotherapy[13,14]. The *cis*-Pt site in the dodecamer is in the vicinity of N7 and O6 of guanines 4 and 16 in the wide groove of the helix. As the *cis*-Pt complex is isomorphous with the native dodecamer only out to 4 Å resolution, it will be refined as an independent structural problem. The *trans*-Pt complex is even less isomorphous as judged by cell dimensions and intensity changes. All three refined structures will ultimately be reported, as a study of the mode of binding of platinum complexes to DNA.

CGCGAATTCGCG was originally synthesized as a substrate for the *Eco*RI restriction endonuclease. Its presence in solutions from which crystals of the endonuclease are being grown leads to a change in crystal form from that of the enzyme alone, fostering the hope that the crystals in the absence of Mg^{2+} contain an abortive binary complex of dodecamer and enzyme suitable for X-ray analysis. If Mg^{2+} is present, the dodecamer is cleaved well by the enzyme (J. Rosenberg, personal communication).

The B helix has been shown here to be the stable conformation of CGCGAATTCGCG in the crystalline state in salt conditions for which CGCG and CGCGCG adopt the left-handed Z configuration. Moreover, the value of 10.1 base pairs per turn and the propeller twist of bases indicate that this crystal structure is close to that which exists in solution. Although the bend in helix axis is probably induced by crystal packing, its presence illustrates the flexibility of the B-DNA structure, and the ease with which the molecule can be continuously deformed to wrap around objects such as the histone core in nucleosomes. Details of the hydration of B-DNA will be of interest as the transitions between B and other forms are generally considered to be a function of water activity[2]. These details, and any sequence-specific modifications of the uniform helix, will be matters of prime concern as refinement continues.

This work was supported by NIH grants GM-12121 and GM-24393, and NSF grant PCM79-13959. H. D. was also the recipient of an NIH Predoctoral Traineeship.

Note added in proof: Further refinement to an R factor of 17.8% has led to a regularization of the O5′-C5′-C4′-C3′ backbone torsion angles to a standard *gauche*$^+$ (about +60°) conformation.

Corrigenda

The following acknowledgements should have appeared in the letter 'Endotoxin-induced uveitis in rats as a model for human disease' by J. T. Rosenbaum *et al. Nature* **286,** 611–613. 'This work was supported by grant AI 11313 from the NIH. J.T.R. was supported by a fellowship from the Arthritis Foundation.'

In the News and Views article 'X-ray astronomy with the Einstein laboratory' by J. L. Culhane *Nature* **284,** 509–510, reference was made to the 'Harvard Center for Astrophysics'. This should have read 'Harvard/Smithsonian Center for Astrophysics'.

In the News and Views article 'Between the galaxies' by M. G. Edmunds, *Nature* **284,** 213, it was erroneously suggested that the number of intergalactic hydrogen clouds discovered by Sargent *et al.* is considerably *higher* than for galaxies—the correct value was quoted, and the incorrect statement was based on an overestimate of the observed number density of galaxies. Nevertheless, the total mass of the clouds remains small compared with that in galaxies. The author apologises for this error.

In the article 'β-Chain contact sites in the haemoglobin S polymer' by R. L. Nagel *et al., Nature* **283,** 832–834, the credit for Fig. 2 was omitted. Figure 2 was modified from *The Structure and Action of Proteins* by R. E. Dickerson and I. Geis (Benjamin/Cummings, Menlo Park, 1969).

Errata

In the letter 'Oscillation of [Ca^{2+}]$_i$-linked K$^+$ conductance in bullfrog sympathetic ganglion cell is sensitive to intracellular anions' by K. Morita *et al., Nature* **283,** 204–205, the column headings for Table 1 should read: 0.5, 1.0 and 3.0 (mM caffeine), not –, 0.5 and 1.0 mM.

In the news item 'Distorting the epidemiology of cancer: the need for a more balanced overview' by R. Peto, *Nature* **284,** 297–300, the caption to the figure on page 299 should have read: Data plotting for 39 countries age-standardized breast cancer death versus total dietary fat (animal or vegetable).

MATTERS ARISING

Leaping dolphins

THE analysis of leaping dolphins by Au and Weihs[1] has some shortcomings. The expenditure of energy during shallow high-speed swimming is presumably correct, although one wonders why a dolphin would not spend at least some time at greater depths if a 4.5-fold decrease in drag can be obtained by going down a metre or so. However, the computation of energy loss during a leaping manoeuvre seems to be at fault. Neglecting spray effects initially, the extra energy required for jumping is given as WH which is the energy required to raise a dolphin of weight W to a height H. However, the energy expended in raising the dolphin against gravity is not lost, but is partially transformed into potential energy at the high point and back to kinetic energy on returning to water-surface level. The dolphin has the same total energy throughout the leap and re-enters the water with the same speed as it had when it emerged. The total loss of energy is zero.

The spray effect, for which an energy loss of mWH is given, has also been computed incorrectly. A dolphin of weight W carries along with it an additional weight of water mW and on leaving the water it leaves this behind in the form of spray. This does not in fact concern the dolphin until it re-enters, when it has to accelerate a similar mass of water up to its swimming speed (U), and so experiences a brief retarding force and a loss of kinetic energy. The loss of energy is clearly $\frac{1}{2}mWU^2/g$, where g is the gravitational constant, and is independent of the angle of the leap. Thus the total energy lost is $\frac{1}{2}m\rho_d VU^2$, where V and ρ_d are the volume and density of the dolphin, respectively, and not $\frac{1}{4}(1+m)\rho_d VU^2$ as the authors claim. They seem to have overestimated the energy loss by a factor of $(1+m)/2m = 3$.

Further, there are more general considerations which could significantly affect the result. It seems unlikely that the dolphin would swim close to the surface between leaps, one reason being the difficulty of launching itself upwards at an angle of 45° from this shallow position. This would require the application of large vertical forces by the fins, of a magnitude several times its own weight. It is more likely that the dolphin follows a sinuous path consisting of leaps out of the water interspersed by dives under the water of a similar shape, thus achieving a clean exit and entry, greatly reducing drag by going deeper while submerged, and presumably breathing while out of the water. It is this total 'flight path' which should be compared with steady shallow swimming in the no-leap case.

Finally, it is unlikely that a dolphin would leap at an elevation angle as great as 45° because of the resulting loss of speed. A dolphin leaping and diving at this angle reduces his forward speed to about 70% of his speed through the water. Reducing this angle has a small effect on the length of leap, which varies as sin 2α where α is the elevation angle, but gives a significant improvement in forward speed, which varies approximately as cos α. A better compromise seems to be about 30°, and this is more in accord with my recollections of leaping dolphins.

Matters Arising

Matters Arising is meant as a vehicle for comment and discussion about papers that appear in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted. Neither contribution nor reply (if one is necessary) should be longer than 300 words and the briefest of replies, to the effect that a point is taken, should be considered.

AU AND WEIHS' REPLY—Gordon's comments on the calculation of energy consumed during the leap, as well as the manner of leaping, are well taken. We originally considered a model such as his symmetric parabola, but adopted our model because we observed shallow, brief swimming between long leaps after the dolphins shifted to the running mode. Therefore, we treated the problem of comparing the cost of shallow swimming with a jump from and to a shallow depth. The potential energy of the leap would not be useful to the dolphin trying to maintain a shallow swimming depth and must be dissipated in the re-entry splash and turning forces necessary to maintain that depth. Our energy loss J is exactly that required to keep the animal from plunging deeper. We suggested that the shallow swimming was due to requirements of increased respiration. Gordon's treatment of the overall problem is relevant to the case of sinuous motion whereas our treatment is based on our observations of saltatory motion.

Gordon's approach to calculation of energy loss due to added mass is more accurate than ours. It would result in a 5% increase in the crossover speed U_c at most.

We believe the centre of mass during the leap approximates a parabola with 45° exit angle that maximizes leap length, both because of the great increase in leap length over that occurring during cruising speed and because photographs often suggest a 45° exit. There is often a steep rise out of the water followed by a flattening-over of the body angle once exited that may give the appearance of a lesser exit angle. The difficulty of leaping from, and returning to, a shallow subsurface depth is acknowledged, but we have not seen the kind of motion Gordon postulates. Perhaps the constant extension of the dolphin's pectoral fins during the entire leap, from exit to re-entry, is explained by the manner of locomotion we describe. The pectoral fins probably act as diving planes to redirect the body angle between leaps and this must contribute greatly to the characteristic splashing. We agree that our differences should be resolved with more careful observations and measurements of this difficult-to-observe behaviour.

Finally, we apologize for an error in the last equation of our letter[1] which should read: $U_c^2 = 65.3 V^{1/3}$.

Climatic warming of the West Antarctic ice sheet

IN our paper on the "Effect of climatic warming on the West Antarctic ice sheet"[1] we included an analysis of the state of equilibrium of the Pine Island and Thwaites glaciers, which drain the northern part of the ice sheet. Our conclusions concerning these glaciers were the result of our own analysis of available data, but we should point out that attention was first drawn to the Pine Island and Thwaites glaciers by Hughes[2,3]. Moreover, hypothetical Eemian collapse of the West

0028–0836/80/430759—01$01.00

Antarctic ice sheet[4] has been under investigation by Hughes, Denton and others as part of the CLIMAP experiments[5]. Results of their analysis were presented during the Symposium on the Dynamics of Large Ice Masses, held in August 1978 at Ottawa; where a review of our work was also presented.

We wish to acknowledge the work of Denton, Hughes and their colleagues concerning the Pine Island and Thwaites glaciers, and we do not claim priority in recognizing the existence of these glaciers, their importance as calving bays, and the possibility that they may currently be "surging".

Terminal Cretaceous catastrophe

THE statements of Smit and Hertogen[1] that the terminal Cretaceous extinctions were "extremely abrupt" (~200 yr), lacked "warning signal," and that "gradual extinction lose their credibility on more detailed inspection," require substantiation. Simultaneous geological-range terminations of numerous taxa in a stratigraphic section usually indicate a hiatus (missing strata). A terminal Cretaceous marine shallow-water $CaCO_3$ dissolution event is noted at most marine localities. Was it not operative at Caravaca? Such an event would have caused a terminal Cretaceous hiatus that, in itself, could have accounted for the simultaneous termination of ranges in the Caravaca section, creating the illusion of catastrophic extinctions. Certainly, the termination of ranges via a hiatus would lack a 'warning signal'. Until it is proved that a terminal Cretaceous hiatus does not exist in the Caravaca section, claims of a terminal Cretaceous 'catastrophe' cannot be accepted.

An instantaneous catastrophe phenomenon such as a meteorite impact would have caused synchronous land and marine extinctions. Smit and Hertogen's claims of "near synchronous extinction" conflicts with Butler *et al.*[2] and Lindsay *et al.*[3] who cast serious doubt on any simultaneity. The statement "the independence of the event from the known normal environmental processes going on in the latest Cretaceous", is unfounded; Smit and Hertogen fail to consider the global warming of deep and shallow marine waters across the Cretaceous–Tertiary boundary noted by Boersma *et al.*[4] and Margolis *et al.*[5] They also fail to explain why only planktonic $CaCO_3$-producing marine organisms were affected significantly by the extinctions. Our Cretaceous–Tertiary dinoflagellate studies along the eastern US—even across a terminal Cretaceous hiatus—record no notable terminal Cretaceous extinctions. Clearly, oceanic *p*H changes seem to have been a factor in the marine extinctions.

Smit and Hertogen have failed to integrate significant aspects of the geobiological record into their extraterrestrial extinction model. As such, their use of the term "holocaust" for the terminal Cretaceous extinctions is inappropriate.

SMIT AND HERTOGEN REPLY—The hiatus assumed by McLean is the least likely explanation for extinctions at the Cretaceous–Tertiary boundary. McLean is confusing the sequence of the thermal events at the boundary and fails to consider the iridium peak, important evidence which we used to postulate a catastrophic (meteoritic) event.

McLean's postulated hiatus would have to be quite large to make it worldwide, and to let it wipe out any geochemical or other 'warning signals'. If such a large hiatus were operative, other taxa like benthic foraminifera and dinoflagellates should reflect a similar "illusion of catastrophic extinction", which is not the case. Further, the expected residual clay deposit from a dissolution event is not present either; a dissolution of the topmost 100 m of the Cretaceous at Caravaca would leave a 20-m thick clay deposit, but only one species would be added to the total of 55 planktonic species that became extinct. We have argued previously[1,2] that all stratigraphic subdivisions known to be connected with the boundary are present at Caravaca, including an additional interval, without signs of a hardground or dissolution. McLean needs to prove that a hiatus is present at Caravaca.

While synchronism of extinction is difficult to confirm, the results of Butler *et al.*[3] and Lindsay *et al.*[4] have been seriously questioned[5–7]. McLean also does not mention a similar magnetostratigraphic investigation by Lerbeckmo *et al.*[8,9], who favour synchronism. The problem has not been satisfactorily resolved and a claim of diachronism cannot yet be accepted.

The independence of the event from the normal environmental processes going on in the latest Cretaceous is inherent in the model and it certainly deserves further testing. McLean, however, is confusing cause and effect of the Cretaceous–Tertiary boundary event, when he brings a 'global warming' into the discussion as a normal terminal Cretaceous process. Data of Boersma *et al.*[10] and Margolis *et al.*[11] which indicate a warming, are exclusively Palaeocene and postdate the event. Rather a slight cooling is observed from the Cretaceous data only. The 'global warming' of Margolis *et al.*[11] indicates that the Cretaceous–Tertiary boundary occurred within a period of high global temperatures, lasting ~40 Myr from mid-Cretaceous to Lower Eocene, but as such there is no reason to relate these to the Cretaceous–Tertiary boundary event.

Lowermost Palaeocene warming[12] may well be a consequence of a large impact; either by direct heat generation or by a sort of 'greenhouse effect' (following oceanic impact) much in the same way as in the model of Alvarez *et al.*[13]. Dinoflagellates may escape the supposed suppression of sunlight by their cyst-forming abilities, as well as the dinoflagellate-like, $CaCO_3$ producing nannofossils *Braarudosphaera* and *Thoracosphaera*. However, we agree that the biological consequences of a very large impact are largely speculative at the moment.

BOOK REVIEWS

Hopes and fears for the Islamic world

Abdus Salam

The Future of Muslim Civilisation. By Ziauddin Sardar. Pp.288. (Croom Helm: 1979.) Hardback £14.95; paperback £4.95. Available from Biblio Distribution Centre, Totowa, New Jersey at $26.50.

THIS is a remarkable book written by a remarkable young author, not yet 30, addressed to Muslim scholars, intellectuals and scientists. Ziauddin Sardar's basic thesis is that, considering the present state of the Muslim world and of Muslim history of the past four centuries, as well as the urgency of the current global crises, it is imperative that Muslim peoples should think out and work for a planned, rather than an "aimless" future. As the argument develops, its two related dimensions emerge: "to operationalise a living, dynamic civilisation of Islam and to make a positive contribution to the Predicament of Mankind and the stabilisation of Spaceship Earth". In Sardar's view the two tasks are, in essence, one and the same; and both require intellectual boldness and courage.

Sardar starts with a critical look at the recent history of the Muslims. In his view, the Muslim civilization is the only civilization which still preserves something of its essence, and which has the potential to stand up to the dominant civilization of the occident. The tragedy, however, is that all attempts to adapt Western norms and values in the Muslim societies, from the eighteenth century Tanzimat reforms in the Ottoman Empire, to modern strategies of development, have failed to revive their dynamism. "The imitation of the West, has reduced the Muslim intellectuals to the status of voluntary mental slaves. It is now necessary for the Muslims to find solutions to their problems from *within* their own culture and traditional heritage."

In the long run, the author argues, Muslim people can discover their lost vigour and dynamism only by sustained research. He calls for a "Project Umran", an organized research programme to produce detailed conceptual maps and operational plans for alternative Muslim futures. The Muslims have not done their intellectual homework and the first aspect of his research programme calls for a new articulation of the age-old Muslim vision of the Medina State: the city established by the Holy Prophet after his migration from Mecca to Medina. "It is indeed a sorry reflection on the state of Muslim scholarship that almost all accounts of Medina State to date are almost as devoid of freshness and depth as they are of analysis." These are sentiments close to heresy in their boldness so far as traditional scholarship is concerned. And, in this context, Sardar's boldest suggestion is the outline of a modern methodology for the revivification of *ijtihad* (sustained reasoning) which was banned by traditional scholars some 600 years ago. This ban he asserts, was the chief reason for the decline of Muslim civilization. His ultimate picture is of a utopian future Muslim society, with the extended family as its base, the mosque as its focus, devising its own strategies of collective fulfilment, reaffirming commitment to Muslim traditions and values, maintaining elite and leadership accountability through the Islamic concept of criticism and self-criticism (*mahasbaah*), rediscovering the Islamic system of education based on personal contact and community awareness, and synthesizing Western and traditional modes of health care.

Mary Evans

Regarding science, Sardar is categorical: "bias-free observation is a myth", he declares. Contemporary science, he argues, is Western science, and only *a* science, and not *the* science.

> Nothing in perception is elementary, instantaneous, objective or strictly factual; it is all full of subconscious or indeed preconscious interpretations in the light of previous experience. The emotionally loaded word 'fact' has no place in science; it is a sign of either ignorance or dishonesty on our part if we believe that data gathered by science are wholly 'pure' and 'external', since they are always intermingled with our world-view and our perceptions [p.208–209].

The Muslims, in his view, must develop their own style of science and rediscover the spirit of science in Islam.

Whether one agrees or disagrees with him — and since I can see no distinction in spirit between, for example, the modern tradition in algebra and that of Omar Khayyam's, or the modern tradition in optics and that of Alhazen's, or Razi's observations on small-pox and their modern extensions, I certainly cannot subscribe to his views so far as *pure* science (as contrasted with goal-orientated technology) is concerned — Sardar's book does mark a sharp departure from conventional Muslim scholarship. He is intellectually demanding of the Muslims, and herein lies the importance of his work. As I indicated above, much of what he has said would spell heresy in some circles (both traditionalist and modernist). By itself, the extensive glossary at the end of the book testifies that his analysis has broken considerable new ground.

But nothing in this brief review can give an adequate idea of the remarkable felicity of Sardar's writing or its urgency and passion. There is his analysis of the "Parameters of Muslim Civilisation", including a historical survey of Muslim intellectual endeavour, an "Anatomy of Muslim Agony", a penetrating analysis of the history of the occidental world-view, and of the present world system.

And then there are the throw-away descriptions — for example of a new breed among Muslim intellectuals, "the professional Muslim" as he is called, whose first characteristic is

> . . . his self-appointed role as a contemporary bishop. The professional Muslim is always at every conference, whatever the theme, whether it is 'Muslim Education' in Mecca, 'Islam and the Challenge of New International Order' in London, 'The Third International Theory' in Tripoli, or 'Muslim Youth' (this despite the fact that he is usually over 45) in Kuala Lumpur.

In the same vein, and even more damning, is Sardar's assessment of the role of Muslim elites in their societies:

> . . . since the day of their independence, the Muslims have been ruled by elite minorities in the name of traditionalism, nationalism, socialism and democracy. These elites have acquired an unchallengeable sense of self-

> importance and omnipotence; they have transformed transient limited goals to universal imperatives. . . . They have sustained a value network characterised by materialism and vulgarity; [putting] blind imitation before critical inquiry, order before justice, obedience before responsibility, elitism and class before humanity, regionalism before universality, packaging before contents, . . . numbers before quality, efficiency before participation, expertise before wisdom, property before people, and economic and political gain before life.

But notwithstanding its power, the book, addressed as it is to the intellectual elites, has its (possibly self-imposed) limitations. There is little assessment of the contemporary Muslim political scene or of the fundamentalist politico-religious or spiritual movements which are currently shaping the Muslim world. It could be that Sardar believes in the transient, limited character of some of the current trends. But whatever these limitations of scope, are we witnessing with this work the emergence of a new, more analytical, impatient and aggressive breed of Muslim scholar? Regrettably, as things are at present in many Muslim countries, such scholars, if they do emerge, will be able to work and write only in the relatively freer atmosphere of the West. □

Muslim astronomers in the observatory at Istanbul, from a manuscript dated 1571.

The impact of volcanoes through human history

Alexander R. McBirney

Volcanic Activity and Human Ecology. Edited by Payson D. Sheets and Donald K. Grayson. Pp. 644. (Academic: 1980.) $52, £33.80.

Volcanism has recently received a new surge of attention, partly as a result of the eruption of Mount Saint Helens; *Volcanic Activity and Human Ecology* arrives, therefore, at an appropriate time. This book is the first of its kind, so far as I am aware, to attempt a comprehensive treatment of volcanic hazards and their effects on human activity, both modern and ancient. It can be divided into two parts: the first gives a brief summary of the main types of volcanic activity, hazards, tephra and volcanic soils; the second is a series of accounts of specific eruptions and how they affected different cultures.

The descriptions of volcanic activity by Fred Bullard and a chapter on tephra deposits and how they are studied, written by Larry Kittleman, are presented in a simple style easily comprehensible to the non-geologist. A contribution on volcanic soils by Ugolini and Zasoski provides a great deal of technical data, but would be far less tedious reading had it given less attention to chemical and mineralogical details and more to the practical aspects that interest most readers. Thorarinsson provides a fascinating account of the impact of eruptions in Iceland, and Warrick considers some of the general problems of dealing with volcanic hazards and their social consequences. The techniques of assessing volcanic risks in the Cascade Range are discussed in a paper that was written by Crancell, Mullineaux and Miller shortly before the eruption of Mount Saint Helens, and it makes interesting reading in the light of more recent events. On the whole, the authors fare quite well.

The topics dealt with in the second part of the book were more interesting to me, probably because they were less familiar. I was fascinated by two case studies by Hodge, Sharp and Marts, who describe the effects of recent eruptions on different cultures and economies, one in Hawaii and the other near Mount Baker in the state of Washington. The paper should be required reading for anyone responsible for assessing hazards and dealing with the public under conditions of stress and uncertainty. It shows quite clearly how people with different cultural backgrounds, economic interests and familiarity with a volcano perceive hazards and the restrictions imposed for their safety.

The eruption of Paricutin in Mexico between 1943 and 1952 is treated in considerable depth. Rees describes the impact on the physical environment, and Nolan gives a perceptive and thoughtful account of how five small communities reacted to the disruption of their lives and customs. The ways in which people responded varied widely, depending on the social structures of the communities, and it is particularly interesting to note that those that proved most resilient were people who had strong community ties and were subjected to the least amount of governmental assistance.

Several papers dealing with prehistoric eruptions in western North America address the question of how much importance can be attached to volcanic eruptions as agents affecting the migration, decline or ascendancy of primitive tribes. The contribution by Dumond on Alaska and the Aleutians is particularly notable for its clarity and readable style. The evidence seems to indicate that volcanism only rarely had the drastic impact on primitive cultures that has been attributed to it. But this is not necessarily true of more advanced societies, such as the classical civilizations of Central America and the Mediterranean. The effects of a huge eruption of Ilopango in El Salvador are shown to have had a profound effect on subsequent patterns of Mayan culture. The degree to which this was true of the eruption of Santorini in 1500 BC is still the subject of controversy. Renfrew discusses evidence for and against the hypothesis that the eruption accounted for the final demise of Minoan civilization, and, using evidence that volcanologists may find less than conclusive, he concludes that the eruption and the destruction of the community on Crete, dated within 50 years of each other, were coincidental.

No book on the effect of volcanism on civilized communities would be complete without a chapter on the eruption of Vesuvius in AD 79. Jashemski gives us a good summary of the eruption and its effects and explains some of the more recent archaeological work at Pompeii.

It is impossible to enumerate all the interesting facets of this volume. The editors deserve to be complimented on a splendid compilation of well-balanced papers, almost all of which are interesting, timely and well written. One of the most difficult tasks in a work such as this is keeping the papers on a level that will interest the average reader who is not concerned with details and the pet theories of individual specialists. The editors have managed to do this quite well. In short, the book is an unusually valuable contribution that will be useful to a wide range of readers. ☐

Alexander R. McBirney is at the Centre for Volcanology, University of Oregon, and specializes in the study of the volcanoes of the circum-Pacific region. He is co-author of Volcanology, *published last year by Freeman and Cooper.*

A star is born

F.D. Kahn

Star Formation. 10th Advanced Course of the Swiss Society of Astronomy and Astrophysics. By I. Appenzeller, J. L. Lequeux and J. Silk. Pp.222. (Geneva Observatory: Sauverny, Switzerland, 1980.) SwFr.30.

THE brightest stars in spiral galaxies line the insides of the spiral arms. The same regions are rich in interstellar gas, much of it ionized and made luminous by the stars themselves, and concentrations of the dust tend to occur nearby. But the spiral arms are manifestations of a wave-like disturbance that travels at some 100 km s^{-1} relative to the material in the galactic disk. The bright stars must therefore be short-lived, and be born and evolve during the time that the star-forming phase of the wave passes through the region. Stellar structure theory confirms that such stars do indeed consume their nuclear fuel in a relatively short time; the most luminous do so in as little as three million years. All this has been known for two decades or so.

These observations suggest that the diffuse interstellar material provides the source of matter for the new stars, and various theories have been proposed to describe how this might happen. But the sequence of events must be complex: the mean mass density is typically 24 orders of magnitude lower in interstellar space than it is in a star. The condensation process will consequently have various stages, each dominated by a different set of physical parameters. In addition, formidable problems are posed by the angular momentum content of the interstellar gas, and by the magnetic flux linked with it. There must be dissipative processes to reduce them both, otherwise star formation would be completely inhibited.

Many new observations have been made in the past few years which bear on these questions. The spatial and kinematical structure of molecular clouds has been revealed by spectroscopic observations at millimetre wavelengths. These clouds invariably contain much dust; any stars that form within them are therefore enclosed at birth within a cocoon of dust. The stars thus become initially detectable as infra-red sources, since it is possible only to observe the radiation from the heated dust that surrounds them, and obscures their surfaces. It seems to take some half a million years for this dust to clear away.

The 1980 Advanced Course at Saas Fee was devoted to this range of topics. As always three lecturers took part, and it is clear that this year each one saw his task in a different way. The first set of talks (I. Appenzeller) describes how to use a computer to simulate the process of condensation of matter into a star. The calculations are reasonably tractable if spherical symmetry is assumed. But should the description not be full three-dimensional? Can one even contemplate such a calculation for a system where some important lengths are as large as 10^{17} cm, and others as small as 10^{12} cm?

In the second group of talks, J. Lequeux sets out to establish some order among the large variety of observational data. He derives empirical formulae to connect the rate of star formation with the local density of interstellar matter, and to describe the distribution of masses (the initial mass function or IMF) among the newly formed stars. But is there an IMF which applies everywhere? Can the IMF for massive stars be reconciled with that for the lighter stars?

In the last group of talks, J. Silk presents a wide-ranging survey, with no less than 157 references, of recent observational and theoretical results. It is easy to appreciate, after reading his contribution, how complex star formation really is, and how many physical interactions are involved. Yet even so he leaves the impression that an acceptable theory will evolve before long.

The Saas Fee courses have deservedly become famous. The present text maintains their high standard, and provides an excellent guide to a very important subject. The book is well produced and the price most reasonable. But would the organizers be willing to consider a small suggestion? In future, when the three lecturers have spoken, might it not be worthwhile to have another speaker to provide a summary and put the different views in perspective? ☐

F. D. Kahn is Professor of Astronomy at the University of Manchester.

A summary of 30 years of solar radio astronomy

R. T. Stewart

Introduction to Solar Radio Astronomy and Radio Physics. By A. Kruger. Pp.330. (Reidel: 1979.) Hardback Dfl.95, $49.95; paperback Dfl.45, $23.50.

THE last monograph on this subject appeared in 1964, and since then a great number of significant radio observations of the Sun have been made from space and from large ground-based arrays. Considerable progress has also been achieved in theoretical aspects of plasma emission processes. Thus, the appearance of this volume in which the author attempts to summarize the work carried out during the past 30 years, is timely.

The book is divided into five chapters. In Chapter 1 a short history is given of the early attempts to detect radio emission from the Sun, leading to its discovery in 1942. This is followed by a brief description of the general properties and structure of the Sun. Chapter 2 is devoted to various types of instruments and techniques used in observational solar radio astronomy.

The great variety of radio emissions from the Sun is the subject of the next chapter, which contains many good illustrations. Recent kilometric and hectometric radio observations from spacecraft of type II and type III bursts are included in this account. Interpretation of these bursts in terms of plasma emission allows the determination of the electron density of the corona from near the Sun to near the Earth. Interpretation of millimetric and centimetric emissions in terms of thermal bremsstrahlung or gyro-synchrotron emission leads to estimates of electron temperatures, electron densities and magnetic field strengths in the chromosphere and low altitudes of the corona. Metric observations cover intermediate altitudes of the corona and give information on electron density, and the direction and strength of the coronal magnetic field. Hence radio observations cover most of the Sun–Earth environment.

The other important aspect of radio observations is the evidence they provide for non-thermal populations of energetic particles released by solar flares. The fourth chapter deals with the theory of solar radio emission and is divided into primary emission processes, such as thermal bremsstrahlung and gyro-synchrotron emission from accelerated particles, and secondary emission processes or wave-mode transformations such as Langmuir waves scattering into electromagnetic (plasma) radiation. Plasma instabilities such as the two-stream, velocity-anisotropy and tearing-mode instabilities are briefly discussed. The important question of amplification of radio waves is also mentioned but not considered in detail. The final chapter attempts to integrate solar radio astronomy with solar physics and solar terrestrial physics. The flare phenomenon is discussed, together with several possible mechanisms for the explanation of how particles are accelerated in the short time-scale of the flare and where the flare energy originates.

It is an ambitious undertaking to attempt to cover the entire span of the field in a single volume, but as an extensive review of the scientific literature the book is very successful and contains a useful list of references for the postgraduate student or research scientist. However, as an introduction to solar radio astronomy, it is less successful, being complicated by detail and lacking the highlights which give the reader an overall picture of an area of research. I feel that more emphasis could have been placed on the significant developments — instrumental, observational and theoretical — which have occurred in solar radio astronomy and that this would have led to a more readable account. However, I would recommend this book not only because of its uniqueness but also because it is an honest description of the work done in this field up until 1976. □

R. T. Stewart is a principal research scientist with the Division of Radiophysics of CSIRO, Sydney, Australia, and for the past 16 years has been closely involved with the interpretation of solar radio bursts observed by the Culgoora radioheliograph and other instruments.

Responses to arbitrary time schedules

J.T. Enright

Time in Animal Behaviour. By M. Richelle and H. Lejeune. Pp.273. (Pergamon: 1980.) Hardback £22, \$51; flexi £9.50, \$23.

Do not be misled by the title, the jacket and the foreward of this book. It does not treat general features of behavioural adjustment to time, but instead deals almost exclusively with the key- and lever-pressing performances of hungry rats, pigeons and a small number of other species. The introductory chapter led me to hope for an integration of biological-clock research (circadian and similar studies) with other broader aspects of temporal regulation, but, as one finally discovers on p.135: "In the almost total absence of [relevant biological-clock] experimental work, we shall content ourselves with defining the type of research that is strongly needed to fill the gap. . .".

The real intent of the authors is to introduce certain sorts of temporally programmed operant-conditioning experiments to the uninitiated. These experiments centre around one of two basic designs. On the "fixed interval schedule", the animal learns not to "emit responses" (I shudder) continually or randomly, but to wait, after a given success, for a major fraction of the imposed unrewarded interval before trying again, and then to try persistently until success finally comes. At the other extreme is "differential reinforcement of low rates", a programme in which any unsuccessful keypress resets the timer to zero; following a reward, the animal is required to wait for *at least* the pre-programmed interval before trying again. Granted proper shaping regimes, most animals can apparently master these schedules, as well as many complex variants. True enough, mastery of the programme usually involves only relatively imprecise indications that the animal has some sort of expectation in the time domain. Nevertheless, the evidence presented in this book clearly demonstrates that animals can evaluate and respond to arbitrarily chosen time intervals ranging from a few seconds to a few minutes.

The arbitrariness of the selected time intervals, based on their convenience in an operant-conditioning context, deserves emphasis. Most biologists are already familiar with certain other animal capacities to utilize time as a variable in an ecological context — matters of microseconds, as when an insectivorous bat uses sonar to home in on its prey, up to intervals of days, in time-training (*Zeitgedächtnis*) experiments with honeybees, and even weeks, in semi-lunar reproductive rhythms. Such aspects of temporal adaptation are presumably the intensely selected consequences of prolonged evolution. The animal skills considered in this book, on the other hand, seem to be completely devoid of any ecological relevance. To me, the impressive aspect of the results is that the animals show any capacity at all to deal appropriately with the arbitrary time schedules provided. These abilities are probably an evolutionary by-product, but the natural context in which they might originate remains obscure.

The general audience, for whom the book is intended, will encounter a number of stumbling blocks. It is easy to lose sight of the central questions when confronted with detailed results from yet another minor variant on the small number of standard experimental designs. A further difficulty lies in the authors' propensity for abbreviations which, once defined, the reader is expected to remember throughout subsequent chapters. The pages are peppered with FI, FR, FT, FI-FR, DRL 20s, DRL 60 LH 6, IRT, TO, RF/R and FRC, on through MULT FR 25 FI 7 min.

The authors emphasize (Chapter 6) that although brain lesions and certain drugs affect the response patterns, such results are fraught with ambiguity. I myself find the authors' attempts at overall interpretation (Chapter 9) to be equally ambiguous. For example, "We are dealing here with a relaxation phenomenon, and not a pendulum-type oscillatory system. . . Temporal regulation involves the buildup of some sort of tension that is suddenly discharged . . ." (p.222). That sort of conclusion seems to me to be inextricably tied up with the experimental designs; if the imposed timing schedule contains major elements of a relaxation oscillation (sudden reset to zero), how could the animals behave otherwise? What we have here, then, is a large body of experimental data which seem, at present, to be begging for adequate explanation at both the evolutionary and the neurophysiological level. The authors deserve our thanks for making these results accessible in a compact form for those — like myself — who have been unfamiliar with this body of empirical knowledge. □

J.T. Enright is Professor of Behavioral Physiology at the Scripps Institution of Oceanography, La Jolla, California.

Why bother to rehabilitate Galileo?

The Vatican has been edging towards a posthumous reconciliation with Galileo Galilei for several years. Since the time of Pope Paul VI in the mid-1960s, commendations of Galileo have been customary in the Vatican. The present pope, John-Paul II, has been still more outspoken. He marked the centenary of Einstein's birth two years ago with a public declaration that Galileo was an honoured precursor. As yet, however, the Vatican has not gone as far as to acknowledge as mistaken Galileo's prosecution in 1633 by the Holy Office — the trial that led to Galileo's abjuration of his heliocentric heresy on 22 June that year. Some such development is now, however, on the cards. The synod of bishops was told last week in Rome of a plan to set up a commission of inquiry under Archbishop Paul Poupard to look into the circumstances of the trial of Galileo and, as they say in the civil service, "to report". It is unthinkable that the outcome can fall short of a public declaration that Galileo should not have been brought to trial, that he should not have been forced by the threat of torture to recant and that his book, *Dialogue of the Two Great World Systems*, might safely have been taken off the Vatican's list of prohibited books a little earlier than 1835.

No doubt the Church is hoping that it will then be able to deal straightforwardly with the criticisms that have been flung at it for the past three centuries. Doctrinally, it should not be too hard for the commission to reach such a position. By good fortune, Pope Urban VIII (once a friend of Galileo's) played no part in the proceedings in Rome in 1633, not so much by design as from indolence. So a re-examination of the history of this shabby affair will not undermine the notion that popes (even bad popes) are infallible. Indeed, with a little luck, the commission may be able to put the blame for Galileo's examination and forced recantation on the two Dominicans, Badino Nores and Augustino Mongardo, who kept the minutes of Galileo's first formal encounter with the Holy Office in 1616, and who appear to have left in the Vatican files a much sharper version of what was then asked of Galileo than he and even his inquisitor, Cardinal Bellarmine, afterwards recalled. In the event, in 1633, Galileo was hauled over the coals not merely for having published his great book but also for having broken his supposed earlier undertaking not to hold heliocentric views. As the past three centuries have amply shown, this would not have been the first or last occasion on which the minutes of an important meeting turned out to reflect more accurately the wishes of the minute-taker than the words spoken.

Certainly, if it chooses, the commission will also be able to convince itself that the root of the trouble with Galileo lay in a misunderstanding between him and the Holy Office about the terms in which Copernicans were allowed to describe their theories. From 1616 on, Galileo understood that the Church required of him merely that the Copernican theory should be advanced only as a "hypothesis", not described in any sense as the "truth". Galileo, in other words, was almost as free to talk about Copernicanism as would be a modern professional brought up in the spirit of Karl Popper. Is not a good hypothesis one that is by definition falsifiable? That was the licence that he indulged in the seventeen years between his first and second encounters with the Holy Office.

The commission will also conveniently discover that Galileo's own behaviour contributed to the dismal outcome. Although his reputation is chiefly that of a fierce controversialist, Galileo was also capable of extraordinary deviousness. Why else would he have written the *Dialogue* as a dialogue between a Ptolemaic and a Copernican, leaving it to his readers to decide to which to give the benefit of the doubt? Throughout his second trial, he lied consistently, denying Copernican inclinations. His final humiliation was his claim that the *Dialogue* had been written to demonstrate that Copernicus was wrong. Pathetically, he told the Holy Office that, in preparation for his examination, he had read the book again after an interval of three years and had been dismayed to discover that his literary intentions had gone awry: on reflection, he allowed, innocent readers might have been given the impression that Ptolemy and not Copernicus was mistaken. The cardinals of the Holy Office can hardly have believed their good fortune. For practical purposes, the trial was over before it had begun. Everybody present must have recognized that Galileo's repudiation of his own witty and incisive book would be a more serious penalty than any they could have dreamed up for him. Willingly, they accepted his lies at face value. The public confession he was required to read before being sent off to house imprisonment was almost a formality. The Holy Office had pulled off a huge success. To have made a heretic recant would have been a minor triumph, an everyday occurrence. To have so humiliated the source of an important heresy that it would afterwards be entirely discredited was a much greater victory.

Now, three centuries after the event, the new commission will be able to point out that Galileo was apparently a willing accomplice in the whole affair. The transcript of the proceedings is full enough for that to be plain. No doubt he was afraid, but does fear not make lying excusable? Indeed, the new commission may be able to proclaim, the events of 1633 might have taken a different course if only Galileo had been straightforward, sticking to his guns. He might even have been able to persuade his judges that the Earth goes round the Sun and not the Sun around the Earth. For much of his life, Galileo had indeed been trying to do just that. His first brush with the Holy Office in 1616 was provoked by a letter he wrote three years earlier in which he noted that "the holy scriptures cannot err" but went on to argue that over-literal interpretations of them might be misleading. In the last resort, he had found out, the Church, not he, held the master cards. The execution of Giordano Bruno in 1600 for a similar (if less cogent) proclamation of heresy would also have shown Galileo that on some important issues the Church was implacable. If Galileo had stuck to his heresy, the chances are high that even he would have followed Bruno to the stake. Then, the Poupard commission would have a much more difficult circle to square.

So why, if the humiliation of Galileo falls short of martyrdom, is it now thought necessary to reopen this old question? What the synod of bishops was told last week is that the trouble about Galileo still serves as a barrier between science and the Church, keeping potential believers away from the congregations to which they would otherwise belong. It is hard to think this can be a substantial consideration. Even those who have no allegiance to the Catholic Church now acknowledge that there have been substantial changes in the past three centuries. Willy-nilly, the old literal interpretation of the Bible has been watered down. Many distinguished clerics take a serious and constructive interest in what is happening in science. Many distinguished scientists are also believers. And if there is a gulf between science and the Church, its origin lies in contemporary issues, not those with which the seventeenth century was preoccupied.

That, indeed, is the reason why the new commission may have a harder task than its planners appear to be expecting. With the passage of all this time, the rehabilitation of Galileo is hardly more significant than the posthumous pardoning of a traffic

0028-0836/80/440767-02$01.00

violater who pleaded guilty in court. The new commission cannot expect to produce a persuasive report on Galileo without going thoroughly into the question of how the Church should make up its mind about scientific issues which are at present contentious. How will the Church make up its mind about Darwinism, for example? Hankerings after directed evolution still play too big a part in the Church's view of biology. What will happen if the Big Bang turns out not to be the cosmological convenience that the Church has leaped at? It is tempting to suppose that in these enlightened days the tragedy of Galileo could not be repeated. But is that so? What is to be made of the way in which the Church, by insisting on its views of how people should behave, frequently flies in the face of what is known about human behaviour? Only last Sunday, Pope John-Paul II, a charismatic publicist but an illiberal pope, was asking that remarried people should refrain indefinitely from sexual intercourse. The Church's views on birth-control, appropriate enough when the chances of newborn children reaching puberty were a good deal less than fifty per cent, are now a means of making millions small-time martyrs, pathetic contemporary analogues of Galileo. The Poupard commission will steer away from cans of worms like these. In doing so, it will fall far short of what seem to be its objectives.

Solutions for transatlantic universities?

Everybody agrees that higher education is important. Many people spend time worrying about its health. Almost nothing is being done. This, it seems, is the lesson to be drawn from the clutch of reports on higher education published in the past few days. The meeting organized by the European Community at Strasbourg last week (see page 773) was presented with a familiar analysis of what the future holds (see *Nature,* 23 October); immobile university teaching staffs unlikely to be renewed on a substantial scale for years ahead, indefinitely straitened budgets and declining student numbers. What the commission's working paper did was to extend to the whole of Europe the gloomy analysis of the future for British universities described just over two years ago when Mrs Shirley Williams was Secretary of State for Education and Science. According to temperament, some academics (and some of their well-wishers) will be heartened to know that misfortune is so widespread while others will be dismayed that the problem is so huge.

Yet the problem is also unchanging, or apparently so. This week's report from the House of Commons Select Committee on Education (see page 770) makes that plain. The committee is still urging action on issues that first became urgent years ago. Has the dual support system for research quite broken down, and if so why? Can something be done to make the Universities Grants Committee a better buffer between the universities and central government? What should be done to help universities deal with the inflexibility that demography has thrust upon them? The committee has some sensible and even original things to say. Whether they will evoke a response from government departments whose present concern is what it seems continuously to have been for the past several years — to find further economies in public spending — is another matter.

Only in the United States does it seem that optimism survives — and even that may be illusory. The report on science and engineering education put together for the White House by the National Science Foundation and the Department of Education (see page 769) is no doubt right to deny some of the wilder fears about the adequacy of higher education in the United States — the charge that the efficacy of United States defence may be jeopardized by the quality of graduates from the universities for example. Moreover, there is no substance in the wish that some sleight of hand by university administrators might of itself beat back the tide of imports from Japan and elsewhere. If the United States is slipping as an economic power, it is largely because its people have elected to enjoy more of the benefits of service industries than the people of states such as Japan (see *Nature,* 2 October). The White House report nevertheless discovers a number of points at which the university system is under stress. The difficulty of persuading engineers to teach other engineers is not an isolated problem but a sign that universities may chronically be least able to recruit the teachers whose services are most needed. And if the terms of reference of the study had been wider, it would probably have come to conclusions that echoed, perhaps less starkly, those of European commentators — ageing teaching staffs, too much immobility among them and the prospect of too few students. What on earth is to be done?

Times like the present, when most governments are preoccupied with serious financial problems, are not propitious for grand designs for reform. Radical and sweeping change is easiest when funds are plentiful. The most serious danger in the prolongation of present difficulties, however, is that university systems on both sides of the Atlantic will be further impoverished in their present pattern until change heralded by crisis is forced upon them. This is why, while waiting for the grand design, some of the common problems of these several university systems need to be tackled piecemeal and empirically.

The question of academic tenure is an obvious problem, with which American universities have grappled for several years. The House of Commons committee deals with the issue judiciously. Tenure is an essential ingredient of academic freedom, but there is no reason why a university that no longer needs a whole department should not invite the teachers concerned to leave, on terms regarded by their academic colleagues as equitable or even generous. Most European academics will resist this notion, familiar though it has unhappily become in the United States. Yet if the choice is between the health of a university and the discomfort of some of its academics, can lifelong tenure be justly held always to be beneficent? European universities are mostly too mealy-mouthed on this delicate subject — and too free with early tenure in any case.

Shortages of teachers in specialized subjects, identified in engineering by the White House report, are commonplace and also chronic. They are, however, by no means as novel as they seem — both in medicine and the law, most university systems have special devices for persuading high-earning professional people to devote themselves partly to the interests of students, their future competitors. In more novel fields, systems engineering for example, there has not been — and probably will not be — time for suitable inducements to be devised. Universities may have to manage indefinitely with unconventional solutions. Part-time teachers drafted in from industry may help but will not solve all the problems that abound. The general solution must however be more flexible and permanent. Is it not time that universities hard-pressed to teach students what only industries know and practise should, without shame, arrange to have their students taught vocational skills on the job?

Another conspicuous element of the common malaise is that universities are no longer as autonomous as they like corporately to pretend. Especially in Europe but also in parts of the United States system, external agencies have an increasing say in the development of policy. The explanation is simple — governments pay an increasing share of the costs, and expect an increased influence. Yet governments, however liberal, are less able to know what are the needs of individual universities than are the academics who work in them. In principle, academics are also best placed to judge their contribution to national needs, and their places in the university systems to which they belong. The precondition, however, is autonomy — the freedom to make decisions for themselves. In this sense, the demand that universities should be free from some of the shackles that at present bind them is not a demand for the right to irresponsibility but the opposite. More autonomy is certain to mean better universities.

More commercial genetic manipulation

Harvard and Biogen establish Cambridge labs

Washington

Not to be outdone by West Coast colleagues, scientists from Harvard University and the Massachusetts Institute of Technology (MIT) are busy with their own plans for the commercial exploitation of research using recombinant DNA techniques.

The president of Harvard, Dr Derek Bok, is expected to announce shortly the university's decision to become a shareholder (although not an investor) in a company being set up to develop gene cloning techniques evolved in the university's laboratories. One candidate technique is Dr Mark Ptashne's methods of cloning human fibroblast interferon genes in *Escherichi a coli,* reported-in the latest issue of *Proc. natn. Acad. Sci. USA* (77, 5230; 1980).

At the same time, Biogen, the Swiss-based genetic engineering company whose board of directors includes Dr Walter Gilbert of Harvard and Dr Philip Sharp of MIT, is seeking permission to construct a $5.5 million research and manufacturing facility in East Cambridge.

Both schemes would make it easier for senior research scientists to maintain their university positions while working as consultants for the companies. In the case of Harvard — which 2 years ago agreed to license the rights to Dr Gilbert's insulin research to Biogen — the university would be able to invest its share of the profits from the new company in further research.

Inevitably, both plans have caused controversy. Harvard faculty members have been concerned about the potential conflict of interests between the goals of the proposed company and the university's commitment to basic research; Biogen's plans were the subject of a public meeting held on Tuesday before the Cambridge Biohazard Committee to discuss whether any conditions should be placed on the company's activities.

The Harvard plan was the brain-child of Dr Mark Ptashne, professor of biochemistry and molecular biology. Initially it had been proposed that the company would, at least temporarily, rent space in the university's biology laboratories; that postgraduate students might be able to work for the company while retaining university appointments; and that finance would be largely provided by the pharmaceutical company Eli Lilly, which had earlier bid unsuccessfully for the licence to Dr Gilbert's research.

Following an intense debate over the summer, various steps have been taken to keep the company, as one university official describes it, "very much at arm's length". For example, it has been agreed that, even if the university's involvement is approved, the company will seek separate premises.

In addition, although some Harvard scientists would be shareholders in the company and could be employed on a one-day-a-week basis as consultants — the generally accepted limit to outside commitments — direct overlap with university research staff would be minimal.

Financial support would probably come from outside sources of venture capital under a scheme being worked on by the Harvard Management Company, which manages the university's endowment.

The proposed organization of the company and its relationship to the university was discussed last week at a meeting of the faculty of arts and sciences. Although no formal decision was taken, Mr Daniel Steiner, Harvard's general counsel, said after the meeting that he saw "no overwhelming obstacles" to the plan being approved by Dr Bok, adding that the university "would not have gone as far as we have" if it had not been seriously interested in the project.

Ironically, the faculty meeting took place the day after Biogen had told the city council in Cambridge that it wished to build a research and manufacturing facilty in the city. At present, Biogen's main research facilities are in Geneva; and it is rumoured that one of the reasons for planning to build the new facility in Cambridge is the difficulty that has been experienced in obtaining Swiss work permits for US postdoctoral students.

Biogen's proposal was due to be presented on Tuesday to the Cambridge City Biohazard Committee, a subcommittee of the City Health Policy Council set up in 1976 after an intense local debate to monitor recombinant DNA research in the area.

More criticism was expected at the meeting. Ex-mayor Alfred E. Vellucci, who previously led an unsuccessful fight to ban all recombinant DNA research in Cambridge, was equally opposed to a "DNA factory" coming to Cambridge now.

Others thought that — particularly in the light of the investment fever that swept Wall Street two weeks ago over the public offer of shares in the San Francisco company Genentech — Biogen is unlikely to encounter substantial opposition.

If the Biogen facility gets the go-ahead, it is likely to be partly financed from a $20 million equity investment which the chemical company Monsanto is to make in the company. Also, the two other major equity holders — Shering Plough and International Nickel — have increased their equity by $8.8 million.

In a separate development, the Dow Chemical Company announced that it was making a $5 million investment in another small Massachusetts biotechnology company, Collaborative Research, of which Dr David Baltimore is chairman.

Few complaints on education

Washington

US science and engineering efforts are basically on an even keel, even if there are a few selective vacancies among the crew, the officers do not understand too much about how the engines work and the passengers occasionally question the course that is being followed.

This seems to be the main message of a long-awaited report on the state of US science and engineering education, requested by President Carter in February from the National Science Foundation and the Department of Education, and published in Washington last week.

The request, largely prompted by the President's Science Advisor, Dr Frank Press, responded to certain concerns expressed about aspects of educational policy in these two fields. These include a well documented decline in performance by US school-children in science-related subjects, difficulties faced by the armed forces in retaining technically trained recruits (much talked about after the failure of the attempt to rescue the hostages from Iran) and warnings of the dire consequences of apparent Soviet educational supremacy.

But whereas in the mid-1950s the launching of the Russian Sputnik was seen as a challenge which led to a massive injection of new funds to revitalize US efforts to improve scientific and technical skills, the new report implies that there is little need for general alarm — or any major investment of resources.

This time, the emphasis is on quality rather than quantity. The report concludes that the number of science and engineering graduates is likely to be adequate for the next couple of decades, apart from possible shortages in fields such as computer science.

Two main problems are identified: first, the increasing cost of providing a good engineering education, both in terms of employing good teachers and purchasing up-to-date equipment, and, second, evidence of a spreading "scientific illiteracy" which could have serious consequences in a world of increasing technical complexity.

It is the latter problem which provokes some of the strongest language in the report, with the claim that there is a

0028-0836/80/440769-02$01.00

"desperate need" for curricula for students who are not interested in professional scientific and engineering courses, and that "the current trend toward virtual scientific and technological illiteracy, unless reversed, means that important national decisions involving science and technology will be made increasingly on the basis of ignorance and misunderstanding".

The evidence used to support this contention — headlined in the US press coverage of the report — is scarce. However, various background studies are quoted. These reveal, for example, that in 1976–77 about 48 per cent of grade 9–12 students were enrolled in at least one science class. This compares with more than 59 per cent in 1960–61, the crest of the post-Sputnik science education boom.

Among the proposals aimed at tackling the growing gap between the two cultures is the setting up of a President's Council on Excellence in Science and Technology Education, to act as a possible vehicle for presidential statements about the need to raise science and mathematical requirements for all secondary school students. Other suggestions include a federal inter-agency coordinating committee of public understanding of science and technology, various regional conferences to help state and local administrators to discuss with teachers and educationalists ways of improving the quality and attractiveness of science courses, and various measures to increase awareness of the need to prepare for career opportunities in science and technology.

On the question of whether the current supply of science and engineering graduates is sufficient, the report is reassuring. In terms of scientists, a background "staff analysis" says that the present supply is adequate to satisfy demand except in a few sub-fields of physical and biological science, and that in 1990 the aggregate number of new science graduates at all degree levels should exceed the number able to find jobs in the broad fields in which they are trained.

In engineering, the picture is less optimistic. The same analysis indicates that there are current shortages of trained computer professionals and most types of engineers at all degree levels, and it says that for computer professionals in particular a shortage at all degree levels is likely to persist beyond 1990.

The general conclusion, however, is that the numbers of new engineering baccalaureates should be adequate to satisfy demand for the services, with neither a rapidly increasing defence budget nor a major programme in synthetic fuels creating significant additional demands.

Where the report does pinpoint a cause for concern is in the supply of engineering teachers and equipment. In the first case, it suggests that increased support for university-based research projects, and possibly salary increases for researchers approved by separate federal agencies, could reduce the rewards gap between industrial and academic careers.

In the second case, officials from the Office of Science and Technology Policy point out that the upgrading of university equipment is a principal objective of the extra $600 million in basic science support which President Carter pledged in his economic revitalization package announced in August.

The report's proposals are now being debated inside the White House to find those which, at a time of general budget austerity, can still be squeezed into the budget request for the fiscal year 1982. In a covering letter to the report, Dr Frank Press says that the Administration intends "to enhance the capabilities of our science and engineering programs for education and research".

However, following a report which throws lukewarm water on some of the more extreme claims and fears that have been expressed over the past year — nothing very dramatic is expected.

David Dickson

UK higher education

Commons take stock

British universities have at last found some friends in the House of Commons, to judge from the report (published earlier this week) of the inquiry by the Education, Science and Arts Committee into the funding and organization of higher education. Specifically, the committee sternly rejects the implications of the question raised by the Secretary of State for Education and Science, Mr Mark Carlisle, that the pattern of university courses should be tailored to the forecast needs of skilled manpower in the United Kingdom.

The committee has also sided with the universities in its urging that steps should be taken to encourage more potential students to go on to higher education, thus denying Mr Carlisle's statement that the present participation rate reflects market forces and should not be "artificially boosted". The question of participation rates is crucial for the universities, faced as they are with the prospect of a declining demand for university places for demographic reasons.

On the administration of institutions of higher education other than the universities (polytechnics, technical colleges and the like), the committee does not go the whole hog with radical opinion and recommend a committee analogous to the University Grants committee for channelling funds in their direction. Rather, it advocates a committee to be responsible for planning and advice in the non-university sector, saying that the local connections that have grown up between local authorities and the institutions which they maintain are valuable.

The committee links its opinion on the participation rate with the financial problems of higher education. It describes as "disappointing" Mr Carlisle's explanation of what is meant by "level funding" — the procedure by which the universities' budgets for the two coming years will "not be very different in real terms" from that for the present academic year. The committee says that the policy of "level funding" leaves no room for potential increases in the age participation rate, and that the government should instead devise a formula relating expenditure to student numbers.

The committee's approach to Mr Carlisle's delphic hope that there would be a "subject balance in broad terms in relation to the future of highly qualified manpower" was first to take advice on its meaning from his officials. For its pains, it won the supposed clarification that the objective was to translate "the very specific requirements of the market-place into very broad subject areas, grouping them in, for example, the technologies, the sciences and the arts subjects . . . to try to work out from such messages as can be derived . . . a subject profile which could be a guiding principle for the institutions of higher education".

While aspects of this opinion were echoed by others among the committee's witnesses, the committee says it found no agreement on what might be called the national need, and no workable suggestions as to how the task might be accomplished were put forward. The committee therefore recommends that the universities should indeed listen to such "messages" as they can hear, but that the suggestion that they should then attempt to work out "principles for higher education" should be rejected as impracticable.

The committee also asks that the University Grants Committee should be made more independent of the Department of Education and Science, perhaps by recruiting its own officials, not borrowing them from the department. It applauds the setting up of the Merrison committee, intended to look into the joint support of the University Grants Committee and the research councils for university research, and approves of the consideration now being given to the concentration of resources in those establishments where research is most vigorous.

For the rest, the committee gives its blessing to the department's present investigation of student loans, asks for a better definition of the problems of different fees for home and overseas students and suggests that the concept of tenure should be re-examined. The committee is judicious on the last point. It acknowledges that tenure is an important ingredient of academic freedom, but asks that it should not stand in the way of change. One solution, the committee suggests, would be for academics displaced from unwanted departments to be offered "fair redundancy".

0028-0836/80/440770-02$01.00

European Space Agency

Supposing stability

The European Space Agency (ESA) is hoping for a budget held steady for a decade, at a real £285 million a year from 1982. The sum is much less than ESA's current budget of £480 million, but it sets a floor below which ESA's rapidly falling spending should not fall.

This comes at a time when all is changing at ESA under Erik Quistgaard, the 58-year-old Danish industrialist who was appointed director-general of ESA in May. The current troubles come from the ending of the development programme for Ariane, ESA's launcher, and its transfer to the private company Arianespace, and the completion of Spacelab, due for launch on the space shuttle in 1983.

Last week Quistgaard presented his proposals to the ESA Council — the top decision-making body of ESA — in an unminuted restricted session of the Council "bureau", which consists of the top national delegates but takes soundings rather than decisions. It was this bureau session which agreed in principle to Quistgaard's budget. The bureau also supported his proposals for a 50 per cent increase over the next ten years in the mandatory science budget (which provides ESA's research satellites — 12 launched so far). This budget has been fixed effectively since 1971 at a level of £60 million a year (1980 prices), and is committed — all but £180 million — to 1990 on six projects.

These are a trip to Halley's comet in 1986 (a mission called Giotto), an astrometry satellite (Hipparcus), an X-ray observatory (Exosat), a 15 per cent involvement in the space telescope, an investigation of the solar corona outside the elliptic, and an experiment to measure the effects on the human body of controlled accelerations in space (SLED).

Whether the money materializes depends on decisions made nationally, and at subsequent meetings of ESA council (the next is this month). Agreement must be reached on the main technological programme of ESA — is it to be improvement of Ariane, Earth resources or communications satellites — against a tendency in France and Germany, opposed by smaller nations, to see ESA primarily as a research and development agency rather than a profit-making space multinational. And there are problems in both France and the United Kingdom over the procedure of contributing to ESA; so a ministerial meeting is being considered for the spring of next year.

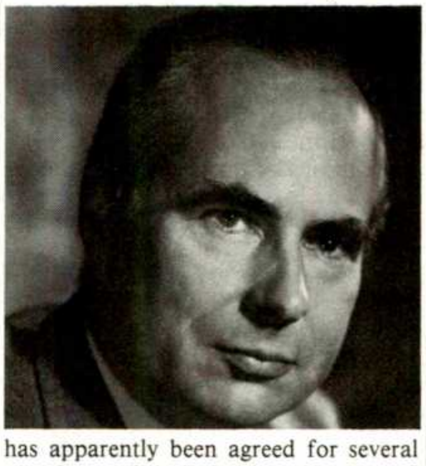
In the United Kingdom, the problem is the division of contributions between the Department of Industry (for applications) and the Science Research Council (for research), so that a change in balance must be decided at ministerial level. In France, the problem is the competition between contributions to ESA and a growing national programme within the budget of a single agency, the Centre National pour les Etudes Spatiales — again a matter for cabinet-level decisions.

But whatever the remaining problems, Quistgaard himself scored a major personal success last week. Delegates came to Council prepared to take their pound of flesh — France, for example, wanted a 10 per cent cut in ESA staff — but in the end they applauded him. In his summing up Quistgaard told delegates "You nearly killed me — but I survived." More than that, he has streamlined ESA, getting Council to agree to eliminate the 40-strong directorate of future programmes and planning, and to set up a think tank of half the size which will report directly to Quistgaard; and to devolve power to the existing directors (now to be called the management team). **Robert Walgate**

Huxley for PRS

Sir Andrew Huxley, the neurophysiologist, is now almost certain to be the next President of the Royal Society in succession to Lord Todd, who comes to the end of his five-year stint at the anniversary meeting, to be held this year on 1 December.

The society's election procedures require that nominations of new council members and also of the new president should first be agreed by the Council, and then submitted to the membership of the society in the form of a single slate of candidates. Sir Andrew Huxley's name has apparently been agreed for several months, and it is known that several insititutions have already engaged him to speak at conferences or to officiate at centenary celebrations well into 1981.



Now that Sir Andrew's nomination by the council is assured, the chances of his not being elected are vanishingly small. This could only happen if a majority of the members of the society were to strike out his name on the ballot paper and to substitute that of some other member.

Sir Andrew, who will be 63 at his election, has been a Royal Society Research Professor in the Department of Physiology, University College London, since 1969.

Indian laboratories

Back to GO

Bangalore

In what is considered to be a major step to tone up the state of Indian research, the government led by Mrs Gandhi has transferred back to the Council of Scientific and Industrial Research (CSIR) four laboratories which the previous Janata government had handed over to user ministries. The laboratories concerned are the Central Fuel Research Institute, Dhanabad; the Indian Institute of Petroleum, Dehra Dun; the Central Road Research Institute, New Dehli; and the Central Building Research Institute, Rourkee.

In April 1978, the Janata government, which under Morarji Desai was firm on "socially committed research", had dissociated these laboratories from CSIR and transferred them to user ministries on an experimental basis. Presumably this "delinking and transfer" was intended to foster a closer relationship between research and industry that would accelerate the country's scientific potential for industrial growth.

However, the decision proved to be counterproductive. Not only did it fail to achieve the desired goal but India's scientific community saw this step as a "vicious attack on scientific autonomy". For the past two years there has been a heated debate on the move in India's administrative and political circles. It was widely alleged that the decision was taken without considering the opinion of the scientific community.

The controversy surrounding the delinking had cast a shadow over scientific research in India. While the advocates of delinking called it an important measure to enhance industry — "research interaction" — the critics saw it as "a dark conspiracy of alien agents acting in collusion with their Indian masters" to subvert indigenous research efforts.

CSIR was established in the early 1950s to promote scientific research into the economic exploitation of India's vast resources. By Indian standards, CSIR is a giant covering four laboratories and research associations, and it has never been handicapped by the paucity of resources or dearth of skilled manpower.

The contribution that the CSIR laboratories have made to indigenous research for industrial development is difficult to assess. While the left-inclined high-technology advocates say that CSIR has been a trail blazer in easing India's poverty and backwardness through innovative research relevant to the socio-economic conditions of the country, pro-Gandhian, appropriate-technology proponents say that CSIR is a "colonial set-up subservient to the capitalistic research" that is alien to the Indian environment.

In recent years, CSIR technocrats have

been complaining that there are virtually no takers for the processes and technologies developed in CSIR laboratories. In fact, most public and private sector industries in India have favoured the wholesale import of foreign technology. This anomaly was said to be the motivation behind the handing over of the laboratories to user ministries. But the import of technology by the bureaucrats in the user ministries has continued unabated.

Trying new tricks

Washington

In an attempt to cut down on the amount of "time and effort" reporting required of scientists, the National Institutes of Health (NIH) are being urged to try a new mechanism for funding research grants that would make the researcher financially accountable to his or her university or research institution rather than directly to the funding agency.

At present, NIH project grants — whose total value is about $1,400 million, over half the total NIH research budget — are awarded on a "cost reimbursement" basis, under which the government agrees to cover all previously agreed costs that can be properly accounted for.

The proposal is to experiment with so-called "fixed obligation grants" (or "fixed price grants") where the research institution merely has to demonstrate to the funding agency that the scientific and technical goals of the research have been satisfactorily pursued.

"Time and effort" reporting is the most controversial of the strict new rules on accounting for research expenditures introduced last month by the Office of Management and Budget (OMB) in a document on cost principles known as Circular A-21.

These rules require all principal investigators to provide a semester-by-semester breakdown of the way they distribute their time between teaching, research, administration and other activities — and to report any change in this distribution to the federal government.

Federal auditors argue that this is necessary to ensure that money is being allocated and spent in the way agreed when a research grant is awarded. But scientists argue that in an over-zealous enthusiasm to minimize fraud and abuse — a popular target of congressional committees — the auditors are reducing the productivity of research laboratories for a minimal return.

Despite earlier protests, OMB had refused to delay the implementation of the new rules, the outcome of several years of negotiation. However, under continued pressure from universities, the agency is now prepared to discuss ways of reaching its accountability goals more effectively.

OMB has already agreed to experiment at ten universities where "time and effort" reporting will be on a statistical basis rather than professor-by-professor. What is now being suggested, however, is considered by NIH director Dr Donald Frederickson to be revolutionary — "as radical as *Finnegan's Wake*".

The outlines of the proposal were presented to the NIH Directors' Advisory Committee (DAC) by Dr Linda Wilson, Associate Vice-Chancellor for Research at the University of Illinois in Urbana, and Mr James Kelly, previously Executive Vice-Chancellor of the State University of New York and a long-time proponent of fixed-price contracts.

The general idea is that there would be no change in the present pre-award proposal process for the selection of research and determining the amount of an award. However, post-award administration would be changed to delegate most of the responsibility to the recipient institution and the principal investigator, in particular the emphasis of accountability would be shifted from the allowability of costs and the adequacy of documentation to criteria that indicate "reasonableness of technical progress".

Supporters of this new proposal, which comes out of a recommendation made in a recent report from the National Commission on Research for Experiments in Grant-in-Aid Support for Research Institutions, argue that it should still be possible to build in enough controls to ensure that public funds are not misused (such as spot auditing checks). The new system might eliminate some existing problems, but there could be new ones. For example, by shifting prime responsibility for the financial conduct of the grant from the federal government to the research institution, tensions between the government and the institutions could be replaced by tensions between the institution and its principal investigators.

Additional pressure would also be incurred on efforts to measure scientific accountability; Dr Wilson emphasizes that research grants should be treated as *assistance* rather than *procurement* funds, to avoid the rigid accountability — and hence loss of flexibility.

Mr Kelly told members of the DAC that there was little evidence that a new system for administering grants would save much money and that any increase in research productivity would not necessarily be measurable. The principal advantage, he said, was that the new approach might reduce tensions between universities and the federal government, currently running high in the wake of the introduction of Circular A-21.

Any experiments in this direction are likely to receive the approval of the Office of Science and Technology Policy (OSTP), whose associate director, Dr Denis Prager, told the committee that reducing non-budgetary constraints on research was one of OSTP's top priorities, particularly by encouraging forms of regulation based on performance.

Polish academy

Flexing muscle

Polish scientists wishing to travel abroad for professional purposes should in future find it considerably less complicated to obtain the necessary passport. Last week, Dr Jan Kaczmarek, Academic Secretary of the Polish Academy of Sciences, announced that the academy now has the right to decide such matters for its members.

This announcement marks a small, but significant step towards the greater academic autonomy widely demanded by Polish intellectuals in the wake of the Gdansk accords. It was made at an extraordinary general meeting of the Polish Academy of Sciences, which was called to discuss and re-evaluate the role of the academy, and of the scientific establishment generally, in the light of the recent changes in the country. The meeting, which participants reported had a warm and open atmosphere, made some sharp criticisms about the situation in Poland during the past few years, in particular, both the over-centralistic attitude of the authorities, which made it extremely difficult to get a

No stay for badgers

This will be a bad week for British badgers. Today (Thursday, 30 October) Lord Zuckerman's report on the practice of gassing badgers thought to be infected with bovine tuberculosis will be made public. This issue is contentious among conservationists because the Badger Act, carried through the British parliament with some emotion, which makes it a criminal offence to kill badgers even when they damage land and crops, provided an exemption for the Ministry of Agriculture, Fisheries and Food to allow the destruction of badger hides thought to be a reservoir of bovine tuberculosis.

Conservationists have since protested that the practice of gassing badgers for the sake of protecting cattle has been too widely licensed, and that it is in any case unnecessary or ineffective. Lord Zuckerman's report it thought to argue in an opposite direction.

0028-0836/80/440772-02$01.00

hearing for constructive criticism, and the consequent lack of responsibility. To remedy this situation, the academy called for clear limits to be set to the competence of anyone in authority and of rank-and-file functionaries.

A comprehensive system, the academy said, must be worked out for the proper functioning of the economy, based on the "broad utilization of all available and permissible self-regulating mechanisms". The authorities, it said, must show they trust the people. One obvious sign of such trust would be freedom of expression and the phasing out of censorship (except for the minimum needs of national security), which constituted a major point in the Gdansk accords.

A prominent speaker on this theme was Dr Jan Kielanowski, a leading nutritionist. He reminded the meeting that he and Dr Edward Lipinski had tried to raise the same issue of academic freedom and the abolition of the censorship at the academy's Annual General Meeting in May 1979 — but on that occasion, the motion was ruled out of order from the chair. Now, however, he observed, when the initiative came not from a couple of members of the academy, but from the broad masses of the Polish workers, the academy was prepared to listen.

The academy, in fact, had not waited until the extraordinary general meeting to take up the issue. Censorship and academic freedom had already been raised at the praesidium of the academy on 30 September. On that occasion, Professor Janusz Groszkowski, a former chairman of the academy, called for a detailed analysis of the situation in Polish research, including the moral and professional scrutiny of those researchers and scientists known to be letting down the intellectual integrity of their profession. Some researchers, said Groszkowski, are guilty of plagiarism, intellectual dishonesty, idleness and ignorance, while young people of genuine talent were given no opportunity to develop freely. "Hence", he concluded, "we have no great names and no great achievements." The academy, he said, must take the initiative in the reform and renewal of the scientific profession, without waiting for a lead; its deliberations should include possible changes in the legislation governing scientific research, the management of scientific institutes and the question of independent, trades unions for scientific research workers.

However, before this last proposal could be put to the general meeting of the academy, Poland's scientists had made their own decision: at the second delegate meeting of the new "Free Trade Union of Scientific, Technical and Educational Workers" (13 October), it was decided to terminate the existence of this body as a separate entity, and to transform it into a branch of the "Solidarity" confederation.

European community

Research without end

Strasbourg

A meeting called by the European Commission here last week ended with a general air of expectancy among its participants. Next June, the commission will be proposing to the Council of Ministers a new research "enterprise". So far, however, it is not known how much the enterprise will cost, when it will start or even what it will do.

Commission officials nevertheless consider that last week's conference gave them a mandate to do something. And whatever it is, the cost will be added to the commission's present research budget, running at five per cent of the member states' research and development budgets.

The impetus for the initiative is twofold. First, there is a feeling in Brussels that there will be some slack in the EEC budget in the near future. Some think the Common Agricultural Policy will collapse, others that some part of agricultural spending will be put to other uses. All the community's directorates-general, including that for research, science and education, are eager to pick up the crumbs.

There is also a sense that something must be done to free posts and talent at the universities. As Sir Hermann Bondi put it last week, "the universities have been static for many years while other things are changing fast". He went on to advocate the setting up of research structures parallel to but in touch with the universities.

Most of those at Strasbourg agreed, but failed to provide the political wrapping or the precision that might lead to practical proposals to create scientific jobs or to improve mobility in Europe. In the end, the commission will work out its policy on the basis of background documents* prepared for Strasbourg, particularly those of Guy Denielou, president of the Technical University of Compiègne, Ilya Prigogine of the Free University of Brussels and Freddie Clarke, research director responsible for renewable energy at Harwell. Dr Günter Schuster, who heads the Brussels directorate-general for research, science and education, will now set up a task force to prepare proposals for June. There will be three scenarios, from ambitious to pessimistic, to cater for the unknown political climate nine months hence.

Schuster will rely largely on Denielou's proposals to define the "enterprise". But, says Denielou, the definition should concentrate on structure rather than topics. How the enterprise should function is more important, at this stage, than what it should do. The structure should not be academic, but like a business. It should be flexible, creating and closing teams as needs change. Its administration should be "very light". It should be cheap, probably based on existing laboratories.

A principal objective would be to foster mobility, for scientists are considered less free in Europe than in the United States. Research teams in the enterprise would therefore be drawn from across Europe. He proposes an experiment — three years, 50 teams of 30 scientists each, costs borne largely by the host laboratories.

To determine the subjects to be studied, the enterprise would need what Prigogine calls "an organ of perception" — something like the National Research Council in the United States — which would also select institutions and teams to investigate the chosen topics, using international referees. Brussels would thus be gaining an instrument for a centralized research policy — and a critical question for June will be what relationship such an instrument should have to the council, the supreme body in the community.

China plays profit

Researchers at the Institute of Physics of the Chinese Academy of Sciences have recently been working on a new project — how to sell their results to industry.

It seems that until the recent economic reforms, what is now officially described as "a lack of communications" and "obstacles inherent in the system" prevented new scientific results from being applied to industry. New findings remained inaccessibly locked away in publications and festchrifts. Consequently, scientists had become upset and frustrated, while factories, unaware of new advances, were unable to modernize.

With the fall of the Gang of Four, however, factory managements were able to approach the scientists for advice on new results and how to apply them. So far, the Institute of Physics has worked out three possible cooperation procedures: (1) outright sale of the new technology, with technical assistance provided until the technology goes into production; (2) contracts for technological guidance, involving sending experts to the factories or training workers at the institute; with the onset of production, the institute is repaid on a sliding scale related to the profits from the new technology; for example, 20% in the first year, 10% in the second, 5% in the third; (3) provision of the new technology, for a decreasing percentage of its profits, for example, 5% the first year, 3% the second, and so on.

So far, the institute has signed contracts with 19 factories, many of which are already benefiting financially from such deals. **Vera Rich**

Dangerous pathogens

New UK committee

The long-awaited reorganization of the British mechanism for regulating research with dangerous pathogens is planned for early in 1981. Last week the Department of Health and the Health and Safety Executive made public the terms of reference of a new regulatory body, to be known as the Advisory Committee on Dangerous Pathogens. The chairman and members of the group, which will replace the Dangerous Pathogens Advisory Group, have yet to be appointed.

The days of the existing advisory group have been numbered since the smallpox accident at the University of Birmingham in August 1978. Set up in 1975, the group was first responsible for drawing up lists of pathogenic organisms supposed to involve various degrees of hazard. The group also advised the Department of Health which laboratories should be licensed to work with organisms in the most hazardous category, category A. Control was voluntary.

The new system will be backed by the statutory requirement that laboratories planning to work with dangerous pathogens should first notify the Health and Safety Executive (HSE) of the people who will be involved and the experiments planned, giving at least 30 days' notice. The draft regulations published by HSE require more cursory notification of other listed pathogens.

Under the proposed arrangements, the new advisory committee will not scrutinize safety arrangements in individual laboratories, which will in future be the responsibility of officials of HSE. Instead, it will be responsible for advising the executive as well as the ministries responsible for health and agriculture on the classification of pathogens, the development of safety procedures and the opportunities for research.

One of the peculiar difficulties of the regulation of dangerous pathogens affects the working of medical diagnostic laboratories, which cannot know in advance whether a corpse on the slab has been laid low by, say, lassa fever. The proposed notification regulations will not apply to such laboratories, which will nevertheless be required not to carry out further work with schedule 1 organisms without going through the full procedure.

The composition of the new advisory group has been settled only in outline. There will be five employers' representatives drawn from universities, public health laboratories and the like, five representatives of employees' organisations and ten scientific members, together with a chairman.

For researchers in British laboratories, the chief consequences of the proposed arrangement will be that in future control will have the force of law. Failure to notify will be an offence, as will be failure to follow approved codes of practice.

Schedule 1 pathogens

Crimean haemorrhagic fever virus (Congo)
Ebola virus
Jumin haemorrhagic fever virus
Lassa fever virus
Machupo haemorrhagic fever virus
Marburg virus
Rabies virus
Simian herpes B virus
Smallpox virus
Venezuelan encephalitis virus

Soviet geophysics

Drilling deeper

Soviet geophysicists have had to rethink their models of the deep strata beneath the European part of the USSR, after processing the preliminary data from the super-deep borehole now being drilled on the Kola peninsula. And, according to Professor Vladimir V. Belousov, head of the Scientific Council on the Earth's Crust and Upper Mantle of the Department of Earth Sciences of the Soviet Academy of Sciences, two and possibly three more such holes will be started in the near future.

The Kola bore can advance at a rate of some 10–12 m per day, and has now passed a depth of 10,000 m. It is sited in an area thought to be geologically "dead", and without risk of earthquakes or volcanic activity. Core samples, however, have revealed that cracking extends to considerable depths, and at these levels, at a temperature of about 150°C, significant quantities of aqueous solutions, carbon dioxide and helium provide evidence of high geological activity.

This remarkable level of activity is not the only surprising result to have come from the Kola bore. It had been predicted that a transition from granites to basalts would be observed at a depth of about 7,000 m, and that, as the bore-hole went deeper, the angle of inclination of tilted strata would gradually flatten out. But so far it has been granite all the way, though of increasing density, and the angle of inclination of the strata remains constant.

The Kola bore has still another 5,000 m to go before it reaches its scheduled depth, but already some of the preliminary data are being used in planning prospecting for new mineral deposits. The other projected bores will also have their practical aspects — the Tyumen' bore will look for deep level oil and gas deposits in Western Siberia, while the Tagil bore will investigate the "foundations" of the Urals — an important range mineralogically.

The most exciting proposal under consideration would entail drilling a bore at the foot of the Avachinskaya Sopka — a large and active volcano in Kamchatka.

Vera Rich

Uranium deposits

France backs basics

Paris

A £1 million laboratory opened last week at Nancy seems intended to give France an incontestable world lead in uranium geology. Nicknamed CREGU, the laboratory will poach its director, Dr Bernard Poty, and five senior staff from the institute next door — the Centre de Recherche Pétrographique et Géochimique, which has already established a lead in using microscopic laser Raman spectroscopy to analyse fluid in inclusions in ore-bearing rocks. Such inclusions are expected also to give a clue to the formation of uranium ores — a complex process because of the extreme geochemical mobility of uranium, and the low concentrations of economically significant ores.

CREGU itself is a £400,000-a-year five-year experiment. Its £1 million buildings are a local enterprise, rented to the Commissariat à l'Energie Atomique and the five principal uranium prospecting firms in France. The Centre National de la Recherche Scientifique (which runs Poty's old lab) will pay the scientists' salaries. After five years, a council composed of members of the sponsoring organizations will decide whether the enterprise has been a success, and if it should continue.

To be successful, the new laboratory will not have to devise revolutionary methods for detecting uranium — though nobody denies this is the long-term aim of the investment. (In fact a proposal that CREGU should look at empirical methods of prospecting using magnetic anomalies was rejected by the laboratory's council.) Rather, it will attempt to extend the very sketchy existing knowledge of how the ore is formed. It is here that the fluid inclusions are significant, for they are relics of the fluids which deposited the ore — but they are so tiny that they have evaded detailed chemical analysis. CREGU, it is hoped, will solve this problem with its Raman techniques.

Other mining interests in France are watching the new laboratory carefully. It will help to train students and to retrain prospecting uranium geologists; and as ores of other minerals become economic at increasingly lower concentrations, greater and greater scientific subtlety is required in the detection of ores, and the judgement of the economic value of potential mines. So, it is believed in France, activities such as GREGU's, bridging basic science and industry, will become increasingly important.

NEWS AND VIEWS

Jupiter's magnetosphere

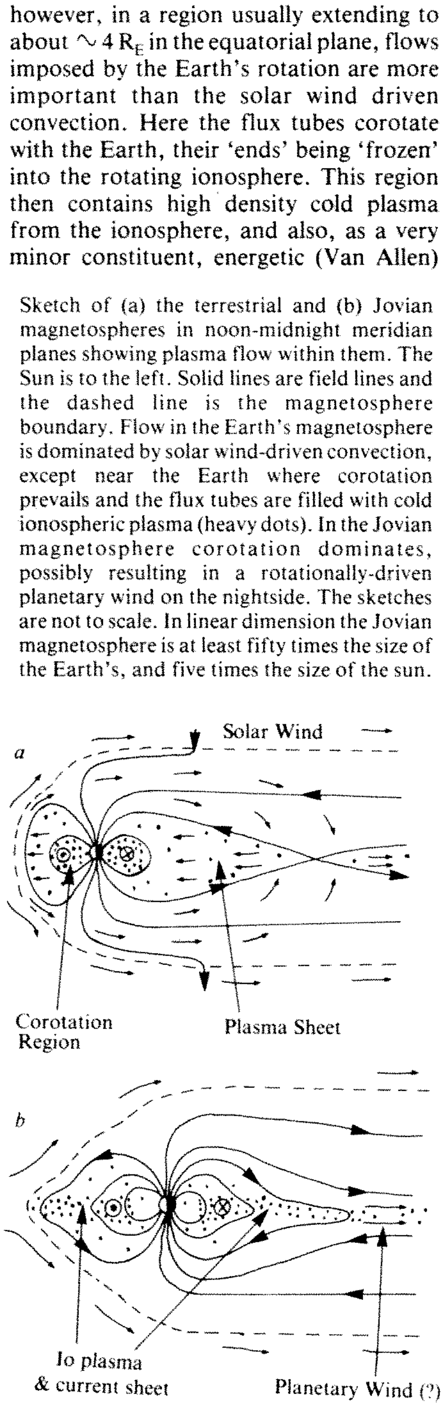
from S.W.H. Cowley

DIRECT observations by space probes over the past decade have shown that at least three planets in our solar system, in addition to the Earth, possess an intrinsic magnetic field. These are Mercury, Jupiter and Saturn. The solar wind, a tenuous proton-electron plasma blowing radially outwards from the Sun at speeds $\sim$ 400 km s^{-1}, confines this magnetic field to a cavity surrounding the planet forming a planetary magnetosphere from which the solar wind itself is largely excluded. Only Venus is known to be without a magnetic field although limited data suggests that this may also apply to Mars.

Of the four observed magnetospheres, that surrounding the Earth is, of course, the most thoroughly investigated and the best understood. Jupiter comes second, having been the subject of four fly-by encounters, by Pioneer 10 and 11 in 1973 and 1974 and by Voyager 1 and 2 in 1979. The Pioneer flights provided the first mapping of the Jovian magnetic field and the energetic charged particle radiation trapped on Jovian field lines. The Voyagers returned the first detailed data on the thermal plasma component and on plasma waves. Here we shall describe recently published Voyager results on low-energy Jovian plasma, setting them within the context of other major Voyager findings published in *Science* (**204**, 1979; **206**, 1979), *Nature* (**280**, 1979), and *Geophysical Research Letters* (**7**, 1980).

The properties of magnetospheric plasmas depend upon the nature of the plasma sources and sinks, and on the internal transport processes. In the Earth's magnetosphere transport is dominated by a large-scale convective flow driven by the solar wind (see Figure *a*). Since highly electrically-conducting plasmas and magnetic fields can be considered to be 'frozen' together we can equivalently describe the flow of field lines. Terrestrial field lines are transported by the solar wind flow from the dayside magnetosphere boundary at $\sim$ 10 R_E (1 R_E = Earth's radius $\sim$ 6,400 km) to the night side, where they are stretched out into a long $\sim$ 1,000 R_E magnetic tail. These flux tubes then flow back to the Earth through the 'centre' of the magnetosphere, heating entrained solar wind plasma and escaped ionospheric plasma up to $\sim$ 10 KeV energies as the tubes contract. A hot 'plasma sheet' is thus formed at the centre of the tail and a hot outer radiation zone around the Earth as shown in the Figure. Near the Earth, however, in a region usually extending to about $\sim$ 4 R_E in the equatorial plane, flows imposed by the Earth's rotation are more important than the solar wind driven convection. Here the flux tubes corotate with the Earth, their 'ends' being 'frozen' into the rotating ionosphere. This region then contains high density cold plasma from the ionosphere, and also, as a very minor constituent, energetic (Van Allen) radiation belt particles. The latter are transported into the region by radial diffusion from the outer radiation zone under the action of fluctuations in the external convection, rapidly gaining energy proportional to the field strength as they move inwards.

Sketch of (a) the terrestrial and (b) Jovian magnetospheres in noon-midnight meridian planes showing plasma flow within them. The Sun is to the left. Solid lines are field lines and the dashed line is the magnetosphere boundary. Flow in the Earth's magnetosphere is dominated by solar wind-driven convection, except near the Earth where corotation prevails and the flux tubes are filled with cold ionospheric plasma (heavy dots). In the Jovian magnetosphere corotation dominates, possibly resulting in a rotationally-driven planetary wind on the nightside. The sketches are not to scale. In linear dimension the Jovian magnetosphere is at least fifty times the size of the Earth's, and five times the size of the sun.



By contrast with the Earth, flow in the main part of the Jovian magnetosphere, extending some 50 R_J (1 R_J = Jupiter radius $\sim$ 71,400 km) on the dayside, is entirely dominated by corotation with the planet (Figure *b*), although this does not preclude the existence of a long (maybe $\sim$ 2 AU) magnetic tail on the night side arising from the solar wind interaction. Thus, like the Earth's corotating 'core' of field lines, the Jovian magnetosphere is dominated by cool plasma from internal sources, but also contains radially diffusing energetic particles of solar wind origin. The radial diffusion is probably driven both by turbulent Jovians atmospheric winds at ionospheric heights and by flux tube interchange motions arising from unstable density distributions of the low energy plasma.

The second important difference between the Earth's and Jupiter's magnetosphere is that the latter is so large that it encompasses the orbits of many of the moons. These bodies can then act both as absorbers of energetic particles, as the Pioneer results demonstrated, and as important sources of low energy plasma. Indeed, the Voyager results indicate that the dominant source of thermal plasma is not Jupiter's ionosphere as might have been expected, but the satellite Io, which orbits at a radial distance of 5.9 R_J, in the inner magnetosphere.

Voyager images show that Io is extremely volcanically active, probably due to intense internal tidal heating, thereby maintaining a tenuous atmosphere which appears to be composed mainly of sulphur dioxide. A small escape flux of this gas (small in relation to total volcanic outflow) followed by ionization then results in the formation of a dense corotating plasma torus in Io's vicinity composed mainly of sulphur and oxygen ions with energies several tens of eV. The torus has a thickness $\sim$ 1 R_J, the ions being retained near the rotation equator by centrifugal forces, and a sharp inner boundary at $\sim$ 5 R_J, where the temperature abruptly drops to a few eV. The latter

---

S.W.H. Cowley is a SRC Advanced Fellow in the Blackett Laboratory, Imperial College, London.

0028-0836/80/440775-02$01.00

observations indicate that inward radial diffusion of the ions towards Jupiter is rather slow, allowing time for the plasma to radiatively cool, thereby generating the considerable UV and optical emissions observed from the inner torus. The cooling plasma collapses towards rotation equator where the ions and electrons eventually recombine to produce relatively fast neutrals which fly off into the outer magnetosphere and solar wind.

By contrast, the outer part of the torus beyond the Io source appears to be unstable, the density gradient generating flux tube interchange motions which rapidly diffuse the plasma outwards into the magnetosphere. The plasma remains strongly concentrated at the equator, but the density rapidly drops with increasing distance due to the expanding flux tube volume as the field strength weakens. From values of several thousand cm^{-3} in the torus, the equatorial density falls to ~ 1 cm^{-3} at ~ 25 R$_J$ and to $\sim 10^{-2}$ cm^{-3} at 100 R$_J$ on the night side. In order to maintain rigid corotation, the Jovian atmosphere must continuously provide a torque on flux tubes in Io's vicinity where the plasma is created, since the coratation speed increases at a rate ~ 12.5 km s^{-1} R$_J{}^{-1}$ as the particles diffuse outwards. The torque is provided by atmospheric drag of ionospheric ions at the 'feet' of the flux tubes, but theoretical estimates (Hill *J. Geophys. Res.* **84**, 6554; 1979) indicate that the coupling may be too weak to maintain rigid corotation out to large distances. Voyager low energy plasma data indicates that is so, $\sim 20\%$ reductions below expected speeds being inferred at ~ 10 to 20 R$_J$. Indeed, even at ~ 40R$_J$ the azimuthal speed is reported as remaining near 200 km s^{-1}, less than half the corotation value. However, analysis of the angular anisotropies of higher energy ions shows good agreement with rigid corotation at such distances and beyond. The reason for this disagreement is currently unknown.

The most recent results on Jovian plasma flow (Belcher & Mc Nutt this issue of *Nature* p813) show that in addition to at least partial corotation, the low energy plasma also has comparably large flows along the field lines, directed toward the equator on the night side and away on the day side. As these authors point out, this flow most probably results from a day-night asymmetry in the magnetic field, which is compressed on the day side relative to the nightside by the dynamic pressure of the solar wind. As flux tubes rotate into the dayside sector they move closer to Jupiter and the plasma flows away from the equator due both to the field compression and to the decreasing centrifugal force. On the nightside the tubes expand and move outwards, the centrifugal force increase and the plasma collapses back toward the equator.

An important feature of a corotation-dominated magentosphere is that if the magnetosphere is large enough, and if corotation is maintained to large enough distances then the plasma kinetic energy density associated with the rotation will always reach and exceed the magnetic energy density at the equator at and beyond a certain distance. At this point the field can no longer retain the plasma, which will break away from corotation and flow rapidly outwards forming a 'planetary wind', a rotationally-driven analogue of the solar wind. Conditions on the dayside Jovian magnetosphere, confined to ~ 50 R$_J$ by the solar wind, seem somewhat marginal for planetary wind formation and no evidence for such an outflow was seen during the Voyager inbound passes near noon. On the nightside conditions are more favourable, and an antisunward flow which may be related to planetary wind formation was observed by Voyager 2 in a layer adjacent to the dawn magnetosphere boundary ~ 130 R$_J$ down-tail from Jupiter, as shown in Figure *b*. One particularly intense burst of such flow was found to consist mainly of heavy ions streaming at $\sim 2{,}000$ s^{-1}.

One final feature of Jupiter's magnetosphere which is receiving much attention is the considerable magnetic field distortions indicated in Figure *b*, due to an equatorial sheet of current carried by magnetospheric plasma in the azimuthal direction. These field distortions are most pronounced on the nightside, where they gradually take on the character of a magnetic tail at sufficiently large distances, but they are also observed on the day side as well. To produce the effects observed beyond ~ 10 R$_J$ the equatorial plasma pressure must be comparable to the field energy density. However, the pressure of the cool (~ 10 to 100 eV) Io torus plasma appears generally to be somewhat too small to account for the observed effects, thus indicating that a significant hot component is also present. Voyager observations at energies above ~ 30 keV show that such a component is indeed present with energies ~ 20–30 keV and an ion composition which includes protons, oxygen and sulphur as major constituents. The heavy ions must originate at Io, but how these particles become heated to such energies remains to be determined. It therefore seems that the Jovian magnetosphere contains at least two thermal plasma components, the cool Io torus plasma which may usually dominate the mass density, and a much hotter plasma also containing Io ions which often dominates the energy density. □

Iron deprivation as a biological defence mechanism

from Thomas Emery

OVER thirty years ago Schade and Caroline discovered that blood contains a specific iron-binding protein that inhibits the growth of pathogenic bacteria, such as *Shigella dysenteriae* (*Science* **104**, 340; 1946). They correctly concluded that the protein bound iron so tightly that the bacteria were deprived of that essential nutrient and were unable to grow. When it was subsequently discovered that the protein in question, transferrin, was responsible for mammalian iron transport, the significance of the bacteriostatic action was virtually forgotten. It now appears that deprivation of invading microbes of iron may be an important defence mechanism in both animals and plants.

Microorganisms excrete low molecular weight iron chelating agents, called siderophores, when they are deprived of iron (Neilands *Adv. in Chem.* **162**, 3; 1977). Siderophores are extraordinarily efficient iron chelators with binding constants of about 10^{30}, very close to the strength of transferrin. A microorganism invading the bloodstream is thus capable of competing with transferrin for the metal. If the microbe succeeds, a potentially fatal infection may result. This battle for iron is known to occur in other animal systems where bacterial growth might otherwise be especially favourable. Milk contains lactoferrin, a protein that binds iron in a manner very similar to transferrin. Lactoferrin is also found in human secretions associated with mucosal surfaces, and there is evidence that its iron binding properties offer bacteriostatic protection (Arnold *et al. Science* **197**, 263; 1977). Another iron-binding protein, conalbumin, is found in raw egg white, and Schade and Caroline were the first to suggest that conalbumin protects eggs from infection (*Science* **100**, 14; 1944). Protection by depriving infecting microorganisms of an essential nutrient has been called 'nutritional immunity' by Weinberg (*Science* **184**, 952; 1974).

It now appears that the plant world makes use of a similar strategy. Certain bacteria, called plant growth-promoting rhizobacteria (PGPR), significantly increase yields of potato, sugar beet and other plants when they colonize the roots. Work from the laboratory of Kloepper *et al.* reported in this journal (*Nature* **286**,

---

Thomas Emery is Professor of Biochemistry in the Department of Chemistry and Biochemistry, Utah State University.

885; 1980) demonstrates that PGPR in the soil produce extracellular siderophores which strongly complex iron and make it unavailable for growth of other potentially harmful microorganisms. A new siderophore, which the authors call pseudobactin, has been isolated from PGPR. *In vitro* experiments show that pseudobactin inhibits growth of the plant pathogen, *Erwinia carotovora,* by depriving the organism of iron. The effect was also demonstrated *in vivo* by greenhouse assays in which the addition of 10 μm pseudobactin in the water supply led to a more than a doubling of the weight of potato plants, attributed to a 74 per cent decrease in the number of pathogenic fungi found in the plant environment. Mutants of PGPR unable to produce pseudobactin did not show this effect.

A corollary to this work is that the plant itself must have a mechanism for utilizing siderophore iron lest it also be threatened by iron starvation. Virtually nothing is known about the possible importance of siderophores as a source of iron for higher plants. However, independent work reported in this journal has shown that siderophore type iron chelates are virtually ubiquitous in soils (Reid *et al.* see this issue of *Nature,* p833). Significant siderophore production was observed in extracts of all 57 soils surveyed. Of all iron binding agents tested, only siderophores proved to be efficient biological sources of iron in soil, and they conclude that microbial siderophores may be an important source of iron for higher plants, a function previously attributed to organic acids and polyphenolic humic material.

The role of siderophores in agriculture should be a subject of serious investigation. Each year many tons of synthetic iron chelates are used to ensure adequate iron supply to plants. Natural siderophores are apparently insufficient to supply this iron, possibly because very low levels of soluble iron are known to repress the excretion of siderophores by microorganisms. An interesting approach might be to produce mutants in the laboratory that are no longer subject to this negative control. Inoculation of solis with these organisms might increase the levels of soluble iron, as siderophore chelates, to a point where no additional supplementation would be necessary. This approach would have the added advantage of suppressing the growth of plant pathogens via iron deprivation. □

The development of animal segments

from Gerold Schubiger

IN this issue of *Nature* Nüsslein-Volhard and Wieschaus (see page 795) describe the isolation of mutations at 15 different gene loci that affect the pattern of segmentation in *Drosophila.* Segmentation is a phenomenon widespread in the animal kingdom; in annelids and arthropods blocks of cells become separated during development and then, within each block, the same components, such as ganglia, muscles and body cavities, differentiate. Even in the chordate embryo a metameric arrangement of some structures is obvious. Although similarity in appearance of metameric structures makes it tempting to conclude that they arise by a general developmental principle, there are still a great many unanswered questions.

We do not know if segmentation occurs by separating groups of cells from all the germ layers, or if one layer — ectoderm, neuroectoderm or mesoderm — first segments and then imprints its pattern on the other germ layers. The latter possibility is supported by observations of the leech, where the first signs of segmentation are seen in metamerically arranged mesodermal founder cells, and *Drosophila,* where the first cells to reveal a segmental pattern are the neuroblasts[1,2]. Normally, development of the insect embryo depends on similar inductive processes, such as the induction of mesodermal differentiation by the ectoderm (see ref. 3 for a review).

The mechanism which brings about segmentation is not understood. One possibility is that positional information is used to determine segment borders. Cells of the early *Drosophila* embryo are segregated into sub-populations or polyclones assigned to develop specific segments[4]. Cells of a polyclone are restricted: that is they can they can form only structures of their particular segments (see, for example, ref. 5). Such clonal restrictions have been found in the abdomen of *Oncopeltus*[6] and in the hypodermal segments of the adult *Drosophila*[7]. Restriction of clones in the hypodermis of the larva has been indicated but any clear compartmentalization of internal structure has not been documented.

It is also possible that development is primed from centres located in specific regions[8]. In some insects segmentation is first visible in the presumptive thorax region; more anterior and posterior segments boundaries arise later. In other insects, however, the role of such controlling centres is less obvious making it very difficult to generalize.

Experimental studies indicate that the segmental pattern in *Drosophila* is already determined in the blastoderm cells[9]. Embryonic fragments isolated before the blastoderm stage form a metameric pattern which is deficient in segment number indicating that different egg parts normally interact to form the full compliment of segments.

Searching for mutations and investigating their effects will tell us the extent to which segmentation is under genetic control. We already know that some genes (the homeotic) control the morphological character of segmental quality. Mutations in these genes transform patterns either within segments (for example, *engrailed*) or between different segments (for example *bithorax*)[10]. The mutation *bithorax* transforms the anterior metathorax into anterior mesothorax[11]. Homozygous *bx* clones have been induced in heterozygous animals during both embryonic and larval life and always express the transformed *bithorax* phenotype, showing that the expression of the normal phenotype requires continual activity of the *bx* locus. In such homeotic mutants the number of segments is not different from wild-type so it may be concluded that these genes control segment character and not number.

Abnormal segmentation may not be a direct consequence of gene mutation. For instance, mutations such as *rudimentary*[12] block pyrimidine synthesis and produce a generally sick embryo. The autophene (enzymatic block) is responsible for many allophenic characters such as abnormal segmentation[13]. Such mutations are obviously not helpful in understanding the genetic control of segmentation. Primary defects are more likely to be detected if the earliest developmental stages are analyzed, as has been done by Nüsslein-Volhard and Wieschaus with some of the mutations. It is important to realise that some genes may not be involved in primary segmentation, but may be responsible for maintaining the proper segmentation once it has formed. Analysis of mutants should also be extended to segmentally arranged structures other than the hypodermis, since there is good evidence that in *Drosophila* inductive processes are also involved in the development of segmentally arranged tissues. This will tell us if these mutations

interfere with induction rather than the process of segmentation.

Temperature-sensitive alleles of the most promising mutations that affect segmentation will enable us to find out when such genes are active during development. From studies of such a mutant (*patch*), Nüsslein-Volhard and Wieschaus were able to conclude that proper segmentation depends on early activity of the gene.

One mutation known to affect segmentation (*fused*) has a male-rescuable maternal-effect[13]. Homozygous mutant offspring from heterozygous mothers can develop normally. Moreover, heterozygous embryos from homozygous mutant mothers can be rescued by the *fused*$^+$ allele of the father. Thus, normal development requires the *fused* gene to be active either during oogenesis or in the zygote. This indicates that some genes that control normal segmentation are active during both oogenesis and early development. ☐

Cosmic spherules

from David W. Hughes

TAKE a kilogram of the sedimentary deposits from the floor of the deep oceans, wash and sieve it carefully and you will find, among a vast jumble of irregular particles, a collection of between a few hundred and a few thousand black 'stony' and 'iron' magnetic spherules with diameters between 30 and 200 μm. You don't even have to resort to deep-sea sediments; spherules can be found in arctic ice, manganese nodules, beach sands, ancient salt deposits and even on roof tops. They are a ubiquitous component of all terrestrial sediments.

The source of the spherules may be either terrestrial or cosmic, and it is the latter source that is of interest here. Collections removed from sediments laid down before the industrial revolution and its accompanying pollution make the selection process simpler but even then vulcanism is a major source of contaminants. The extraterrestrial nature of a specific spherule can be confirmed if it contains wüstite — a metastable iron oxide formed at high temperatures and low oxygen partial pressures. Wüstite slowly decomposes into α-iron and magnetite in most terrestrial environments and is thus almost unknown in nature. Having iron, nickel and cobalt in meteoritic ratios and free iron and nickel metals are also strong clues as is a low abundance of manganese, titanium and chronium.

Once a sample of cosmic spherules has been found and recognised we reach the major difficulty of deciding exactly where they come from. There are two classes of theory. The first postulates that cosmic spherules are molten spray from meteorites and meteoroids that have ablated as they decelerate in the Earth's atmosphere. The spray solidifies and drifts down to the surface. The second theory, advanced by Öpik nearly thirty years ago (*Irish Astr. J.*, **1**, 145; 1951), postulates that the spherules existed essentially as spherules in free space, entered the Earth's atmosphere in such a way that they survived evaporation and then fell earthward. D. W. Parkin, R. A. L. Sullivan and J. N. Andrews of the University of Bath, support the second theory and go even further in suggesting that cosmic spherules are condensed 'sparks' formed by collisions in the asteroidal belt. Their findings are published in a recent edition of the *Philosophical Transactions of the Royal Society of London*, **297**, 495; 1980.

From the qualitative standpoint both theories seem reasonable. A quantitative assessment is more stringent. Parkin *et al.* estimate that 5,000 tonnes of spherules fall to the Earth's surface per year. The dried clay sediment contains about one part per million by mass of cosmic spherules and the mass sedimentation rate is taken as 10 g of dry clay per square metre per year. Hughes (*Space Research*, **15**, 531; 1975) calculated that the total amount of interplanetary matter collected by the Earth each year is about 16,000 tonnes (upper and lower error limits being 30,000 and 8,000 tonnes respectively). So according to Parkin *et al.* spherules make up a considerable percentage of the total influx.

In 1976 Ceplecha (*Lecture Notes in Physics*, **48**, 385) suggested that most of the cosmic dust in the atmosphere (and by implication in sediments) came from the disintegration of meteoroids with in-space masses of between 10^5 and 10^9 g. The influx of these objects produce brilliant fireballs. Each day there will be about 4 of − 17 magnitude, 2 of − 18 magnitude and so on in the Earth's atmosphere. The mass flux is relatively uncertain simply because considerable disagreement exists as to the luminous efficiency of the incident bodies. Also the mass influx of large bodies to the Moon, measured by Apollo seismic stations, yield much smaller values than those predicted by Ceplecha.

Obviously, particulate matter is generated by fireballs. The massive injection of dust into the atmosphere following the Tunguska event in 1908 and the great daylight fireball of 1972 illustrate this. But what percentage of the fireball mass would end up as spherule-sized particles and what size distribution do these have? Complete ablation is common. Most fireball parents release the large majority of their mass at heights below 90 km and are still travelling at velocities above 4 km s^{-1} at the end of their luminous trails. Particles released at these low altitudes and high speeds are at least molten and in extreme cases completely vaporized. The liquid layer created at the front of the incident body by atmospheric friction will be carried round to the rear where sustained boiling may eject droplets in the vaccum wake behind the meteorite. The molten spray then cools by radiation but also undergoes considerable frictional power loading before retarding to free fall velocity. Whether this would produce a second melting or even complete evaporation would depend on the atmospheric density and particle velocity at emission. Meteorite parent bodies definitely undergo surface melting. Retrieved meteorites are covered with a millimetre or so of thick, black crust which may be either glassy (in stony meteorites) or composed of magnetic iron oxides (in iron meteorites).

Moving to the small-size end of the incident mass spectrum, it is rather remarkable how effective the Earth's atmosphere is as a collector of dust. Many incident microparticles are slowed down so gently that they remain virtually unaltered. The frictional power generated over the particle surface is low enough to be thermally radiated without the particle reaching it's melting point. However, the actual temperature that the particle reaches depends strongly on its initial velocity, size and entry angle. Particles larger than 100 μm usually melt even if their initial velocities are only slightly above the escape velocity of 11.2 km s^{-1} (the minimum velocity of an incident particle). 10 μm particles can enter at 45° to the vertical with an initial velocity of 15 km s^{-1} without melting. All particles moving faster than 50 km s^{-1} burn up.

Cosmic spherules straddle this size range, the Parkin *et al.* sample having sizes between 30 and 200 μm. They would melt at a temperature of 2,000 K. All can get through the atmosphere if they have low enough velocities and, for the larger particles, if they 'graze' into the atmosphere, arriving almost tangentially.

Parkin *et al.* go even further. From scanning electron microscope observations they are convinced that none of their collected spherules melted during entry. But some incident particles must melt. The authors suggest that these do not re-solidify. At best they evaporate and at worst they are blown to pieces by the sudden release of adsorbed solar wind gases. A 100 μm lunar soil grain exposed for about 1,000 y adsorbs about 10^{-4} mol per g of ^{4}He, sufficient to burst a molten spherule against surface tension.

David W. Hughes is in the Department of Physics, University of Sheffield.

We are left with the problem that too many spherules are found to be produced by meteorite or fireball parent body spalation alone. Indeed, according to Parkin *et al.* X-ray microprobe chemical analysis and examination with a scanning electron microscope indicate considerable differences between spherules and meteorite fusion crusts. To them the spherules seem to have survived the passage through the atmosphere relatively unscathed. Where did they come from?

The authors point to the asteroid belt and suggest that spherules are quenched sparks formed by colliding asteroids. They even went so far as to collect rounded, quenched grindwheel sparks from a wheel being used to grind a steel bar and to claim that there were distinct similarities to the deep sea spherules. Microdebris from asteroid collision would take about 10^6 y to spiral in to the Earth's orbit under the influence of the Poynting-Robertson effect, ample time to adsorb solar wind. It is even possible to imagine a temporary hot oxidising atmosphere at the collision site due to the abundance of hydrated minerals thus producing the requisite wüstite. But are asteroid collisions frequent enought to produce 5,000 tonnes of spherules per year?

Many people think that the asteroids have been around since the dawn of the solar system and that this permanence relies to a considerable extent on a collision rate which is decreasing with time. Individual collisions may produce swarms of spherules followed by long time periods when the production rate is much smaller. The beauty of core analysis is that, assuming a constant sedimentation rate, you have a perfect means of measuring the spherule influx rate as a function of time. In a note added in proof the authors claim to be able to see evidence for individual collision events. By considering the way in which spherule size varies as a function of core depth and the spiraling time varies as a function of particle size these events are placed in the asteroid belt.

Adherents to the first 'meteoritic ablation' theory are still not convinced. U-2 aeroplanes flying in the stratosphere at altitudes of 20 km collect many particles with meteoritic, extraterrestrial compositions. Brownlee, Blanchard, Cunningham, Beauchamp and Fruland (*J. Geophys. Res.* **80**, 4917; 1975) find that about 10 per cent of them are spherules. To them X-ray diffraction, mineralogy and texture all point to a very strong similarity between spherules and meteorite fusion crusts. It is possible that both theories are right and spherules can be formed either from ablation droplets or from quenched asteroid sparks. Indeed, still further sources are not ruled out — maybe comets contain spherules and maybe planetary cratering events produce spherules in the ejector. We have plenty of possibilities available. What is needed are more scientific investigators. ☐

Did the Santorini eruption destroy the Minoan world?

from Jörg Keller

THE recent report in *Nature*[1] of the discovery of volcanic ash from Santorini on the island of Rhodes raises once again the possibility that Minoan Crete was destroyed by the effects of a volcanic eruption.

Marinatos[2] was the first to postulate a direct connection between two of the most dramatic events in the early history of the Aegean area — the tremendously powerful eruption of the volcano of Santorini (Thera) early in the 15th century BC and the sudden and enigmatic decline of the flourishing Minoan civilization on Crete.

Seismic tidal waves, volcanic earthquakes and ash-fall were the physical effects considered most likely to have seriously damaged Minoan settlements all over Crete. A blanket of ash, thick enough to suffocate the agricultural economy on Crete, was widely thought to have fallen since deep-sea sediment cores drilled north and south of Crete had proved that the tephra had reached the island[3].

Since 1967, the settlement of Akrotiri has been excavated from underneath a thick pumice cover on the island of Thera (Santorini). An unexpectedly wealthy, cosmopolitan Minoan community has come to light. Countless examples of fine pottery, both of local manufacture and imported from Crete, and frescoes of incomparable beauty were found in three-storied houses and mansions[4]. The catastrophic dimensions of the Santorini eruption are very obvious. With increasing knowledge, however, the original idea of the direct physical destruction of Crete by volcanic phenomena has become more and more questionable[5,6].

Recent research in the Aegean area, both on land and in the deep sea has produced a distribution map for the Minoan ashfall[7,8], which shows an easterly dispersion away from the volcano towards Western Anatolia. Substantial fall-out must have affected the Eastern Aegean Sea and Western Anatolia (for example 30cm of tephra have been found on the Island of Kos[8]), but it is inferred that Crete received only a few centimeters of ash, too thin to account for the desertion of the Late Bronze age settlements.

The findings on Santorini also suggest that the volcanic destruction of the city of Akrotiri occured one stage earlier on the pottery-based time-scale of the archeologists than the devastation of Minoan cities and palaces on Crete. The Bronze age pottery style "Late Minoan IA" is fully developed in Akrotiri and the pottery record ends with this stage. In contrast, all over Crete LM IA is followed by pottery of Late Minoan IB, with its highly characteristic decoration showing marine subjects. It is thought that the time difference between the two substages is about 30-50 years. This suggests a date of 1500-1480 BC for the end of Akrotiri on Santorini and 1450 BC for the sudden end of the Minoan civilization on Crete.

Various ideas have been presented to account for the difference in the timing of the two events. Multistage volcanic activity, the possibility that the pottery might have been more old-fashioned in provincial Akrotiri, the destruction of Akrotiri by precursor earthquakes, or evacuation of the settlement some 30 years before the fatal eruption, have all been considered as explanations.

Only when Dorothy and Charles Vitaliano[9,10] found microscopic traces of Santorini tephra in archeological sites on Crete and Melos, and within strata believed to be uncontaminated Late Minoan IA did the possibility emerge that the climax of the Santorini eruption actually preceeded the end of the Minoan civilization by about 30 years.

This interpretation seems now to be fully supported by the new findings on Rhodes. The future investigations which Doumas and Papazoglou have announced will hopefully yield a complete pottery inventory from both below and above the tephra layer. They should characterize a possible LM IB destruction level. But already their conclusions appear to be inevitable: life continued without any significant break after the ash fall. The later destruction of Minoan Crete is once more an enigma. The influence of other civilizations especially neighbouring Mycenae, will certainly have to be re-evaluated. Whether a Mycenaean invasion and conquest of Crete happened during the aftermath of one of the most catastrophic volcanic eruptions known in the Mediterranean will only be revealed by continuing research. ☐

Global dendroclimatology in sight

from A. Barrie Pittock

Dendroclimatology, the systematic study of past climates using tree growth characteristics as proxy climate data, is a relatively young science. It is often confused with the much older and related science of dendrochronology, the dating of specimens by the use of tree-ring sequences. Dendroclimatology has only really developed as a science since the 1940s, primarily as a result of the pioneering efforts of workers at the Laboratory of Tree-Ring Research at the University of Arizona. Elsewhere, the serious application of dendroclimatic methods has only begun in the last five years or so.

It was, therefore, encouraging to find at a recent workshop* attended by 56 scientists from 14 countries that dendroclimatology is making great strides. Greater global coverage was reported in contributions from Europe, Asia, South America, South Africa and Australia, as well as eastern North America and the Arctic. A striking departure from early research in the semi-arid southwest United States was the documentation of useful climatic sensitivity in trees from other than obviously stressed environments. This was particularly well demonstrated for Southern Hemisphere rain forest environments by La Marche and co-workers, for the eastern United States by Cook and for Europe by several groups (Schweingruber, Eckstein, Baillie, Pilcher, and see Hughes *et al.* **272**, 606; 1978; Dunwiddie & La Marche *Naturer* **286**, 796; 1980; Garfinkel & Brubaker *Nature* **286**, 872; 1980). Major research groups (outside the western United States) now exist in several regions, including the United Kingdom, continental Europe and the eastern United States. Strong interest is also being shown in China (two workers were present at the meeting), Argentina, Australia and the Soviet Union. The Chinese plan to use tree-ring data in regions such as the northwest where historical data are not abundant.

Climatologists were also present at the conference and this led to a stimulating interaction between the potential users of dendroclimatic data and the data producers. It was suggested that attempts should be made to reconstruct a wider range of climatic variables, alongside temperature, precipitation and surface pressure and that sampling should be concentrated in regions which are climatologically important and/or where there are gaps in coverage from instrumental, historical or other proxy data. There is growing confidence that with some modification existing methods can extract useful climatic information from trees in many different parts of the world.

As dendroclimatology has expanded into new geographical areas over the last decade, techniques have been modified and refined. One example is the use of density as well as ring-width measurements for climate reconstructions. Density data have been used recently to reconstruct temperature data in Europe (Schweingruber *et al. Tree-Ring Bulletin* **38**, 61; 1978). Although basically similar, the climate-growth response appears simpler for density than ring width (Parker *Syesis* **9**, 163; 1976). New techniques take into account that growth in a particular year is influenced by growth in prior years, that growth is a function of tree age and that the climate-growth response may change as trees age. A recent innovation has been the use of selective filter techniques in calculating the response and transfer functions.

Of special interest were plans for European climate reconstructions put forward by one of the global data base working groups. The plans gave high priority to building up a dense network of chronologies back to at least 1750 covering the whole of Europe. Using instrumental data from 1880 to the present for calibration and earlier instrumental and historical data for verification, it should be possible to produce a detailed and continuous climate reconstruction from 1750. Because of the abundance of data for calibration and verification, this could prove the best continent-wide proxy climate data set in existence and Europe could become a test bed for refining dendroclimatic methods.

Five-hundred-year long chronologies are available already from living conifers in the Alps and at the northern tree-line and are expected from living oaks in Scotland, northern France and south-central Germany. These should allow the reconstructed record to extend back into the 15th century, and extension back for 1,000 years at a reduced spatial density is possible (see Serre *Tree-Ring Bulletin* **38**, 25; 1978). Abundant sub-fossil and archaeological material may be used to extend the chronologies still further. However, the use of such material poses methodological problems in matching series from dead wood with living trees, especially in a way which will not distort the low-frequency climatic information. Work on these problems is being actively pursued and its importance may be gauged from the potential development of several-thousand-year chronologies from various parts of the globe including Europe, North America and New Zealand. The application of densitometric and possibly isotopic methods may well overcome some of the more serious problems in using these long tree-ring chronologies. □

A. Barrie Pittock is in the Division of Atmospheric Physics, Commonwealth Scientific and Industrial Research Organization, Australia.

---

*The Second International Workshop on Global Dendroclimatology was held at the Climatic Research Unit, University of East Anglia, July 7-11, 1980. It was sponsored by the World Meteorological Organisations, the United Nations Enviroment Programme, the Scientific Affairs Division of NATO and the US National Science Foundation and was organised by M. K. Hughes (Liverpool Polytechnic), P. M. Kelly (University of East Anglia) and J. P. Pilcher (Queen's University, Belfast). A report on the proceedings will be published in 1980 and a book in 1981.

100 years ago

It is stated that at the National Exhibition to be opened at Milan next year there will be a captive balloon, on the model of the one which was so successful in Paris in 1878. It will measure not less than 180 feet in circumference, 84 feet in height, and contain 15,000 cubic feet of gas. To it will be attached a safe and solid car, capable of containing seats for at least eight persons. A steam-engine is to regulate the ascent and descent, and it will rise to a height of about 900 feet, affording a splendid view of Milan and the plains of Lombardy. The balloon will be constructed at Milan, m. Henri Beudet, the well-known and experienced aëronaut, having been sent for to direct the work.

THE *Boston Herald* gives the following account of an American experiment made on September 2: — "A novel exhibition of powerful electric lights was made last evening in the vicinity of the Sea Foam-house, Nantucket Beach, and the display was witnessed by quite a crowd of interested spectators. The Northern Electric Light Company have erected three wooden towers, each 100 feet high, and mounted upon each of these a circular row of twelve electric lights of the Weston patent, each light being estimated at 2,500-candle power. As these towers are but 500 feet apart and in a triangle, it will be seen that the light of 90,000 candles was concentrated within a limited territory. The design of the exhibition was to afford a model of the plan contemplated for lighting cities from overhead in vast areas, the estimate being that four towers to a square mile of area, each mounting lights aggregating 90,000-candle power, will suffice to flood the territory about with a light almost equal to midday. Last evening a motive power of thirty-six horses was used in generating the electricity from three Western machines, and the lights, with one single flicker, burned steadily and brilliantly all the evening. It is difficult to say whether the experiment proved anything or not. The claim put forward by the company is for an original plan of lighting cities and towns by grouping and elevating electric lights of any kind."

REVIEW ARTICLE

Hormone families: pancreatic hormones and homologous growth factors

T. L. Blundell
Laboratory of Molecular Biology, Department of Crystallography, Birkbeck College, University of London, Malet Street, London WC1E 7HX, UK

R. E. Humbel
Biochemisches Institut der Universitat Zürich, Zürichbergstrasse 4, CH-8028 Zürich, Switzerland

The growing realization that biologically active polypeptides can be grouped in families, the members of which show structural and functional relatedness, is illustrated by the four families which are represented in the pancreas by the hormones insulin, glucagon, somatostatin and pancreatic polypeptide.

THE study of the origins of hormone-like activity is revealing great complexity in endocrine control systems, but a degree of simplicity in that most hormones belong to a family group. Members of any family are related in chemical sequence in a way which suggests their evolutionary relationships. In some cases members of a family retain common biological activities as a vestige of their common ancestry; however, for many the divergence of biological function is complete. Moreover these families are becoming extended with the inclusion of growth factors from the serum and neurotransmitters and neuroregulators from the central nervous system. These trends are well illustrated by examples drawn from the four families of peptide hormones represented in the pancreas by insulin, glucagon, somatostatin and pancreatic polypeptide.

Insulin

Porcine pancreatic insulin, shown schematically in Fig. 1, is a globular polypeptide. It has a hydrophobic core and two mainly hydrophobic surfaces which may be involved in intermolecular interactions stabilizing insulin dimers and 2-zinc insulin hexamers[1]. The sequences of vertebrate insulins[2] (Fig. 1) show that the residues of the hydrophobic core are conserved, and that all insulins might attain the same tertiary structure as porcine insulin. Although teleost fishes, reptiles, birds and most mammals have insulins which form dimers and hexamers[3], certain hystricomorph rodents such as the guinea pig and the casiragua, lack the zinc-building histidine at position B10 (Table 1) and have lost the ability to self-associate. The insulin of the primitive cyclostome, the hagfish, also lacks B10 histidine; it can form dimers but not zinc hexamers[4]. The sequence of proinsulin[5,6], the precursor of insulin, is shown in Fig. 1; a C-peptide connects B30 and A1. The probable structure of proinsulin is indicated in Fig. 2. The evidence for this structure[1] is indirect and is based on the similarity of proinsulin to insulin in circular dichroism, self-association, immunological studies and the ability of the two peptides to co-crystallize.

It has been recognized for some time that two species of rodents (rat, mouse) and at least one species of fish (toadfish) contain two different insulins, almost certainly derived from two nonallelic insulin genes[7]. Goodman and co-workers[8] have determined the sequence of the DNA for the rat insulins I and II and have shown that each contains an intervening sequence of 119 base pairs in a region corresponding to the 5′ untranslated portion of the mRNA. In addition, the rat insulin II gene contains a 499 base pair intervening sequence in the region of DNA coding for the C-peptide. More recently it has been shown that the human and chicken insulin genes resemble the rat II gene in having two intervening sequences, the second at exactly the same position in the C-peptide encoding region of the gene[9,10]. (Could the presence of the intervening sequence in the C-peptide region account for its being the most highly variant part of the proinsulin molecule in which deletions and additions also occur?) The similarity of the human chicken and rat II genes implies that their ancestral insulin probably contained two intervening sequences. Gene sequencing also suggests that there are two non-allelic insulin genes in humans which differ by at least one base pair[9]. This would be consistent with the report of an unusual insulin, which results in diabetes and hyperproinsulinaemia and which is produced in addition to a normal insulin, implying codominant expression of two alleles[11].

It is not known for certain whether the two rat insulins are synthesized by the same cell. Some indication that this might be the case comes from the electron microscopy of rat insulin storage granules within a single cell which show morphologies characteristic of both insulins[12].

Insulins bind to receptors from tissues of differing species in a way which reflects the origin of the hormone rather than the receptor. Hence, with the possible exception of hystricomorphs[13], there seems to have been evolutionary conservation of the insulin receptor. Studies of the potency and receptor binding of differing insulins and synthetic analogues have demonstrated that for full potency the general tertiary structure needs to be conserved[14-16]. Of the surface of the insulin molecule an extensive region around residues A21, B24 and B25, perhaps involving as many as eleven residues appears to be important in receptor binding.

Relaxin, a member of the insulin family?

For many years it was thought that insulin was not a member of a larger family of hormones. Recently, however, it has been suggested that relaxin, a polypeptide hormone from the corpus luteum and responsible for dilation of the symphysis pubis prior to parturition, may be a member of the insulin family. Relaxin has two chains (A and B) linked by disulphide bridges as shown in Fig. 1[17,18]. Model building shows that the backbones of the relaxin and insulin molecules may have similar conformations (see Figs 2 and 3), although the hydrophobic core of relaxin involves different side chains, close-packed into the same volume[19,20]. The absence of residues in relaxin equivalent to position A21 or to the B-chain C-terminal of insulin probably destabilizes the insulin fold but should not prevent its formation. The relaxin A-chain N-terminus has two extra residues and lies

close to the B-chain C-terminus in the proposed structure. Preliminary sequence data from the laboratories of H. D. Niall and C. Schwabe indicate that similar structures may be assumed for rat and shark relaxins. Like insulin, relaxin is synthesized as a single chain precursor, prorelaxin. This molecule appears to be much larger than relaxin itself even though only a short connecting peptide of one or two residues would be necessary to allow the correct conformation of the hormone[21]. Although the tertiary structures of insulin and relaxin are most likely very similar, the surfaces of the two molecules are very different. It is therefore not surprising that they are not immunologically cross-reactive, and that relaxin shows neither insulin-like biological activity nor the ability to bind insulin receptors[22,23].

Would the similar tertiary structure of insulin and relaxin, if proven, amount to evidence of common ancestry and divergent evolution, given the low (~20%) sequence homology between the two peptides? If we begin with the assumption that there are only few stable structures for small proteins, then the folding of each structure implies restrictions on the residues if the secondary structure preference in a region is to be maintained. In particular, glycine residues alone give the unusual conformational angles that are found, for instance, at B8 and B20 of insulin, and only cystines could link the A and B chains. How significant, then, is the sequence similarity between relaxin and insulin, most of which comprises six homologous cystines and two homologous glycines? The need for a hydrophobic core further restricts the residues which can be accepted as evidence for divergent evolution. Insulin and relaxin therefore may share a similar structure, simply because it is one of comparatively few which are globular, contain disulphide bridges, and are formed by polypeptide chains of between 50 and 80 amino acid residues; the polypeptides might have converged to this structure. Nevertheless, it remains true that no molecule lacking hormone activity has been shown to have a similar structure, a fact which may be presented as evidence in favour of divergent evolution.

Insulin-like growth factors (somatomedins)

Recently, the insulin-like growth factors (IGFs) have also been added to the insulin family. Whereas insulin and relaxin are structurally distant relatives, giving no cross-recognition at the receptor level, insulin and the IGFs are structurally and functionally more closely related. IGFs or somatomedins are polypeptides purified from human serum and from media conditioned by cultured cells. The designation somatomedin was introduced by Daughaday[24] for substances fulfilling the following four criteria: their concentration in serum is regulated by growth hormone, they stimulate incorporation of sulphate into proteoglycans of cartilage, they have mitogenic activity in fibroblasts and they have insulin-like effects on adipose and muscle tissue. Four factors or groups of factors meeting these criteria have been described so far: non-suppressible insulin-like activity (NSILA)[25]; somatomedin A[26,27]; somatomedin C[28]; and multiplication stimulating activity (MSA)[29].

The concept that some or all of the four factors might be structurally related to insulin had been slowly emerging from numerous studies on their biological and chemical properties[30-32] and from the initial observation by Hintz *et al.*[33] that somatomedin-C competes with insulin for binding to the

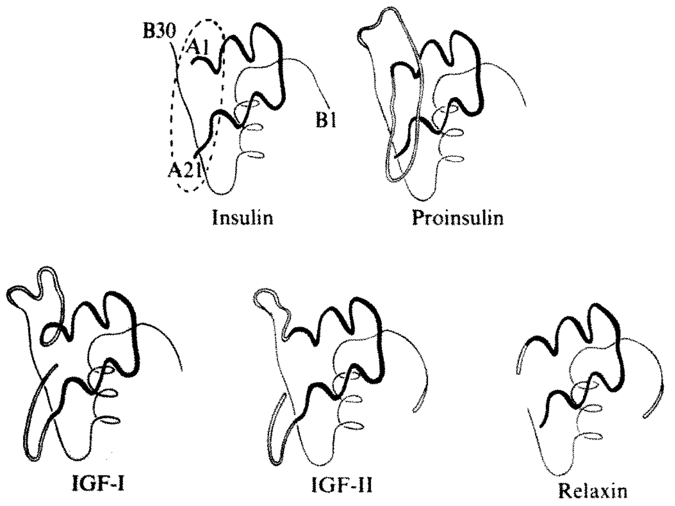

Fig. 2 Schematic diagrams showing the chain folding of insulin as derived from the X-ray analysis of insulin crystals[1] and proinsulin[1], IGF-I[42], IGF-II and relaxin[19] as proposed by model building experiments using the known sequences. The putative receptor binding region of insulin[1,14] is indicated.

insulin receptor on cell membranes. Eventually, the isolation of two homogenous polypeptides from purified NSILA[34] and the subsequent determination of their amino acid sequences[35,36] established unequivocally the long-suspected structural kinship of NSILAs to insulin and led to the new designation of insulin-like growth factors (IGFs) I and II[37].

A partial primary structure of somatomedin C has recently been shown to have considerable, although not complete, identity to IGF-I[38]. However, for somatomedins A_1 and A_2, the only data so far available are amino acid compositions[39] which do not suggest a structural relationship to insulin and the IGFs. The same is true of several forms of rat MSA which have been purified and have had their amino acid composition determined[40,41]. Thus out of the four groups of somatomedins, the IGFs and somatomedin C are clearly akin to insulin, whereas the putative structural relationships of somatomedin A and of the MSAs to insulin have yet to be shown.

The primary structures of IGF-I and -II in fact show more structural similarity to proinsulin than to insulin[35–37] (see Fig. 1). Like proinsulin IGF-I and -II are single-chain polypeptides with three intra-chain disulphide bridges. The regions of structural similarity in IGF are confined to the B- and A-chain part of proinsulin. An intermediary or connecting region between these A- and B-chain homologous parts consists of 12 and 8 residues compared to 35 in human proinsulin with little homology between these sequences. Also IGF-I and -II exhibit a carboxy-terminal extension of 8 and 6 residues, which is not present in proinsulin.

The structural similarity of IGF and proinsulin suggests a common ancestor from which these molecules diverged during evolution. From the number of identical residues between IGF and insulins from different species[2,36], the divergence between insulin and IGF can be surmised to have occurred before the appearance of the vertebrates provided that the rate of evolutionary change was similar in the two molecules. Likewise, the divergence between IGF-I and IGF-II can be timed at the appearance of the first mammals.

Based on the sequence similarity of IGF and insulin and the known three-dimensional structure of insulin, models have been constructed for IGF-I[42] and IGF-II (Figs 2 and 4). These indicate that the two growth factors can have an identical hydrophobic core and an identical conformation of those residues corresponding to the A- and B-chains of insulin. Their short connecting peptides are easily accommodated in the models although they cover less of the molecular surface than the C-peptide of proinsulin; this appears to be compensated by the extension of the A-chain termini in both IGF molecules. Part of the putative receptor-binding region of insulin described above is thus modified whereas the remaining region has many residues in common.

This structural model is entirely compatible with the notion that some effects of somatomedins may be due to an interaction with the insulin receptor. Earlier studies had demonstrated that impure preparations of NSILA-s inhibit the binding of ^{125}I-insulin to insulin receptors in direct proportion to their insulin-like activity[43]. However, the potency of IGF-I and -II as measured by the stimulation of the conversion of glucose to CO_2 in adipocytes is about 120 and 60 times, respectively, lower than that of insulin[44]. Interestingly, Piron and de Meyts[45] could show in lymphocytes that both IGF-I and -II induce, as insulin, negative cooperativity with potencies in perfect agreement with their apparent affinity for the receptor. More recently, compelling evidence for crossreactivity of somatomedins with insulin receptors has been obtained by the use of monovalent antibodies against the insulin receptor in adipocytes. These Fab fragments derived from a patient with extreme insulin resistance produced a 30-fold rightward shift in the dose response for stimulation of glucose oxidation by both insulin and MSA[46].

The discovery that somatomedins are recognized by the insulin receptor could not explain why the somatomedins have a relatively weak insulin-like metabolic effect, while their potency in promoting growth effects in fibroblasts is about 150 times the potency of insulin[44]. Since the initial studies of Morell *et al.*[47] it was therefore suspected that the metabolic effects of the somatomedins were secondary phenomena due to crossreaction with the insulin receptor, and that their main effects on growth parameters were due to an interaction with a second set of receptors of high affinity for somatomedins and a lower affinity for insulin. The studies of Van Wyk *et al.*[28] and Megyesi *et al.*[43] were the first observations of distinct somatomedin receptors.

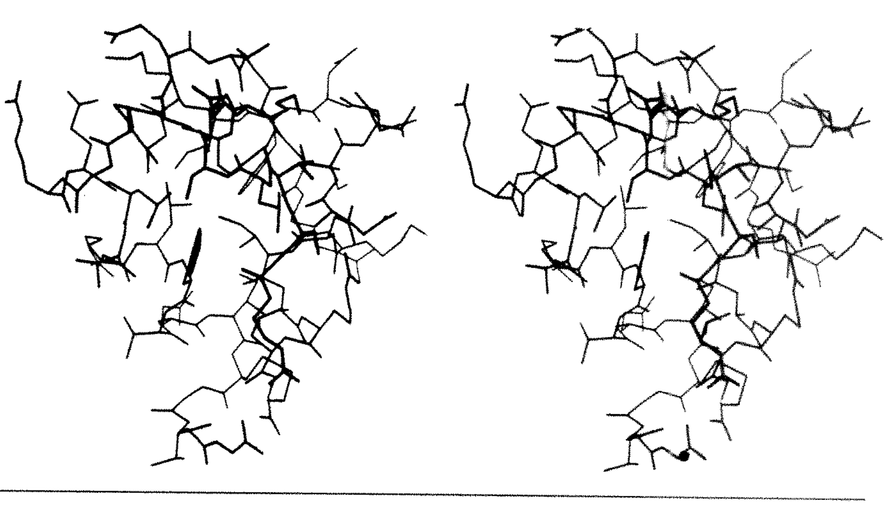

Fig. 3 Stereo view of the three-dimensional structure proposed for relaxin based on an assumed homology with insulin. (Reproduced with permission from *Nature* **270**, 449–451 (1977).)

Later, numerous other studies from several laboratories (see ref. 31) provided ample evidence for the existence of specific somatomedin receptors in several tissues. Of special interest is the observation that, relative to insulin, proinsulin is ten times more effective in binding to the MSA receptor than to the insulin receptor[48]. This observation is entirely compatible with the proinsulin-like structure of IGF-I[42]. The elegant studies of King *et al.*[46] demonstrate that blockage of the insulin receptor of cultured human fibroblasts does not abolish the effect of either insulin or MSA on thymidine incorporation into DNA. It appears, therefore, that interaction with the somatomedin receptor is responsible for the growth-promoting effect of somatomedins and of insulin.

On the basis of the model-building, IGF-II with its shorter connecting peptide is expected to bind insulin receptors with a greater affinity than either IGF-I or proinsulin, a prediction borne out by studies of Zapf *et al.*[44] on adipocytes and by preliminary results of de Meyts and co-workers[22] on lymphocytes. The question, however, remains whether more than one type of somatomedin receptor is present on target cells. Preliminary evidence for at least two receptors, one preferentially binding IGF-I, the other IGF-II and MSA has recently been obtained in several cell types by Rechler *et al.*[49].

In native serum, the somatomedins are bound to a large extent to at least one type of carrier protein[50] which also seems to be under the control of growth hormone[51,52] and to be released concomitantly with somatomedin from the liver[53,54]. The presence of such a specific and saturable binding protein in serum is unique among peptide hormones. Neither insulin[44] nor relaxin or nerve growth factor compete with the IGFs for binding. It may be speculated, therefore, that regions of the IGF molecules not homologous to insulin are making contact with the binding protein.

None of the somatomedins crossreacts with antibodies against insulin, despite the similar structures of the IGFs and of somatomedin C with insulin. However, the immunogenic region of insulin appears to be different from the receptor region and comprises residues mainly within the sequences B1–B10 and A8–A10 (refs 1, 55). The surface side chains in these regions of IGF molecules are quite different from those of any of the insulins, thus explaining the lack of cross-reactivity of the IGFs and of insulin with their respective antibodies. Antibodies against IGF-I crossreact 100-fold better with IGF-I than with IGF-II and antibodies against IGF-II 35-fold better with IGF-II than with IGF-I[56]. In radioimmunoassays for IGF-I and for somatomedin C, somatomedin-C behaves almost or completely identically to IGF-I[56,57], whereas somatomedin A and MSA are less than 5% as potent as somatomedin-C and IGF-I[57]. Surprizingly, in a radioimmunoassay for somatomedin A, IGF-I is 10 times more potent than somatomedin A[58], adding to the bewilderment about the identity of somatomedin A.

The recently developed radioimmunoassays for somatomedin C[59] and IGF-I and -II[56] have allowed the levels of these somatomedins to be determined in clinical conditions such as acromegaly and hypopituitary dwarfism. IGF-I seems to be stringently regulated by the levels of circulating growth hormones whereas the levels of IGF-II are only marginally influenced by growth hormone. Thus, *in vitro*, IGF-I and -II have qualitatively identical effects with some variation in potency, whereas *in vivo* a distinct difference in regulation suggests they play different roles. Further support for different physiological functions of IGF-I and -II comes from preliminary studies showing synthesis in chick liver cells of a somatomedin similar to human IGF-I, but not to IGF-II and the presence of IGF-II, but not IGF-I, in human cerebrospinal fluid. Thus, IGF-I and the somatomedins seem to be growth-hormone-dependent growth factors, whereas a physiological role for IGF-II has yet to be found.

The last-mentioned fact adds considerably to the deplorable semantic confusion in this field. Since somatomedins are defined as growth-hormone-dependent growth factors, IGF-I and somatomedins A and C qualify as true somatomedins, whereas IGF-II does not. Conversely, somatomedins such as somatomedin A or MSA cannot unreservedly be classified as insulin-like growth factors unless and until their structures can be shown to justify such a designation.

Nerve growth factor has also been proposed as a member of the insulin family on the basis of a suggested sequence similarity (see ref. 18 for review). However, the model of NGF that can be derived from its sequence does not contain a conserved hydrophobic close-packed core and deletions give rise to a different conformation of those residues equivalent to the B-chain helix of insulin. Definition of the degree of structural homology must await the determination of the three-dimensional structure[60]. It also appears that nerve growth factor is not able to compete with insulin for its receptor[22].

Glucagon

Compared to insulin, glucagon has a shorter polypeptide chain which is insufficient to allow a hydrophobic core to be shielded from the solvent. In dilute solution therefore, glucagon is flexible and many differing conformers are in equilibrium, with evidence for a stable interaction only between Val 23 and Trp 25 (ref. 61). At increasing concentrations (*p*H from 3.0 to 9.5) the molecules self-associate to α-helical trimers and higher oligomers[62]. An α-helical region exists between residues 6 and 27 resulting in the formation of two hydrophobic 'sticky' patches on the surface of each helix[63]. As with insulin, these hydrophobic patches are involved in self-association; glucagon trimers are formed. A similar hydrophobic interaction may account for the formation of α-helical conformers which occur in nonpolar solvents and in the presence of phospholipids[64].

All mammalian glucagons which have been sequenced are identical[2] and turkey and duck glucagon show only one and two conservative changes respectively from the mammalian sequence. It therefore appears that there are strong selective

functional restraints on the glucagon molecule during evolution, although preliminary results on guinea pig, angler fish and shark glucagons indicate some divergence[65].

Study of the data on receptor binding and activity of glucagon on the glucagon-sensitive adenylate cyclase system of hepatocyte membranes led Rodbell *et al*[66] to suggest that almost the entire molecule is required for full biological potency. Their results and subsequent detailed studies by Epand *et al.*[64] have shown that modification at the COOH-terminal or NH_2-terminal regions and on polar groups invariably leads to decreased receptor potency, although modification of some nonpolar groups (such as tyrosine by iodination) can enhance activity, indicating the importance of the whole glucagon molecule to receptor binding. Des-His^1-glucagon and other glucagons modified at the N-terminus are partial agonists with reduced affinity for the glucagon receptor suggesting that this region might be involved in hormone action whereas the major part of the molecule, including the C-terminal hydrophobic region, might be responsible for enhancing receptor affinity[67]. Receptor binding studies of smaller N-terminal fragments of glucagon are consistent with this model[68]. Evidence that interaction with the receptor is entropy driven suggested a model in which a helical conformer, stabilized by hydrophobic interactions, is induced or selected at the receptor from a population of conformers[63].

Glucagon is a member of a large family of homologous polypeptides, found in the alimentary tract and elsewhere, including secretin[69], the first hormone to be discovered, vasoactive intestinal polypeptide[70] (VIP) and gastric inhibitory peptide[71] (GIP, now renamed glucose-dependent insulinotropic peptide) (see ref. 2 for review). Evidence for the existence of further homologous intestinal peptides[72] indicates that the family may be much more extensive.

Glucagon is more effective than either VIP or secretin in hepatic adenylate cyclase activation and appears to act through a receptor distinct from those for secretin and VIP[68,73]. Neither secretin nor VIP competes with ^{125}I-glucagon at the receptor on hepatocytes. In view of the close homology at the N-terminal region of glucagon, VIP and secretin, these observations might indicate that the C-terminal residues of glucagon are responsible for selecting the correct receptor. However, recent results indicate that the N-terminal region may also play a role in receptor selection since glucagon$_{1-6}$ is a partial agonist of glucagon, whereas the equivalent regions of secretin and VIP are not[74]. Secretin and VIP are both recognized by each other's receptors although each binds to its own receptor with greater affinity[75,76]. The results of these and many other comparative studies indicate that the secretin and VIP receptors, although perhaps not the glucagon receptor, have evolved from a common ancestor. Confirmation of this proposal must await chemical characterization of the receptors themselves.

Glucagon also has an ill defined relationship to glicentin, a 100-amino acid polypeptide isolated from the intestine. Glicentin is known to carry the immunodeterminants of glucagon and to account for most of the glucagon-like activity in the intestine[77]. Although it is tempting to believe that glicentin is the precursor of glucagon, particularly since it is found in the specific glucagon-containing granules of the pancreatic α-cell, recent evidence suggests that glicentin and glucagon are in topographically separated granules[78].

Pancreatic polypeptide and somatostatin

Two further peptides which may be classified as hormones are produced by specific cells of the islets of Langerhans. Pancreatic polypeptide[79,80] is a 36-amino acid peptide which appears to have gastrointestinal functions and may act as a satiety factor; it is released after a protein meal and leads to a decrease in weight of certain genetically diabetic mice[81,82]. Since Tatemoko and Mutt[72] find a homologous peptide in pig intestine, pancreatic polypeptide may be a member of a larger family of gastroenteric pancreatic hormones. All sequenced pancreatic polypeptides have amidated carboxytermini and there is close homology amongst the mammalian sequences[79,80] (Fig. 5). In contrast to glucagon, however, there are considerable differences between mammalian and avian pancreatic polypeptide sequences[79,80]. This is also reflected in the species specificity of immunological and some biological activities[80–82].

Although this polypeptide is only seven residues larger than glucagon, it appears to have a relatively stable tertiary structure[83–85] comprising a polyproline II-like chain segment folded against an α-helical region as shown in Fig. 6. In a similar way to insulin the molecules can self-associate to dimers. It seems that all mammalian and avian pancreatic polypeptides can attain this conformation and can dimerize; in addition the avian polypeptide, like insulin, can form higher oligomers in the presence of zinc.

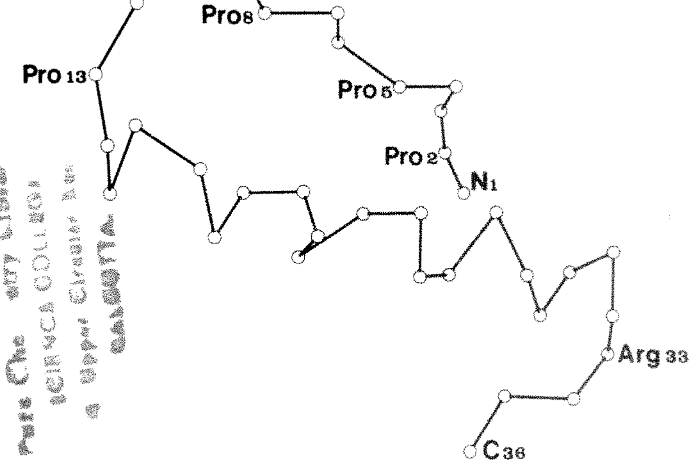

Fig. 6 The conformation of avian pancreatic polypeptide, PP, as determined by X-ray analysis. The α-helix and the polyproline-like helix pack together to give a compact structure. A similar structure may also be assumed by bovine pancreatic polypeptide, even though they are species specific in some of their biological activities. (Unpublished results of J. Pitts, S. P. Wood, I. J. Tickle and T. L. Blundell.)

Somatostatin[86] is the smallest of the pancreatic hormones. It contains 14 amino acids with one disulphide bridge; in fact an even smaller, relatively rigid peptide of residues 7–10 can be a potent agonist[87]. Somatostatin is widely distributed and was originally identified in the hypothalamus, although peptides in different organs and in different mammals (pig and sheep) seem to be identical. In general the peptide appears to act locally—in the pancreas it inhibits the release of insulin and glucagon; it is therefore strictly a local hormone or paracrine agent.

Evolution of pancreatic hormones and relation to gastroenteric and neuroendocrine systems

Finally, we consider whether pancreatic hormones or close relatives are also active in the nervous system. This question is being approached by the study of the developmental and evolutionary origin of hormone-producing cells and by attempts to localise and even extract the hormones from the central nervous system (see ref. 88 for a review).

Examples of pancreatic hormone-like activity are found in the alimentary tract (see ref. 89 for review) of both protostomian and deuterostomian lines of invertebrate evolution. For instance, an insulin-like substance which has a role in carbohydrate metabolism is found in the mucosa of the alimentary tract of molluscs[90]. Evidence for this insulin-like activity is derived from biological and radioimmunological assay, as well as ultrastructural, histological and histochemical techniques, but it has not yet been chemically characterized.

Van Noorden and Falkmer[89] have traced the movement of the four pancreatic hormones from the alimentary canal into the islets during vertebrate evolution. They have shown that the first hormone to be found in a well defined islet is insulin in cyclostomes such as the hagfish. Somatostatin also appears in the islet at that stage. Glucagon is the third hormone to reach the pancreas, being restricted to the gut mucosa in cyclostomes, but appearing in the pancreatic islets of the holocephalan cartilaginous fishes. In these fish pancreatic polypeptide immunoactivity is still located in the gut mucosa, but at the next evolutionary stage, the elasmobranchian cartilaginous fish, this molecule finally moves into the pancreatic islets.

Immunoreactive evidence of all pancreatic hormones has been observed in the central nervous system. Somatostatin is found immunocytochemically in the neurones of the N-paraventricularis of the hypothalamus and in other hypothalamic nuclei[91]. Insulin-like activity in the blowfly[92] has its origins in the median neurosecretory cells, and in the hookworm[93] an insulin-like molecule of the corpus cardiacum/corpus allatum capable of decreasing haemolymph trehalose, may also derive from neurosecretory cells. Much interest has been stimulated by the recent reports of Roth *et al.*[94,95] that insulin-like protein levels in many rat tissues including brain extracts are higher than in plasma. The marked similarity between this insulin-like activity and pancreatic insulin in radioimmunoassay, radio-receptor assay, and bioassay indicates that all tissues contain either genuine insulin or a very similar polypeptide rather than a proinsulin-like peptide or insulin-like growth factor. Roth *et al.*[94] find that genetically obese (*ob*/*ob*) diabetic mice in which circulating insulin is markedly increased, and insulin receptors in liver, fat and other tissues are severely depressed, have normal concentrations of insulin and insulin receptors in the brain. These and other related observations on rats made hypoinsulinaemic and diabetic by treatment with streptozotocin have been held to indicate the synthesis of insulin locally in the brain and other extrapancreatic tissues, and to suggest a possible role of insulin in neurotransmission, either as a neurotransmitter itself or as a neuromodulator. However, these reports have been disputed by Eng and Yalow who contend that insulin concentrations in the brain of larger animals never exceed plasma levels[96]. Much work remains to establish whether or not insulin is synthesized in the mammalian central nervous system; the high levels of insulin may well result from insulin which has crossed the blood–brain barrier, diffused through the brain and concentrated on brain receptor sites[96]. The discovery of many of the gastroenteric pancreatic hormones in the central nervous system of higher vertebrates indicates that neuronal peptide production may represent a primative capability. The explanation of this distribution of peptide hormones may lie in the APUD theory of Pearse[88,97] which proposes that the embryonic neuroectoderm of nerves and peptide hormone-producing cells have a common origin in the neuroendocrine-programmed cells of the ectoblast. The diffuse regulatory mechanism of the neuronal system may have become partially replaced by aggregation of cells of the endocrine system. These ideas do not preclude an even more primitive evolution of hormones and neurotransmitters from lysozomal proteases as suggested by Hales[98]. At the level of molecular evolution, duplication of ancestral genes—perhaps coding for neurotransmitters—must have given rise through natural selection of mutated sequences to a series of hormones and growth factors: families of molecules with homologous sequences.

We are grateful to many colleagues for helpful discussions and to Drs P. de Meyts, S. Falkmer, M. M. Rechler, S. Van Noorden and J. J. Van Wyk for making available unpublished results and reviews.

The Tieschitz unequilibrated H-group chondrite accreted at (800 ± 100) °C during rapid cooling[11]. *From their mineral chemistry, nine other H-group chondrites, exhibiting greater degrees of equilibration, also formed hot. Degree of equilibration is equated with slowness of cooling, especially below about 700 °C. If metamorphism is defined as change brought about by an increase in temperature, in the H-group chondrites it is recognized only in the localized effects of transient reheating, probably induced by shock.*

THE ordinary chondrites are stony types composed of silicate, metal and sulphide phases. Because of this mixture and because they were never completely melted, the ordinary chondrites are considered to represent primative, condensed matter of the early Solar System. Chemically they are subdivided into three groups. One of these, the high iron (H-) group, has a total iron content >24.5 wt% and iron-nickel metal generally in the range 12–21 wt%. Many members of this group have been unaffected by shock events which post-date crystallization and which caused veining, 'blackening' or brecciation in most members of the other two chemical groups[1–3]. The H-group, therefore, seemed most appropriate to re-investigate using modern techniques. Our work will be published in detail elsewhere[4,5]. Here, in summarizing our data, we favour a simpler early history for the H-group parent body (or parent bodies) than is currently accepted. Furthermore, we interpret for the first time the cooling history of all petrological types consistently in terms of the chemistry of both silicates and metal.

On a textural and mineralogical basis, Van Schmus and Wood[6] subdivided the chondrites into six petrological types. Types 1 and 2 do not occur in the ordinary chondrites. Type 3 refers to unequilibrated chondrites with prominent chondrules, sub-spherical masses of silicate, some of which are quenched liquid droplets, the remainder were fashioned from solid or plastic pre-existing rock[7,8]. In contrast, petrological type 6 applies to meteorites in which chondrules have crystallized and intergrown with the matrix. Types 4 and 5 exhibit integration of chondrules with matrices intermediate between that in types 3 and 6. The pyroxenes and feldspars of type 4 ordinary chondrites are partly chemically heterogeneous, but almost all of those in types 5 and 6 are not. In petrological type 3, metal and sulphide may form rounded droplets—metallic chondrules[9,10]—outside silicate chondrules, or they may occur separately or together as droplets within silicate chondrules. But in higher petrological types metal and sulphide are generally absent from silicate chondrules and occur as grains with irregular outlines

0028–0836/80/440787—04$01.00

indicative of partial to complete crystallization to fill the available spaces between the chondrules.

For our study, 10 H-group chondrites (named in Fig. 2) were chosen from the collection in the British Museum (Natural History) as unshocked or lightly shocked representatives of the different petrological types. The wavelength-dispersive electron microprobe at the British Museum (Natural History) was used for analysis of metal and sulphide; other phases were analysed using the energy-dispersive microprobe system at Cambridge. The 1-MV transmission electron microscope at Birmingham University provided information on the fine-structure of the chondrites.

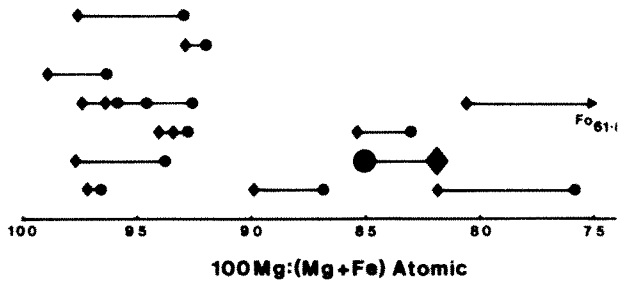

Fig. 1 Compositions of the 'cores' of co-existing phenocrysts of olivine (●) and low-calcium pyroxene (◆) in 12 Tieschitz chondrules. Except in one case (large symbols), pyroxenes are more magnesian than olivines. Because the plane of the section cuts each crystal at random, we cannot be sure that an analysis is representative of a crystal core; this accounts for the compositional differences shown. The vertical axis has no significance.

Silicate mineralogy

Tieschitz is the only highly unequilibrated chondrite among the 10 studied. In both olivines and low-calcium pyroxenes the molecular ratio of 100 Mg: (Mg+Fe) is variable within crystals and between crystals. In every zoned crystal studied the core is more magnesian than the rim, consistent with an earlier observation on the Sharps, H3 chondrite[7]; pyroxene cores are usually poorer in calcium than the rims[11]. Of some 40 chondrules, 12 contain phenocrysts of both olivine and low-calcium pyroxene. Of these, 11 have pyroxenes more magnesian than the co-existing olivine (Fig. 1). In Tieschitz the bias in favour of pyroxene in the partitioning of magnesium between pyroxene and olivine was undoubtedly the result of crystallization of chondrule liquids. In our sample of Bremervörde (H3/4) and in the chondrites of higher petrological type, on average, the 100 Mg: (Mg+Fe) ratio is ~2% higher in low-calcium pyroxenes than in the co-existing olivines; this is consistent with earlier data[12]. There is thus little difference in the partitioning of Mg between pyroxene and olivine among chondrites which exhibit different degrees of equilibration.

In Tieschitz and Bremervörde, low-calcium pyroxenes are typically of the polysynthetically twinned, monoclinic variety; they may have crystallized directly from chondrule liquids during rapid cooling but they are more probably inverted protopyroxene[5,13]. Most pyroxene cores contain <0.75 wt% calcium (Fig. 2), as do those in the remaining, more equilibrated chondrites. Although our calcium determinations broadly agree with those quoted by Dodd[12], we observe no correlation between calcium content of pyroxene cores and the increasing petrological type. Calcium-rich pyroxene occurs in both Tieschitz and Bremervörde as overgrowths of pigeonite on twinned, low-calcium pyroxene cores or as the minor phase in intergrowths with low-calcium, monoclinic pyroxene. Pigeonites exhibit exsolution on ~10 nm scale. Diopside has not been observed, but some chondrule mesostases are rich in normative diopside. In the two least equilibrated chondrites, crystallization of olivine or low-calcium clinopyroxene or protopyroxene resulted in the enrichment in calcium of residual chondrule liquids. Cooling was so rapid, however, that only pigeonite was able to crystallize on a pre-existing substrate of low-calcium pyroxene[5]. In the petrological type 4 and 5 chondrites the low-calcium pyroxene is typically the striated orthopyroxene which has been interpreted as "the disordered product of inversion from a high-temperature polymorph"[13]. In the H4 chondrites, low-calcium pyroxene cores may have overgrowths of pigeonite or even subcalcic augite; augite and diopside, however, were encountered only as components (normative) in chondrule mesostases, except in the TEM study of Quenggouk[5]. Here, some chondrule mesostases contain tiny crystallites of orthopyroxene, diopside, and plagioclase. The diopside lacks exsolution lamellae, even on the finest, sub-micrometre scale. It is evidence of slower cooling and a closer approach to equilibrium crystallization than by the pigeonites in Tieschitz and Bremervörde. In the two chondrites of petrological type 5, orthopyroxene or striated pyroxene often has overgrowths of augite or diopside which are resolvable by microprobe. Finally, in the H6 chondrites the low-calcium pyroxenes are represented by orthorhombic crystals only, and diopside occurs both as overgrowths and as individual, anhedral grains.

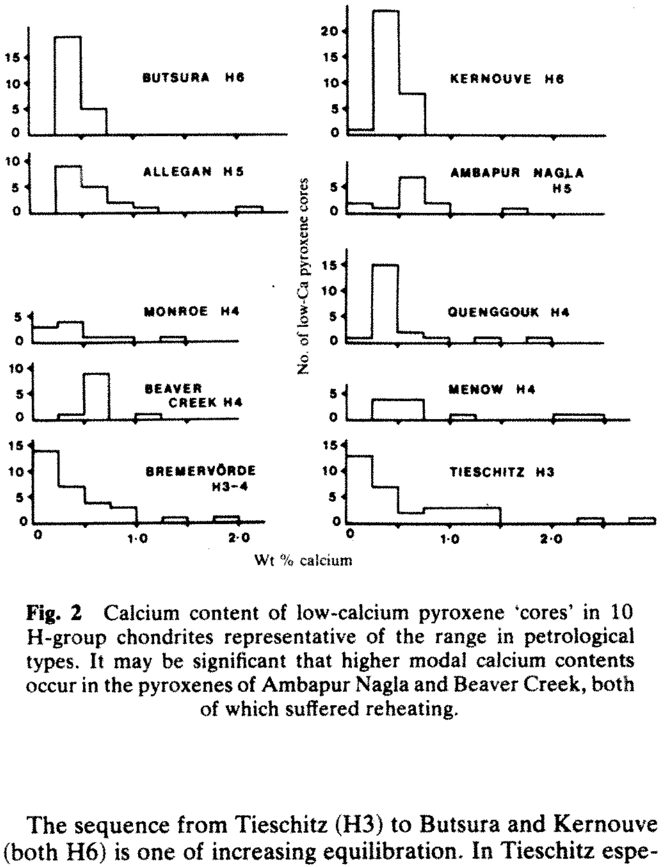

Fig. 2 Calcium content of low-calcium pyroxene 'cores' in 10 H-group chondrites representative of the range in petrological types. It may be significant that higher modal calcium contents occur in the pyroxenes of Ambapur Nagla and Beaver Creek, both of which suffered reheating.

The sequence from Tieschitz (H3) to Butsura and Kernouve (both H6) is one of increasing equilibration. In Tieschitz especially, but also in Bremervörde and the chondrites of type 4, olivines and monoclinic, low-calcium pyroxenes undoubtedly crystallized from chondrule liquids. Structurally, the 'striated orthopyroxene' of Allegan (H5) is intermediate between these monoclinic, low-calcium pyroxenes and the orthorhombic pyroxenes of Butsura and Kernouve. It is surprising that the low-calcium pyroxenes have uniformly low calcium contents throughout (Fig. 2). In addition, the partition of magnesium between olivines and pyroxenes always favours the latter. Had crystal–liquid and solid–solid equilibria been responsible for elemental partition between the phases at the respective extremes of the petrological sequence, systematic compositional differences should be evident. In their absence we conclude that, throughout the sequence, elemental partition was established by a single process acting in uniform physical conditions. In types 3 and 4, this process was undoubtedly crystallization from chondrule liquids; this must also be true for the type 6 chondrites which do contain relict chondrules. It seems, therefore, that in the H6 chondrites the partition of calcium between the pyroxenes was dominated by the crystallization of large amounts of very low-calcium clinopyroxene or protopyroxene from chondrule liquids. Subsequently, inversion to the orthorhombic form occurred. Had orthorhombic pyroxenes crystallized directly from liquids, the crystals should contain a higher calcium content or exsolution lamellae of calcium-rich pyroxene, as for example, do the bronzites of Bushveld type[14]. On the contrary, even on a sub-micrometre scale, no exsolution lamellae of calcium-rich pyroxene were found in the bronzites of Butsura or Kernouve.

Conventional mineral thermometers[15,16] are based on equilibrium partition of an element between two co-existing solid phases; a metamorphic environment has to be assumed. Our evidence indicates that these thermometers may not apply to the H-group chondrites, and this might also be true for the oxygen isotopic thermometer[17]. However, in addition to the above arguments based on the mineral chemistry of olivines and pyroxenes, we have observed chemical heterogeneity among the feldspars and chromites of Butsura. Thus, in at least one H6 chondrite, equilibration was not completely achieved; this conclusion was reached by Bunch and Olsen[15], who used data on pairs of crystals in contact for their assessment of the various mineralogical thermometers.

Metallography

It has been argued[10] that in Tieschitz, metallic chondrules and droplets in silicate chondrules cooled rapidly enough to preserve structural and chemical evidence of an origin by fractional crystallization from Fe–Ni–S melts. This is based on an interpretation of polycrystalline taenite as the relict of a solidification structure (Fig. 3*a*). In Tieschitz this does not seem to be in doubt because there is ample evidence of quenching in silicate chondrules and the meteorite is completely unshocked[5,11,18]. However, polycrystalline taenite occurs also in Bremervörde, Menow, Quenggouk, Butsura (Fig. 3*b*) and, rarely, even in Kernouve, the most equilibrated of our sample of H-group chondrites. Is then the polycrystalline taenite in H6 chondrites a relict solidification structure, or could it have formed in some other way? If the former is true, then the H6 chondrites could not have been metamorphosed during a reheating episode at a temperature above 700 °C, for this would have caused all metal to homogenize as the γ phase. Subsequent, slow cooling could not produce the crystal boundaries in the parent γ. Internal grain boundaries in γ crystals, if produced by deformation at high temperature, could be stabilized at low temperature only by quenching or by the widespread precipitation of α Fe–Ni along the crystal boundaries. Crystallites of α are very rarely observed in polycrystalline taenite. Finally, there is no evidence that polycrystalline taenite could have formed by brittle deformation of taenite below 700 °C.

We are forced to conclude that polycrystalline taenite in H6 chondrites is a relict solidification structure. For its preservation in Tieschitz, Bevan and Axon[10] state that cooling to below about 700 °C (entry of metal into the $\alpha + \gamma$ field) took days to weeks. In Butsura and Kernouve, polycrystalline taenite is rarer and more modified than in Tieschitz, indicating slower cooling in the case of the H6 chondrites; they may have taken weeks to months to cool from over 1,000 °C to below about 700 °C. However, the most important conclusion from these observations is that compositional variation in the metal of H-group chondrites was established at temperatures above 700 °C, and subsequently enhanced by the effects of solid-state diffusion at lower temperatures.

Discussion

Wood[9] modelled the development of nickel-distribution profiles in metal grains in the ordinary chondrites. He began, however, by assuming that above ~700 °C all metal was in the form of homogeneous γ crystals. On cooling into the $(\alpha + \gamma)$ field, α nucleated and grew at the expense of γ by solid-state diffusion of nickel. By computer modelling the build-up of nickel relative to grain-size in taenite (γ), Wood estimated the rates at which various ordinary chondrites cooled through about 500 °C. The presence of polycrystalline taenite in some of the H-group chondrites indicates that above 700 °C, in the γ field, metal was inhomogeneous and that initial nickel gradients had already been established by crystal–liquid fractionation. Therefore, Wood's model[9] must always underestimate the rate of cooling in the H-group chondrites, although for the type 6 meteorites it will produce a closer approximation to the true cooling rate than for the H3, Tieschitz.

Interpretation of polycrystalline taenite as a relict solidification structure parallels our conclusion that the

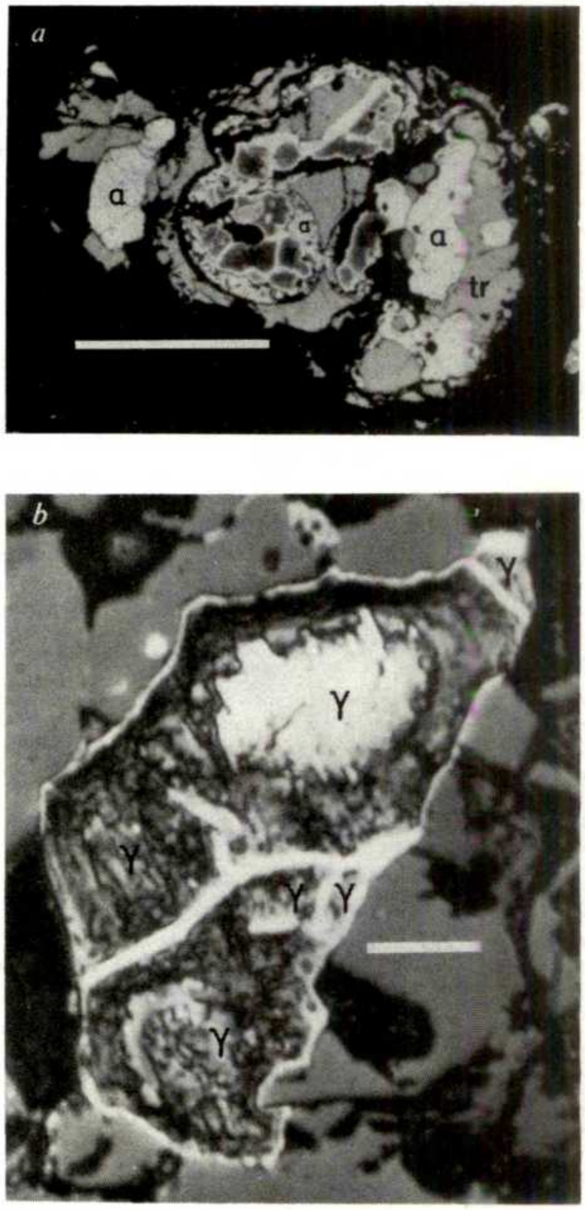

Fig. 3 *a*, Metal–sulphide chondrule in Tieschitz (H3). Scale bar, 100 μm. tr, troilite; α, kamacite; γ, taenite. Two adjacent crystallites of polycrystalline taenite (γ) are indicated; each has a dark-etching core and a rim of clear taenite. *b*, Polycrystalline taenite, Butsura (H6). Scale bar, 20 μm. Clear taenite (white) bounds the grain and wholly or partly delimits six crystallites (γ) each with a martensitic, dark-etching centre.

distribution of magnesium between olivine and low-calcium pyroxene, and of calcium between low-calcium and calcium-rich pyroxenes, was established by crystal–liquid equilibria during the crystallization of chondrule liquids. Moreover, survival of polycrystalline taenite and/or of monoclinic or 'striated' low-calcium pyroxene in H5 and H6 (refs 13, 19) chondrites indicates fairly rapid cooling to about 700 °C, after which there could have been no prolonged reheating at higher temperatures. 'Metamorphism' in the strict sense apparently then played no part in determining the major textural features in the H-group chondrites. Rather, we favour a model of hot accretion during cooling at various rates; H3 chondrites were rapidly cooled whereas H6 meteorites cooled more slowly, which allowed crystallization and some solid-state diffusion to occur by a self-annealing process. Based on textural and mineralogical observations, Fredriksson (see ref. 20) has argued against metamorphism in ordinary chondrites. However, the meteorites chosen are brecciated and, we believe, from Fredriksson's evidence, metamorphism followed by further chondrule formation cannot be ruled out. Dodd[12] favoured 'progressive metamorphism' as the process responsible for the varying degrees of equilibration exhibited by the ordinary chondrites. Our new interpretation of the cooling history of the metal and our observations on the uniformity of the calcium contents of the low-calcium pyroxenes remove Dodd's main objections to a self-annealing ('autometamorphic') model for the thermal history of the H-group chondrites.

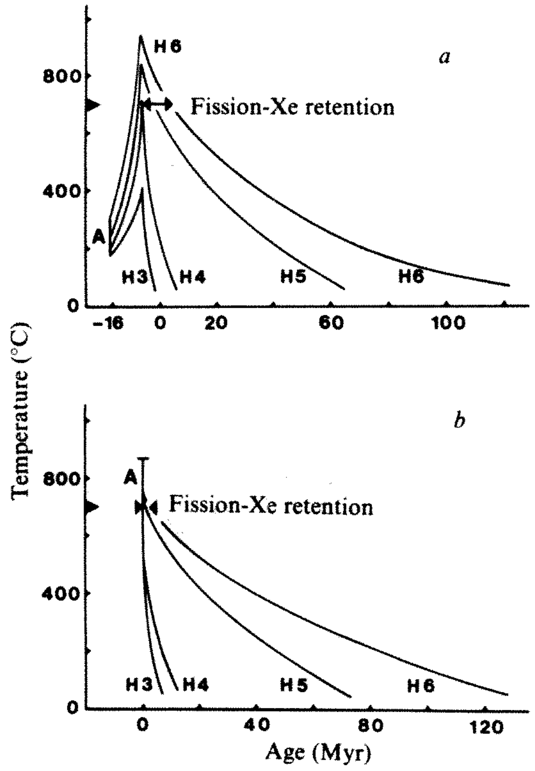

Fig. 4 Two schematic models of the cooling-history of H-group chondrites: *a*, metamorphic; *b*, self-annealing. 'A' indicates the approximate temperature of accretion. 'Fission-Xe retention' indicates the temperature at which half of the Pu-fission Xe is retained by phosphate during cooling; this temperature was attained by H4, H5 and H6 chondrites within 10 Myr (ref. 21). In both models zero time is set within this 10-Myr span. In the metamorphic model *a*, cold accretion may have taken place up to about 16 Myr before the final cooling through 700 °C. The time-limit is fixed by the content of iodine-correlated ^{129}Xe, which is released from specimens in the laboratory between 1,100 and 1,500 °C (refs 26, 27). Model *b*, inferred from the mineralogy, seems preferable because of its simplicity.

In Fig. 4 the generally accepted, progressive metamorphic model is compared with our preferred self-annealing model. The latter is favoured by the synchronous retention of plutonium-fission xenon, within 10 Myr, by H4, H5 and H6 chondrites; also in support are the revised plutonium-fission cooling rates[21] of H4, H5 and H6 chondrites. Furthermore, ^{39}Ar–^{40}Ar ages of H-group chondrites indicate that representatives of all petrological types began to retain radiogenic argon within a 60-Myr period from 4.51 to 4.45 Gyr ago, all ages being within experimental error of the mean[22]. Such synchronism seems less readily attainable if the history had been complex (that is, accretion at 200 °C followed by heating to metamorphic temperatures then slow cooling to gas retention temperature) rather than simple.

Support for the metamorphic hypothesis must now be based on the interpretation of the abundances of the volatile metals thallium, bismuth and indium. It has been argued that these elements were introduced into chondritic parent bodies as part of a low-temperature fraction which became mixed with a more abundant high-temperature fraction. Calculations based on the condensation of a gas of solar composition fix the temperature of accretion within a few tens of degrees of 200 °C (Fig. 4*a*) (ref. 23). However, the oxygen isotopic ratios favour 'condensation and accretion at high temperature'[24], and we have already argued that Tieschitz aggregated at higher temperature[11] and that an ambient gas was probably depleted in hydrogen relative to the solar composition. Uranium-lead systematics indicate that, at room temperature, chondrites become contaminated with lead from the terrestrial atmosphere[25]. We argue, therefore, that the H-group chondrites could have received their complement of volatile metals during cooling on a small, planetary body from ~700 °C, over 10^5–10^7 yr.

For either model of the thermal history our conclusions point unambiguously to a stratified parent body of the H-group chondrites. Slowly cooled, petrological type 6 material derives from greater depth than the near-surface location of type 3 which may have been within 20 m of the planetary surface[10]. As a corollary, this parent body could not have been externally heated after accretion of the H-group chondrite material.

We thank H. J. Axon for helpful discussion, and M. Christophe-Michel-Lévy and R. T. Dodd for helpful comments. Part of the work was supported by the NERC.

Measuring metamorphic history of unequilibrated ordinary chondrites

A thermoluminescence sensitivity technique is used to give a new measurement of the degree of metamorphism of unequilibrated ordinary chondrites. Consequently the petrological assignment of these meteorites is modified.

THE wide range of textures in chondritic meteorites indicates a variety of metamorphic histories[1-4]. Most meteorites are metamorphosed and it is estimated that they have experienced maximum temperatures of around 1,200 °C (ref. 5). A few (described as type 3 in the scheme of Van Schmus and Wood[6]) have apparently experienced little or no metamorphic heating and their relatively unaltered state makes them interesting subjects for study[7]. We report here measurements which seem to enable the degree of metamorphism experienced by these unequilibrated ordinary chondrites to be quantified. Based on our findings, we propose a modification to the petrological type assignment of these meteorites.

We have used a thermoluminescence (TL) sensitivity technique, sensitivity being defined as the amount of TL induced in a sample by a standard radiation dose. Any previously accumulated TL is first drained by annealing the sample to ≥500 °C. The TL sensitivity, or TL per rad of absorbed radiation, is an intrinsic property of the luminescent mineral in the meteorite. It should not be confused with the level of natural TL, which is additionally governed by a complex interplay between the thermal and radiation environment of the meteorite.

This work was prompted by a study of H chondrites organized by Hutchison[29]. H chondrites are distinguished from the other ordinary chondrites (L and LL) on the basis of bulk chemistry, but the TL properties of the three ordinary chondrite classes are remarkably similar. This is presumably because TL is produced almost entirely by feldspar[12], which is present in the same proportions and has similar composition in each group[8]. When the results of our H-group study were available, it was decided to examine some type 3 meteorites. Most of the observed falls studied by Dodd *et al.*[9] were included (Table 1). Our measurements were made at the University of Leicester, UK[10] and at Washington University, St Louis[11]. Samples were lightly crushed and the metal and adhering sulphide removed with a hand-magnet. Three samples produced brown powders due to small quantities of terrestrial corrosion (Kernouvé, Butsura and Limerick). These were shaken for a few seconds in 10 M HCl to restore their normal grey colour, thus reducing an albedo effect which reduces TL[12]. The nonmagnetic portions of the chondrites were ground fine enough to pass through a 100-μm sieve and then heated to 500 °C to remove their natural TL. Leicester samples were given a test dose of 50 krad from a ^{60}Co γ source, whereas the St Louis samples were given a test dose of 25 krad with a ^{90}Sr β source. Samples of the Dhajala meteorite were run on both sets of apparatus and used for normalization to enable a comparison of data from the two laboratories. Using different test doses introduces a small error, but this is not thought to be significant in view of the large effects discovered. The TL sensitivity measurements are reproducible to within ±5%.

Results

Three plots of TL sensitivity against sample temperature ('glow curves') are shown in Fig. 1. These three curves demonstrate the range of shapes observed, although most meteorites produce glow curves which closely resemble those from Khohar. Variations in glow-curve shape are caused by the presence of several separate TL peaks whose relative contributions vary slightly. The shape variations seem unrelated to any of the factors considered here. We have also looked at the best method of extracting data from the curves; two possibilities are to measure the peak height or the area under the curve. We found no difference in the two approaches and present here the former. It also makes very little difference if the TL is measured at a given temperature rather than at the peak, as the glow curves are generally so similar and the effects discovered so large.

The thermoluminescence data are shown in Fig. 2 and listed in Table 1. The average TL sensitivity of the highly metamorphosed type 5 and 6 meteorites is appreciably higher than for the type 3 samples. Furthermore, the TL sensitivities range over a factor of ≤10 in samples of type 4–6 compared with a range of ~1,000 for type 3 chondrites.

A detailed examination of the accuracy of the TL sensitivity measurements for type 4–6 meteorites has been given else-

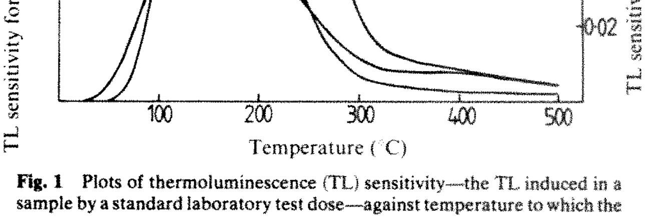

Fig. 1 Plots of thermoluminescence (TL) sensitivity—the TL induced in a sample by a standard laboratory test dose—against temperature to which the sample has been heated ('glow curves'). The TL is emitted mainly in a broad peak between 100 and 300 °C. Most chondrites studied here have glow-curve shapes resembling Khohar, but a few, like Manych and Ngawi, have shapes which differ in detail.

where[13]. The standard deviation in 10 different meteorites which were expected to have similar TL sensitivity was 21%. Type 3 meteorites are highly inhomogeneous and only small quantities were available for our measurements, so a second chip taken from a different location on the available sample was run. The root-mean-square deviation on the duplicate values is 48%. The error bars on Figs 3 and 4 are ±1 σ of the means.

Discussion

Several parameters for assessing the extent of equilibration in type 3 meteorites have been discussed, but none of them covers the range observed for TL sensitivity or is as free from ambiguity as TL (Fig. 3). The best indication of unequilibration available to Van Schmus and Wood[6] was the inhomogeneity of the silicates. This is expressed as the per cent mean deviation (PMD) shown by the fayalite content of the olivine or pyroxene. The olivine data of Dodd *et al.*[9] are compared with the TL data in Fig. 3*a*; the pyroxene data give a similar plot, but the range in pyroxene PMD is smaller. The inverse correlation indicates that as the meteorites equilibrate, TL sensitivity increases and the silicates become more homogeneous.

In an analogous way, the range of Co contents of the matrix kamacite becomes smaller as the meteorite becomes more equilibrated[7]; we have calculated the PMD of Co in the kamacite and added our own unpublished Tieschitz datum (Fig. 3*b*). Again, there is a clear negative relationship. Figure 3*c* compares our data with the percentage matrix recrystallization[14]. There is some uncertainty in this measurement because it is necessary to discriminate between chondrule fragments and other non-matrix components, but there is a trend in which TL sensitivity increases with the percentage of recrystallized matrix. Huss *et al.*[14] have shown that the FeO content of olivine in the matrix (normalized to the same parameter for the whole rock) decreases with equilibration. One possibility is that FeO is reduced out of the matrix and into the metal, consistent with the views of Wood[15] and Afiattalab and Wasson[7]. This parameter also shows an inverse correlation with TL sensitivity (Fig. 3*d*).

Changes in bulk chemistry can be related to metamorphism in ordinary chondrites, although the causes of these relationships

‖ Samples were powders taken from a larger reservoir of homogenized, nonmagnetic powder of unknown sample weight.

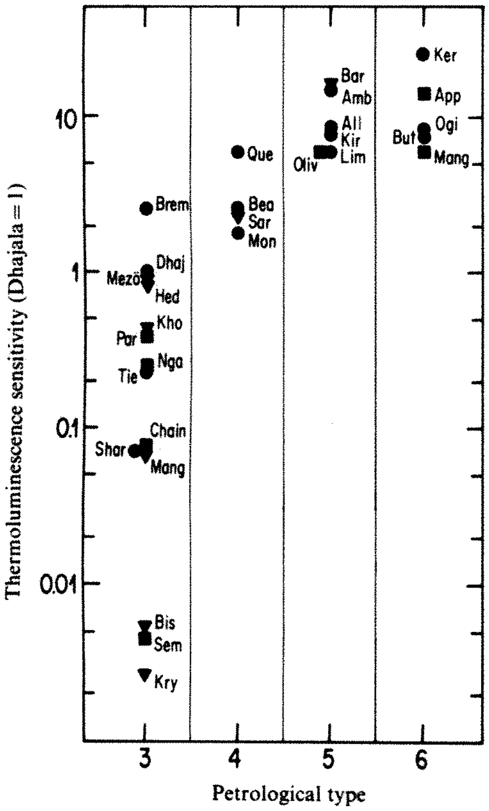

Fig. 2 Plot of TL sensitivity against petrological type for 29 meteorites, normalized to Dhajala. Note the much greater range displayed by type 3 compared with the other types. In this and Fig. 3, meteorites are identified by the first three letters of their names (see Table 1) or some simple variant. ■, LL chondrites; ▼, L chondrites; ●, H chondrites.

are debatable[4,16–18]. The carbon[6] and the primordial ^{36}Ar (ref. 19) contents of chondrites decrease with petrological type. These are compared with TL sensitivity in Fig. 4 (the sources of the ^{36}Ar and C data are given in the legend). These, too, display clear inverse relationships with TL sensitivity.

A relationship between TL sensitivity and petrological type was first suggested by Liener and Geiss[20], but their data fail to display such a relationship because only two of their 70 specimens are unequilibrated[12]. The relationship between TL sensitivity and petrological type is believed to be associated with changes in the crystalline structure of the phosphor, which in most ordinary chondrites is feldspar[21]. However, in unequilibrated ordinary chondrites, the feldspathic material is in the form of a glass[6]. Glasses are intrinsically poorer phosphors than crystalline substances of the same composition because the TL mechanism involves lattice defects or impurity ions in a crystal lattice[16]. The small TL sensitivity that glasses possess is probably due to localized areas of short-ranged order. The transition from glass to crystalline feldspar takes place in meteorites of type 3. In type 4, glass is generally absent, having been replaced by microcrystalline feldspar, although there may be occasional instances of turbid glass. In meteorites of type 5, glass is entirely absent and in type 6, the feldspar has grown to clear, coarse grains[6]. It seems reasonable, therefore, that TL sensitivity should be rather sensitive to the extent of equilibration in type 3 meteorites.

It has been proposed[22,23] that radiation damage will also cause changes in TL sensitivity. Evidence for this has long been sought[20,22,23], but the largest effects so far observed[24] are at most of the order of 25%. In fact, there is some evidence[12] that they may be zero for the TL emitted between 100 and 300 °C (Fig. 1).

The reheating and shock believed to have been suffered by the black chondrites causes a decrease in TL sensitivity comparable with the range observed here. The cause is similar to that responsible for the relationship between TL and petrological type; shock causes a vitrification of the feldspar[25]. The shock events required to affect TL are very large ($\gtrsim$250 kbar) and also cause loss of ^{40}Ar—reflected in K–Ar ages very much less than 4,600 Myr—and characteristic changes in the metallography. None of these meteorites are among those examined for shock effects by Heymann[24], although Wood[15] describes Manych as reheated and Huss *et al.*[14] mention shock effects in their descriptions of type 3 chondrites. Of the three meteorites with the lowest TL sensitivity in the present suite of specimens, ^{40}Ar data are available for two of them. Assuming a K content of 800 p.p.m., taking ^{40}Ar contents from ref. 26 and using the usual decay constants and other data, these meteorites have K–Ar ages of 4.060 Myr (Bishunpur) and 4,100 Myr (Krymka), where in each case the uncertainty is probably ±15%. It seems unlikely that these meteorites have had their TL appreciably lowered by a recent shock event of the magnitude responsible for the low TL sensitivities which have been observed in L chondrites[12]. However, we cannot rule out some complex relationship between very early shock and petrological type which also implicated TL.

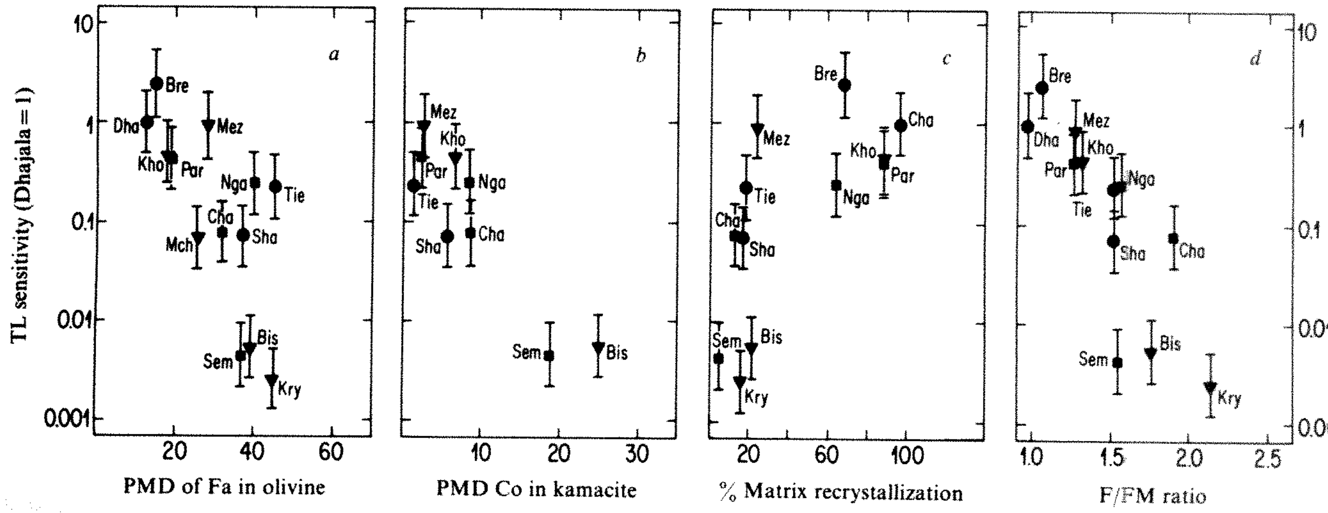

Fig. 3 Plots comparing the TL sensitivity of the type 3 meteorites studied here with literature data which attempt to measure the extent of metamorphic equilibration. *a*, Per cent mean deviation of the FeO content of the olivine[9]. *b*, Per cent mean deviation of the Co content of the kamacite (calculated from data in ref.7 with our own unpublished data for Tieschitz). These two parameters decrease during metamorphism as the silicate and metal compositions become more homogeneous. *c*, Per cent matrix recrystallization[14]. *d*, FeO/(FeO + MgO) in the matrix normalized to the same parameter for whole-rock[14]. This last parameter decreases with equilibration as FeO is apparently reduced out of the matrix. ■, LL chondrites; ▼, L chondrites; ●, H chondrites.

Subdivision of petrological type 3

In many respects, and especially in their TL properties, the unequilibrated ordinary chondrites display a more excessive behaviour than shown by any other petrological type. For instance, Bishunpur bears as little similarity to Dhajala, another type 3, as Dhajala does to Kernouvé, a type 6 chondrite. To emphasize this point, we believe that some subdivision of petrological type 3 is desirable. There is no doubt that the metamorphism experienced by type 3 chondrites is gradational and shows no hiatuses. This is reflected in most of the data in Figs 2–4. (The only exception seems to be a possible discontinuity in matrix recrystallization.) This is also true of the more equilibrated meteorites. The sharpness of chondrule outlines and an olivine PMD of 5 are examples of parameters used to define higher petrological type boundaries (5–6 and 3–4 respectively), but neither is a sharp, single-temperature effect and both reflect gradational proceses. The lack of hiatuses in the equilibration parameters for type 3 chondrites, such as TL sensitivity, is not an argument against subdivision.

Afiattalab and Wasson have already proposed subdivision on the basis of metal homogeneity; they divided their nine unequilibrated ordinary chondrites into: four with 'high'; two with 'moderate'; and three with 'low' metal uniformity[7]. Huss *et al.* have proposed subdivision into four categories which they described with Roman numerals[14]. The utility of any subdivision scheme is governed not only by its necessity but also by its simplicity and consistency with existing schemes. Ideally, any subdivision should merge into existing schemes so naturally that it is largely self-explanatory. Terms like 'highly', 'moderate' and 'somewhat' unequilibrated are cumbersome; they cannot always be neatly incorporated into graphs or tables. Letter abbreviations, such as L3h, L3m and L3l, are confusing because current practice is to use letters for chemical class and numbers for petrological types. The simplest approach is to modify the present system by using decimal numbers. We propose that type 3 be considered to consist of 10 subdivisions going from type 3.0 to type 3.9. It might be logical to go from 2.5 to 3.4, so that the numbers round off to 3, but we believe our proposed range will be more popular.

Table 2 summarizes our proposed subdivision scheme for type 3 ordinary chondrites, based on the trends observed in Figs 3 and 4. Three of the subdivisions are unpopulated at present, but we see no obvious reason why these will not eventually be filled. One subdivision contains members which we have not examined, but literature data (mainly PMD olivine) suggest that they should be assigned to petrological type 3.9. They were included for the sake of completeness because they are more equilibrated type 3 members than those examined here. It is possible to assign a petrological subtype on the basis of each of the parameters in Table 2, and such assingments are generally in very good agreement with the TL sensitivity assignment. (We have arbitrarily chosen the upper value where data fall on the boundary between subtypes.) In general, most petrological subtype assignments are within ±0.1 of those listed in Table 2, and this is the uncertainty we would assign to the petrological

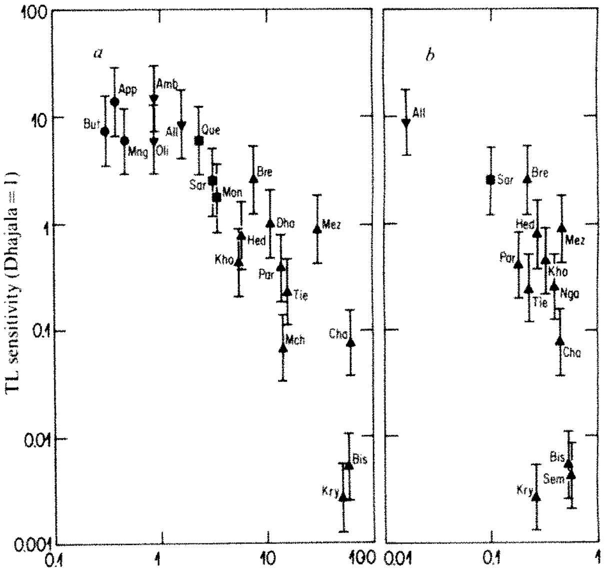

Fig. 4 Two bulk chemical parameters which are known to decrease with increasing equilibration during metamorphism, compared with TL sensitivity; *a*, primordial ^{36}Ar content, calculated from data in ref. 26 and unpublished supplements, assuming primordial ^{36}Ar/^{38}Ar = 5.6 and spallogenic ^{36}Ar/^{38}Ar = 0.65 (ref. 28); and *b*, carbon content. As with TL, the range of primordial ^{36}Ar and C contents is much greater in meteorites of type 3 than any other type. Types: ▲, 3; ■, 4; ▼, 5; ●, 6.

subtype of a given meteorite. There are only three meteorites for which the literature data assignments differ systematically from the TL assignment; the Mezö-Madaras subtype could be decreased by 0.1, the Parnallee value increased by 0.1 and the Semarkona value increased by 0.2. Clearly there would be no problem in assigning a petrological subtype in the absence of TL data, provided there were other good quality data available.

We thank the donors of meteorites listed in Table 1 and John Wasson for many discussions and encouragement; also Drs J. A. Wood, R. T. Dodd, and W. R. Van Schmus for advice, and Joanna Pai and Clare Marshall for technical assistance. This research is supported by NASA grant NGR 05-007-329 (at UCLA) and NSF grant EAR78-22440 (at Washington University).

Mutations affecting segment number and polarity in *Drosophila*

Christiane Nüsslein-Volhard & Eric Wieschaus

European Molecular Biology Laboratory, PO Box 10.2209, 69 Heidelberg, FRG

In systematic searches for embryonic lethal mutants of Drosophila melanogaster *we have identified 15 loci which when mutated alter the segmental pattern of the larva. These loci probably represent the majority of such genes in* Drosophila. *The phenotypes of the mutant embryos indicate that the process of segmentation involves at least three levels of spatial organization: the entire egg as developmental unit, a repeat unit with the length of two segments, and the individual segment.*

THE construction of complex form from similar repeating units is a basic feature of spatial organisation in all higher animals. Very little is known for any organism about the genes involved in this process. In *Drosophila*, the metameric nature of the pattern is most obvious in the thoracic and abdominal segments of the larval epidermis and we are attempting to identify all loci required for the establishment of this pattern. The identification of these genes and the description of their phenotypes should lead to a better understanding of the general mechanisms responsible for the formation of metameric patterns.

In *Drosophila*, the anlagen for the individual segments arise as equally sized subdivisions of the blastoderm, each segment represented by a transverse strip of about three or four cell diameters[1]. A cell lineage restriction between neighbouring segments is established at or soon after this stage[2]. Two basic types of mutation have been described which change the segmental pattern of the *Drosophila* larva. Maternal effect mutations like *bicaudal* lead to a global alteration of the embryonic pattern[3]. Bicaudal embryos develop two posterior ends arranged in mirror-image symmetry, and lack head, thorax and anterior abdomen. The *bicaudal* phenotype suggests that the initial spatial organisation of the egg established during oogenesis involves a morphogen gradient that defines antero-posterior coordinates in early embryonic pattern formation[3,4]. The subdivision of the embryo into segments is thought to occur by a differential response of the zygotic genome to the maternal gradient. Homeotic mutations (for example, *bithorax*[5,6]) seem to be involved in a final step of this response process. These mutations change the identity of individual segments; for example, *Ultrabithorax* transforms the metathoracic and first abdominal segments into mesothoracic segments. However, the homeotic loci do not affect the total number, size or polarity of the segments, nor do they point to any other step which might intervene between the maternal gradient and the final pattern of segments.

We have undertaken a systematic search for mutations that affect the segmental pattern depending on the zygotic genome. We describe here mutations at 15 loci which show one of three novel types of pattern alteration: pattern duplication in each segment (segment polarity mutants; six loci), pattern deletion in alternating segments (pair-rule mutants; six loci) and deletion of a group of adjacent segments (gap mutants; three loci) (Table 1, Fig. 1).

The segmental pattern of the normal *Drosophila* larva

Figure 2 shows the cuticular pattern of a normal *Drosophila* larva shortly after hatching. The larval body is comprised of three thoracic and eight abdominal segments. Although differences are observed in different body regions, all segments have certain morphological features in common. The anterior of each segment is marked with a band of denticles, most of which point posteriorly. The posterior part of each segment is naked. The segment borders run along the anterior margins of the denticle bands[7], they have no special morphological features. The polarity of the pattern is indicated by the orientation of the denticles and, in the abdomen, by the shape of the bands (Fig. 3). In the thoracic segments the bands are narrow with fine denticles whereas those in the abdominal segments are broader and comprised of thick pigmented denticles (for a detailed description of the cuticular pattern see ref. 1).

0028-0836/80/440795—07$01.00

Segment polarity mutants: deletions in each segment

Mutants in this class have the normal number of segments. However, in each segment a defined fraction of the normal pattern is deleted and the remainder is present as a mirror-image duplication. The duplicated part is posterior to the 'normal' part and has reversed polarity (Figs 1–3).

Six such loci have been identified. Three loci, *fused*[8], *wingless* (ref. 9 and G. Struhl, personal communication) and *cubitus interruptus*^{D}, were previously known whereas *gooseberry*, *hedgehog* and *patch* are new (Table 1). All the mutations in this class are zygotic lethals and the phenotypes are only produced in homozygous embryos. One of the loci, *fused*, also shows a maternal effect in that a wild-type allele in the mother is sufficient to rescue the mutant phenotype of the homozygous embryos.

In all mutants except *patch* the region deleted includes the naked posterior part of the pattern and the duplication involves a substantial fraction of the anterior denticle band. In mutant larvae, the ventral side of each segment is almost entirely covered with denticles, the posterior fraction of which point anteriorly. The segment identity seems to be normal, the denticles of the abdominal segments being large and pigmented whereas those of the thorax are short and pale (Figs 1, 2). The anterior margin of the region duplicated in these mutants coincides with the segment boundary in only two cases, *fused* and *gooseberry* (Fig. 3). In *wingless* and *hedgehog* it lies posterior to the boundary, such that these larvae apparently lack all segment boundaries.

The phenotype of embryos homozygous for *patch* contrasts with that produced by the five loci described above in that the duplicated region includes some naked cuticle anterior to each denticle band. The duplicated unit thus involves structures of two adjacent segments. *Patch* larvae, despite the normal number of denticle bands, have twice the normal number of segment boundaries (Figs 1, 3).

Despite these differences, the common feature of all mutants in this class is that a defined fraction of the pattern in each segment is deleted. This deletion is associated with a mirror image duplication of the remaining part of the pattern. We suggest that these loci are involved in the specification of the basic pattern of the segmental units.

Pair-rule mutants: deletions in alternating segments

In mutants of this class homologous parts of the pattern are deleted in every other segment. Each of the six loci is characterized by its own specific pattern of deletions (Table 1, Figs 1, 4). For example, in *even-skipped* larvae, the denticle bands and adjacent naked cuticle of the pro- and metathoracic, and the 2nd, 4th, 6th and 8th abdominal segments are lacking. This results in larvae with half the normal number of denticle bands separated by enlarged regions of naked cuticle (Figs 1, 4). In *paired* larvae the apparent reduction in segment number results

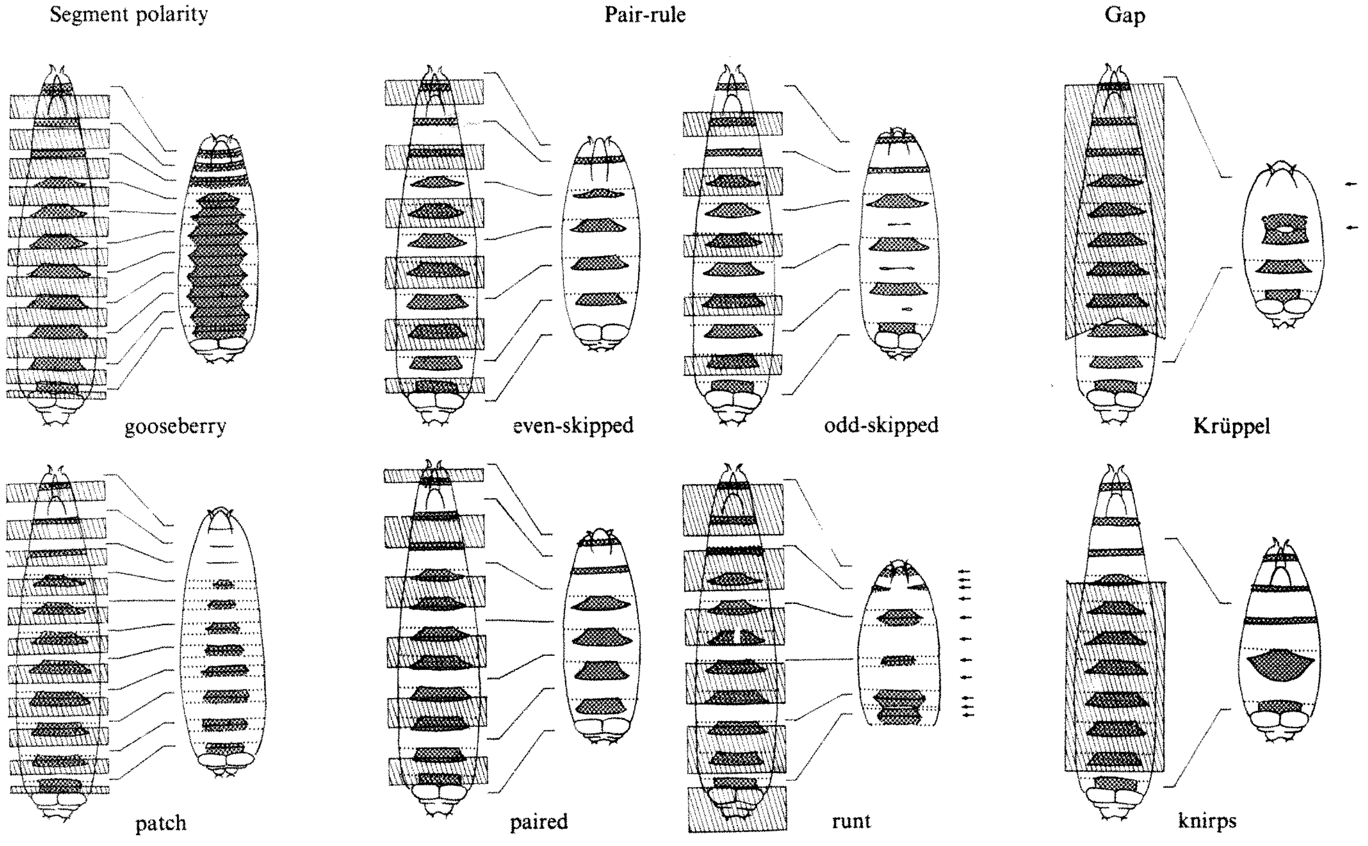

Fig. 1 Semi-schematic drawings indicating the regions deleted from the normal pattern in mutant larvae. Dotted regions indicate denticle bands, dotted lines the segmental boundaries. The regions missing in mutant larvae are indicated by the hatched bars. The transverse lines connect corresponding regions in mutant and normal larvae. Planes of polarity reversal in *runt* and *Krüppel* are indicated by the arrows. The two segment polarity loci *patch* and *gooseberry* are represented at the left. For indication of the polarity of the patterns, see Fig. 3. The patterns of *fused* and *ci*^{D} (not shown) look similar to the *gooseberry* pattern, whereas in *hedgehog* and *wingless* the deleted regions are somewhat larger, cutting into the denticle bands at either side. Four pair-rule mutants are shown in the centre. The interpretation of their phenotypes is based on the study of weak as well as strong alleles, combinations with *Ubx* (see text) and, in the case of *runt*, on gynandromorphs (unpublished). They probably represent the extreme mutant condition at the respective loci. The phenotypes of all known *barrel* and *engrailed* alleles (not shown) are somewhat variable and further studies are needed to deduce the typical phenotype. At the right, the two gap loci *Krüppel* and *knirps* are shown. Both patterns represent the amorphic phenotype as observed in embryos homozygous for deficiencies of the respective loci. The only known *hunchback* allele (not shown) deletes the meso- and metathorax.

COLLEGE Upper Circular Rd CALCUTTA

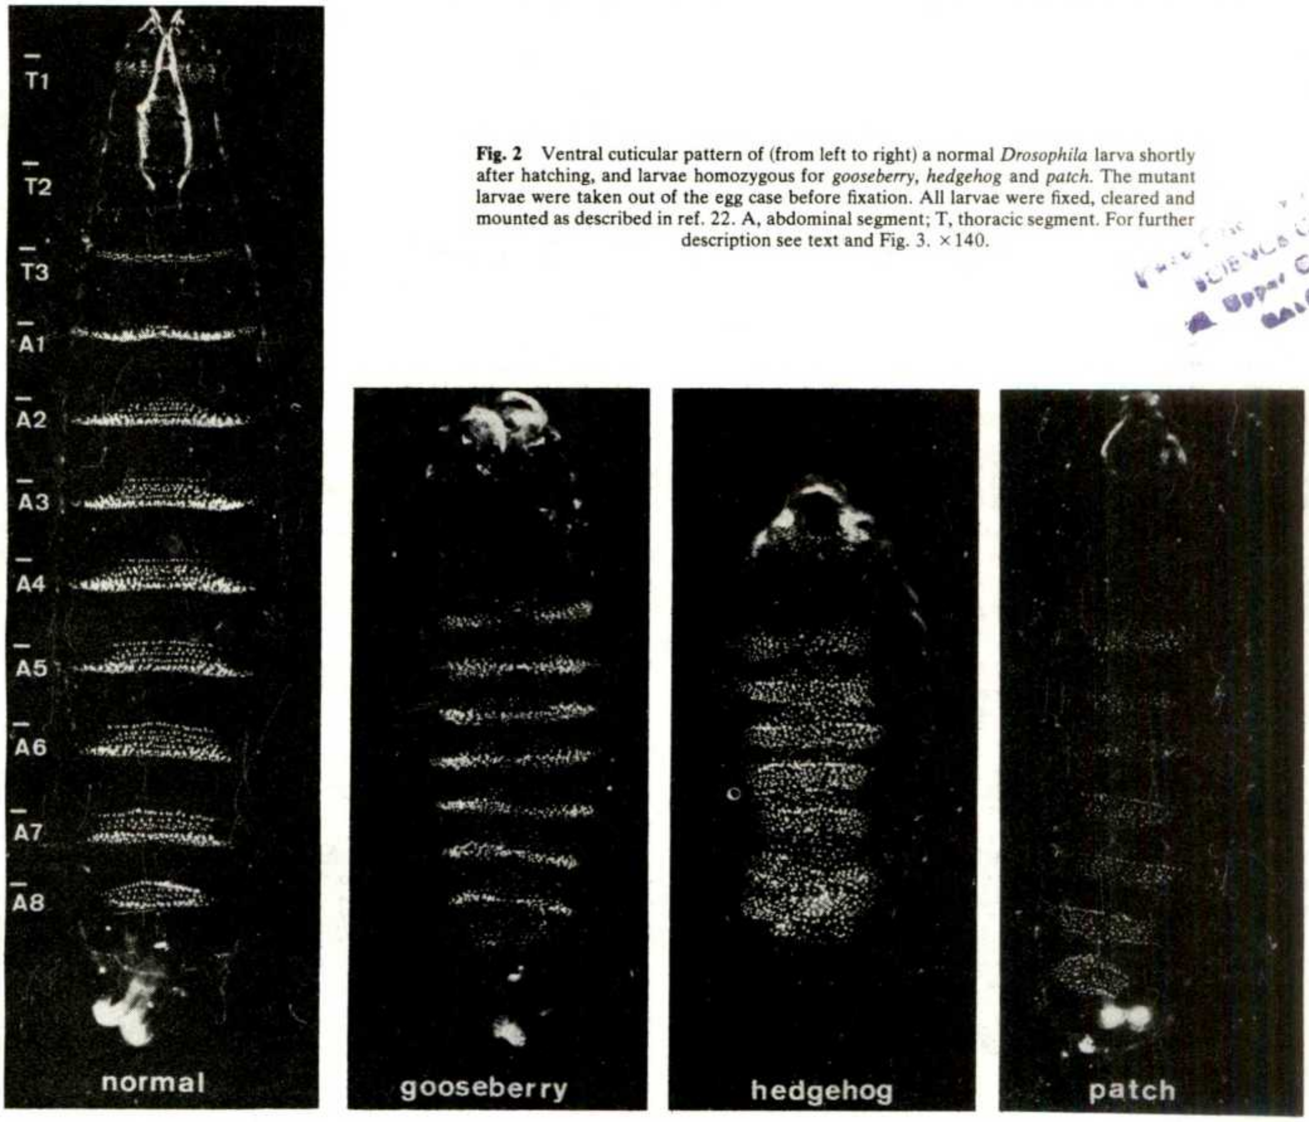

Fig. 2 Ventral cuticular pattern of (from left to right) a normal *Drosophila* larva shortly after hatching, and larvae homozygous for *gooseberry*, *hedgehog* and *patch*. The mutant larvae were taken out of the egg case before fixation. All larvae were fixed, cleared and mounted as described in ref. 22. A, abdominal segment; T, thoracic segment. For further description see text and Fig. 3. ×140.

essentially from the deletion of the naked posterior part of the odd-numbered and the anterior denticle bands of the even-numbered segments (Figs 1, 4). The double segments thus formed are composites of anterior mesothorax- and posterior metathorax, anterior first abdominal and posterior second abdominal segment, etc. The identification of the regions present or deleted in mutant larvae is based on the phenotypes produced by alleles with lower expressivity. In such embryos the deletions are in general smaller and variable in size. In a 'leaky' allele of *even-skipped*, the denticle bands of the even-numbered segments are frequently incomplete, whereas in *paired*^{2} (*prd*^{2}) the pattern deletions often involve only part of the naked cuticle of the odd-numbered segments, leading to a pairwise fusion of denticle bands (Fig. 4).

Further support for the composite nature of the segments in *prd* larvae was obtained in combinations with *Ultrabithorax* (*Ubx*), a homeotic mutation which when homozygous causes the transformation of the first abdominal segment into mesothorax[5]. In such *prd*; *Ubx* larvae, only the *denticle band* of the first double segment in the abdomen is transformed. The posterior margin of this band and the naked cuticle which follows remain abdominal in character and lack, for example, the typical mesothoracic sense organs. The composite nature of the segments in *paired* shows that the establishment of segmental identity does not require the establishment of individual segments as such.

The segmentation pattern in *prd*; *Ubx* larvae is typical of that of *paired* alone and is not affected by the *Ubx* homeotic transformation. Similarly, in *prd*;*Polycomb* larvae the naked cuticle of alternating segments is deleted just as it is in *paired* alone, even though in *Polycomb* embryos all the thoracic and abdominal segments have an 8th abdominal character[5]. These combinations, and similar ones with *even-skipped*, indicate that the observed grouping of segments in pairs depends on the position of segments within the segmental array rather than the segmental identity. These combinations thus provide evidence that mutations such as *paired* and *even-skipped* affect different processes from those altered in homeotic mutants.

Other mutants in this class show different deletion patterns. The phenotype of *odd-skipped* is similar to that of *even-skipped*. However, in this case it is the odd-numbered denticle bands that are affected. In *odd-skipped*, the deleted region is smaller and is restricted to a more posterior part of the segment than in *even-skipped* (Figs 1, 4). *Barrel* has a phenotype similar to *paired* although the pattern is often less regular (Fig. 4). *Runt*, on the X chromosome, is the only pair-rule mutant showing mirror-image duplications. *Runt* embryos have half the normal number of denticle bands, each a mirror-image duplication of the anterior part of a normal band (similar to the duplications found in *patch*). The bands in *runt* embryos, as well as the region of naked cuticle separating them, are of unequal sizes (Figs 1, 4).

To the list of pair-rule loci we have added the *engrailed*[10] locus. Lethal *engrailed* alleles[11] lead to a substantial deletion of the posterior region of even-numbered segments. In addition, the anterior margin and adjacent cuticle of each segment are affected. Thus, the defect pattern in *engrailed* shows repeats which are spaced at both one- and two-segment intervals.

Each of the six different pair-rule loci affects a different region within a double segmental repeat. In no case does the margin of the deleted region coincide with a segment boundary. When the deleted region corresponds in size up to one entire segment (*paired*, *even-skipped*) it includes parts of two adjacent segments.

The phenotypes of the pair-rule mutants suggest that at some stage during normal development the embryo is organized in repeating units, the length of which corresponds to two segmental anlagen.

Gap mutants: one continuous stretch of segments deleted

One of the striking features of the mutations of the first two classes is that the alteration in the pattern is repeated at specific intervals along the antero-posterior axis of the embryo. No such repeated pattern is found in mutants of the third class and instead a single group of up to eight adjacent segments is deleted from the final pattern. Three loci have been identified which cause such gaps in the pattern (Table 1, Figs 1, 5). *Krüppel* (*Kr*) was originally described by Gloor[12]. Embryos homozygous for *Kr* lack thorax and anterior abdomen. The posterior-terminal region with the abdominal segments 8, 7 and 6 is normal, although probably somewhat enlarged. Anterior to the 6th abdominal segment is a plane of mirror–image symmetry followed by one further segment band with the character of a 6th segment oriented in reversed polarity. The exact position of the plane of symmetry varies and does not usually coincide with a segmental boundary. A large part of the *Krüppel* pattern is reminiscent of the pattern observed in embryos produced by the maternal-effect mutant *bicaudal*, although no maternal component is involved in the production of the *Krüppel* phenotype (in preparation).

Table 1 Loci affecting segmentation in *Drosophila*

Class	Locus	Map position*	No. of alleles†	Ref.

	knirps (*kni*)	3-47	5	This work
	hunchback (*hb*)	3-48	1	This work

* For the new loci (see last column) the map positions are based on recombination between the markers *S*, *Sp*, *Bl*, *cn*, *bw* for the second chromosome, and *ru*, *h*, *th*, *st*, *cu*, *sr*, e^S, *ca* for the third chromosome. For description of markers see ref. 20. The loci *runt*, *Krüppel* and *knirps* were further mapped using the breakpoints of deficiencies and duplications for the respective regions. All mutants were mapped by scoring the embryonic progeny of single recombinant males backcrossed to heterozygous females from the original mutant stocks.

† The numbers in parentheses refer to the alleles listed in Lindsley and Grell[20]. All other alleles, except the *runt* allele, three *Kr* alleles and one *knirps* allele, were isolated in a screen for embryonic lethal mutants on the second chromosome. 5,800 balanced stocks were established from individual males heterozygous for an ethyl methane sulphonate-treated *cn bw sp* chromosome using the DTS-procedure suggested by Wright[21]. 4,500 of the stocks had one or more new lethal mutations. Unhatched embryos from 2,600 putative embryonic lethal stocks were inspected for cuticular abnormalities[22]. Third chromosomal mutants discovered in the second chromosomal balanced lines were recovered after selection through individual females by balancing individual third chromosomes over TM3. Complementation tests were carried out between mutants with similar phenotypes whereby the occurrence of mutant embryos among the progeny of the crosses served as the criterion for allelism. Three new *Kr* alleles were isolated in a screen for lethals over the original *Kr* of Gloor[12], and one *knirps* allele of presumably spontaneous origin was discovered on a TM1 chromosome. The *runt* allele was isolated in a screen for X-linked lethals.

‡ *fused* is a male-rescuable maternal-effect locus[8]. Thus, the segment polarity reversal is observed in *fu*/*fu* embryos from *fu*/*fu* mothers. The progeny of *fu*/+ females show a normal embryonic pattern regardless of embryonic genotype.

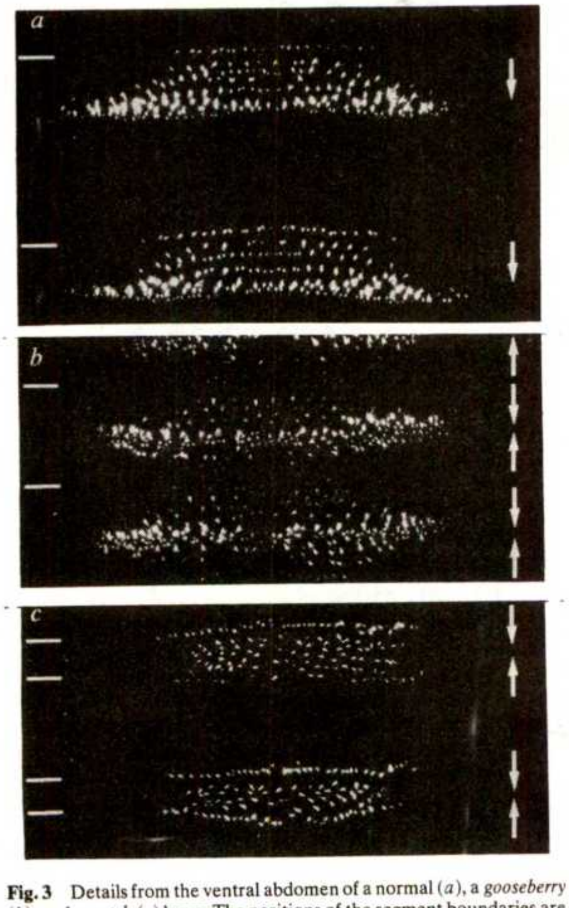

Fig. 3 Details from the ventral abdomen of a normal (*a*), a *gooseberry* (*b*), and a *patch* (*c*) larva. The positions of the segment boundaries are indicated at the left by the transverse lines. The arrows at the right indicate the polarity of the pattern as judged by the orientation of the denticles as well as the shape of the denticle bands.

In the other two loci of this class, the gap in the pattern occurs in specific morphologically defined subregions of the larval pattern, in the thorax and in the abdomen, respectively. In *hunchback*, the meso- and metathoracic segments are deleted. In embryos homozygous for *knirps*, only two rather than eight denticle bands are formed in the abdomen. The posterior-terminal region including the 8th abdominal segment seems normal whereas the anterior abdominal denticle band is considerably enlarged. The anterior margin of the denticle band is morphologically similar to the first abdominal segment but combinations with *Ubx* show that the band is a composite with more than one segmental identity.

All three loci are required for a normal segmental subdivision of one continuous body region. The lack of a repeated pattern of defects suggests that the loci are involved in processes in which position along the antero-posterior axis of the embryo is defined by unique values.

When are genes affecting segment number active?

The phenotypes described above are observed only in homozygous embryos, indicating that the loci identified by these mutations are active after fertilization and are crucial for the normal segmental organisation of the embryo. We have described the mutations in terms of their effect on the differentiated pattern. However, in many instances their effect can be observed much earlier in development. In normal embryos segmentation is first visible 1 h after the onset of gastrulation as a repeated pattern of

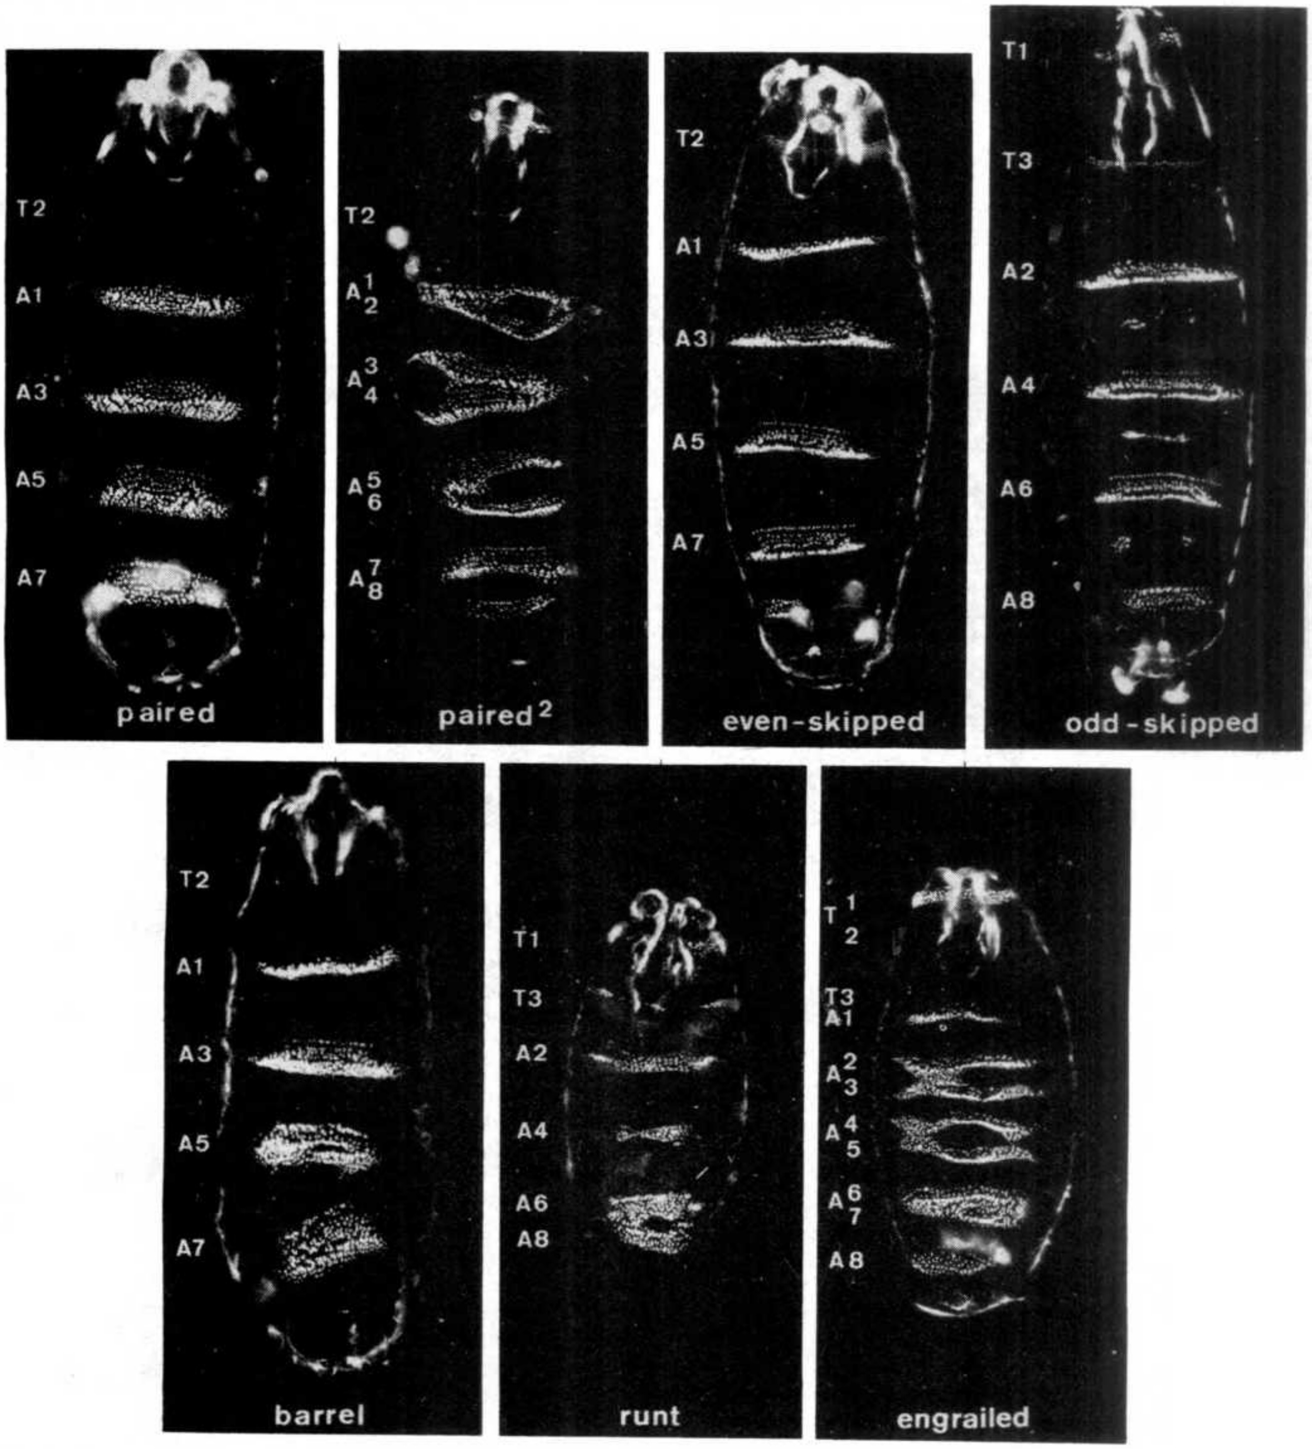

Fig. 4 Larvae homozygous for mutations at the six pair-rule loci. The segmental identity of the denticle bands is indicated at the left of each picture. A, abdominal band; T, thoracic band. For comparison with the normal pattern see Figs 1 and 2.

bulges in the ventral ectoderm (unpublished observations). In *paired* and *even-skipped* embryos the number of bulges is reduced and corresponds to the number of segments observed in the differentiated mutant embryos. *Krüppel*, *runt* and *knirps* embryos can be identified 15 min after the onset of gastrulation. All three mutations cause shorter germ bands, a phenomenon clearly related to the strong reduction in segment number observed in the differentiated larvae. Further evidence for an early activity at the *paired* locus was obtained using a temperature-sensitive allele. The extreme phenotype is only obtained when the embryo is kept at the restrictive temperature during the blastoderm stage. All these results indicate that the wild-type genes defined by the mutations are active before the end of gastrulation during normal development.

Discussion

Segmentation in *Drosophila* proceeds by the transition from a single field into a repeated pattern of homologous smaller subfields. Mutant alleles at the 15 loci we have described interfere with this process at various points. Although each locus has its own distinct phenotype, we were able to distribute the mutations in three classes. In one class only a single large subregion of the embryo is affected, whereas in mutants of the other two classes a reiteration of defects is produced with a

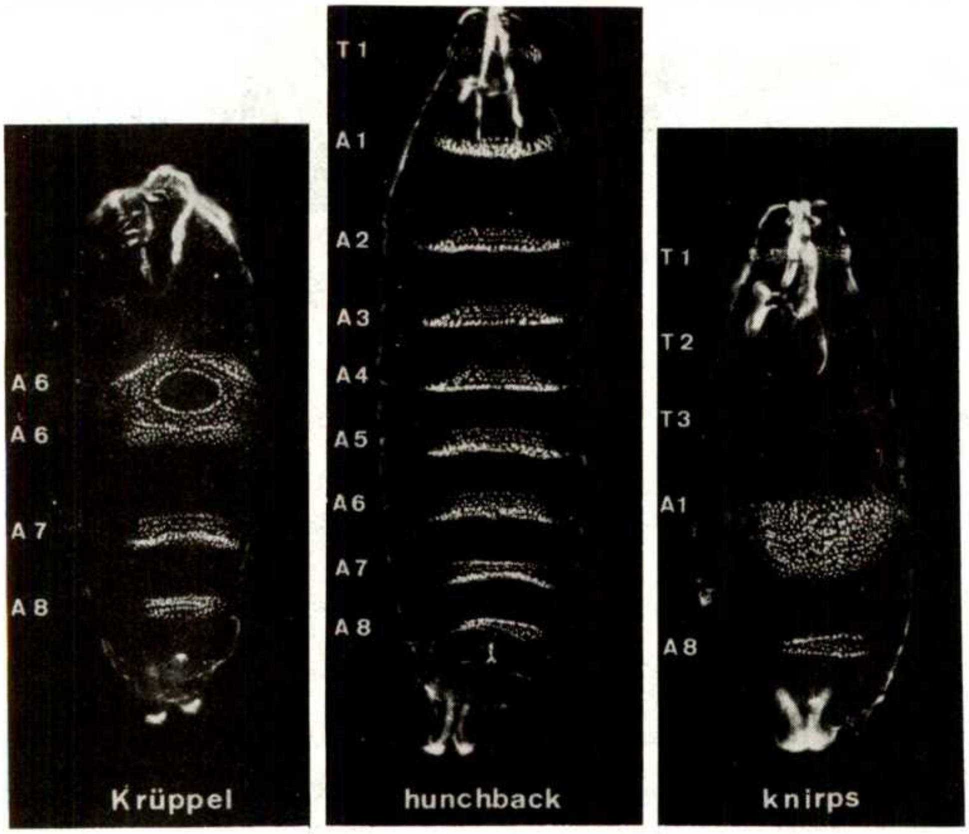

Fig. 5 Larvae homozygous for mutations at the three gap loci. A, abdominal segment; T, thoracic segment.

repeat length of one or two segments, respectively. This suggests that the process of segmentation involves three different units of spatial organization.

The organization of the egg is thought to be controlled by a monotonic gradient set up during oogenesis under the control of the maternal genome[3,4]. All the mutants we have described depend on the embryonic rather than the maternal genome. None of them alters the overall polarity of the embryo, the head always being at the anterior and the telson at the posterior end of the egg. The most dramatic alterations of the pattern are produced in the gap mutants and involve one large subregion of the egg. *Hunchback* and *knirps* affect the development of thorax and abdomen, respectively, and might be involved in the establishment of these large morphologically unique subregions of the embryo. The large mirror-image duplications found in the posterior pattern of *Krüppel* embryos are similar to those of *bicaudal*. The *bicaudal* phenotype has been interpreted as resulting from an instability in the maternal gradient[3,13], and thus *Krüppel* might be involved in the maintenance of elaboration of this gradient in the posterior egg region after fertilization.

The smallest repeat unit, the individual segment, is affected in mutants at the six segment-polarity loci. The pattern alteration consists of a mirror-image duplication of part of the normal pattern with the remainder deleted. In these mutants the deleted region corresponds in size to more than half a segment. Mutations causing smaller deletions in the segmental pattern do not lead to polarity reversals (unpublished observations). The mirror-image duplications produced by the pair-rule mutation *runt* are also associated with a deletion of more than half a repeat unit, that is, more than one segment. The tendency of partial fields containing less than half the positional values to duplicate is well described for imaginal disks in *Drosophila*[14], as well as for the larval epidermis in other insects[15,16]. On the other hand, the same types of pattern duplication are also produced in conditions which do not involve cell death and regeneration, but rather a reorganization of the positional information in the entire field[3,17]. More detailed studies of early development in mutant embryos may reveal which mechanism is responsible for the different mutant phenotypes.

Given the evidence for a homology between segments, the existence of a class of mutants affecting corresponding regions in each individual segment is perhaps not surprising. The discovery of a mutant class affecting corresponding regions in every other segment was not expected and suggests the existence at some time during development of homologous units with the size of two segmental anlagen. It is possible that the double segmental unit corresponds to transitory double segmental fields which are established early during embryogenesis and are later subdivided into individual segments. At the blastoderm stage the epidermal primordium giving rise to thorax and abdomen is only about 40 cells long[1]. An initial subdivision into double segments would avoid problems of accuracy encountered in a simultaneous establishment of segment boundaries every three to four cells. A stepwise establishment of segments implies that the borders defining double segments be made before the intervening ones. The mutant phenotypes do not definitely show which, if any, of the segment borders define a primary double segmental division in normal development. The mutant phenotypes which come closest to a pattern one would expect if the transition from the double segment to the individual segment stage were blocked are the patterns of *paired* and *even-skipped*. Both suggest the frame meso- and methathorax, 1st and 2nd, 3rd and 4th abdominal segment, etc.

It is also possible that the double segmental units are never defined by distinct borders in normal development. The existence of a double segmental homology unit may merely reflect a continuous property such as a wave with a double segmental period responsible for correct spacing of segmental boundaries (see, for example, refs 18, 19). We have not found any mutations showing a repeat unit larger than two segments. This may indicate that the subdivision of the blastoderm proceeds directly by the double segmental repeat with no larger intervening homology units. However, the failure to identify such larger units may reflect the incompleteness of our data.

Drosophila has been estimated to have about 5,000 genes and only a very small fraction of these when mutated result in a change of the segmental pattern of the larva. Some of the loci described here were known previously but only in the case of *Krüppel* has the embryonic lethal phenotype been recognized as affecting segmentation.[12] The majority of the mutants described here have been isolated in systematic searches for mutations affecting the segmentation pattern of the *Drosophila* larva. These experiments are still incomplete. Most of the alleles on the second chromosome were isolated in one experiment which yielded an average allele frequency of four or five alleles per locus (based on 42 embryonic lethal loci). From this yield and similar calculations for the third and first chromosomes, we estimate that we have identified almost all segmentation loci on the second chromosome and about 50% each of those on the third and first chromosome. Our sample of 15 loci should therefore represent the majority of the loci affecting segmentation in the *Drosophila* genome. Thus, in *Drosophila* it would seem feasible to identify all genetic components involved in the complex process of embryonic pattern formation.

We thank Hildegard Kluding for excellent technical assistance, Adelheid Schneider, Maria Weber and Gary Struhl for help during various parts of the mutant screens, Gerd Jürgens for stimulating discussion and our colleagues from the *Drosophila* laboratories in Cambridge, Freiburg, Heidelberg and Zürich for critical comments on the manuscript, and Claus Christensen for the photographic prints. Thomas Kornberg and Gary Struhl provided us with lethal alleles of *engrailed* and *wingless* respectively which facilitated the identification of our alleles. All mutants are available on request.

Note added in proof: All known *barrel* alleles fail to complement *hairy*[20], suggesting that the *barrel* mutations are alleles at the *hairy* locus.

Chemical synthesis of a polypeptide predicted from nucleotide sequence allows detection of a new retroviral gene product

J. G. Sutcliffe, T. M. Shinnick, N. Green, F.-T. Liu, H. L. Niman & R. A. Lerner

Department of Cellular and Developmental Immunology, Research Institute of Scripps Clinic, La Jolla, California 92037

We previously determined the nucleotide sequence of the 3′ end of Moloney leukaemia virus and discovered the potential coding region for an unknown protein, R. We now show that this region does encode a protein. A pentadecapeptide of R was chemically synthesized and antibodies raised against it. Antisera to the synthetic peptide recognize the R protein and the env *precursor polyprotein in infected cells. The strategy presented here should provide a general method for accessing proteins predicted by nucleotide sequences.*

THE accepted genetic structure of replication-competent murine leukaemia viruses, such as Moloney, Rauscher, Friend and AKV, includes three genes. These genes, *gag*, *pol* and *env*, are arranged, in respective order, along the single-stranded RNA genome. They are transcribed from the integrated double-stranded DNA provirus[1]. The protein products of these three genes are understood in considerable detail. The *gag* gene encodes a polyprotein of about 65 kilodaltons which is proteolytically processed to proteins, amino to carboxy terminal, of 15, 12, 30 and 10 kilodaltons, respectively[2]. These proteins are found in the core of the virion, and one, p30, has been associated with virus tropism[3]. The second gene, *pol*, is expressed as an apparent extension of the *gag* gene such that an approximately 180-kilodalton polyprotein containing both *gag* and *pol* components is observed. The polyprotein is processed to a 70-kilodalton protein which is the reverse transcriptase[4]. This enzyme is responsible for copying the single-stranded RNA genome of an infecting virus into the double-stranded DNA structure which can integrate into host DNA. The third gene, *env*, encodes a polyprotein which is glycosylated and processed into components gp70 and p15E (ref. 5). gp70 is the major envelope component and determines viral host range. It is sometimes found disulphide linked to p15E, a hydrophobic protein which may anchor gp70 to viral and cellular membranes[6]. Messenger RNA molecules have been described which can account for the expression of these three genes[7].

To understand fully the genetic structure of this class of viruses, we have been analysing their nucleotide sequences. We began our study at the 3′ end of Moloney murine leukaemia virus (Mo-MuLV) because of our particular interest in the *env* gene which was thought to be the most 3′-proximal gene. Surprisingly, we found an open reading frame which extended beyond the coding region for known viral products[8]. Even though we then had no evidence for a gene product, we provisionally named this the R-region because it is the coding region that is the furthest to the right in the genome. Here we report the detection of the R product. We chemically synthesized part of the R protein, raised antibodies to the synthetic peptide and detected immunologically cross-reactive material in infected cells.

The DNA sequence

For orientation purposes, several features of the previously reported[8] DNA sequence are presented here (Fig. 1). The DNA sequence was initially generated from an 1,108-base pair cDNA clone obtained by cloning the product of reverse transcription of purified detergent-disrupted Mo-MuLV. We have also sequenced most of this region of a full-length virus clone that can be demonstrated by transfection studies to carry all biologically active Mo-MuLV coding sequences. This new DNA sequence agrees with the original except for the differences described in Fig. 1 legend. We consider these differences to represent either variability in the population of biologically active genomes or artefacts due to the slight 'unfaithfulness' of the reverse transcriptase reaction (unpublished observations) which generated the clone we initially examined.

Proceeding from 5′ to 3′ along the DNA strand corresponding to genomic RNA, we see: the coding region for most of p15E (the carboxy-terminal *env* coding region); the origin of second-(positive) strand DNA replication; the inverted repeats, IR_L and IR_R, which flank the portion of viral sequences that are duplicated at the 5′ and 3′ ends of the integrated provirus (the so-called long terminal repeats, LTRs) and are responsible for the structure of the DNA of the virus resembling bacterial transposons[8,9]; and the poly(A) addition signal and presumptive 3′ ultimate nucleotides preceding the poly(A) tail[8]. Also indicated are features which are active at the 5′ copy of the LTR—the putative promoter for genomic expression and the first transcribed base[8].

A new protein predicted by DNA sequence

The new genetic region that we found can best be understood by considering what was previously thought to be the right-most coding region of the provirus—that for the viral protein p15E. The amino terminus of p15E can be positioned precisely by overlap between the protein sequence predicted by our DNA sequence and the protein sequence obtained by Copeland and Oroszlan (personal communication) (Fig. 1). The carboxyl terminus of p15E is not yet precisely defined. The apparent molecular size of p15E as determined on SDS gels is about 15 kilodaltons, a size estimate compatible with the mobility of a hydrophobic protein of about 100 residues. Surprisingly, we do not find a translational termination codon in this region. Instead, the open translational reading frame extends for a total of 196 triplets before encountering a stop. Thus we suspected that the primary *env* gene protein product in fact contained three peptides—gp70, p15E and the newly identified protein, R (positions ~100–196 in Fig. 1). Therefore, we looked for the R protein.

Chemical synthesis and detection of the R protein in infected cells

To detect and determine the cellular location of the R product, several peptides of the predicted Mo-MuLV R protein were synthesized by solid-state methods[10] and antibodies raised to these synthetic peptides. The predicted C-terminal peptides were synthesized because the N-terminus is not precisely known. Specifically, the C-terminal 15 residues (Leu-Thr-Gln-Gln-Phe-His-Gln-Leu-Lys-Pro-Ile-Glu-Cys-Glu-Pro) were attached to the carrier molecule keyhole limpet haemocyanin (KLH) and injected into six rabbits and four mice. We assayed the sera for the ability to precipitate immunologically a 36-residue synthetic substrate containing the 35 C-terminal residues of the R protein preceded by ^{125}I-tyrosine (^{125}I-Tyr-Ile-Leu-Asn-Arg-Leu-Val-Gln-Phe-Val-Lys-Asp-Arg-Ile-Ser-Val-Val-Gln-Ala-Leu-Val-Leu-Thr-Gln-Gln-Phe-His-Gln-Leu-Lys-Pro-Ile-Glu-Cys-Glu-Pro). Sera from all the immunized animals showed a positive response of 10–70-fold over normal serum (Table 1). We then looked for the R protein in lysates of MuLV-producing SCRF 60A cells that had been labelled by a 2-h ^{35}S-methionine pulse (the R protein contains no tyrosine and so was not expected to label with iodine). As can be seen in Fig. 2, an anti-R serum detects a protein with an apparent molecular size of approximately 80 kilodaltons in infected cells. All the individual immune rabbit and mouse sera detected proteins with the same molecular size. Additionally, no target molecules were observed in uninfected mouse lymphocytes, but the same band was seen after infection with Mo-MuLV (not shown). Because the nucleotide sequences showed that p15E and R were in the same reading frame, we expected that this molecule was, in fact, the *env* precursor. Antibodies to gp70, including an anti-gp70 hybridoma, detect a molecule with the same apparent molecular size as that precipitated by anti-R,

Fig. 1 Nucleotide sequence of the 3′ end of the Mo-MuLV provirus. The sequence of the 1,123-nucleotide plus-strand from the 3′ LTR and carboxy-terminal virus coding region was determined from an 1,108-base pair long cDNA clone[8] and extended slightly by sequence from an infectious clone. The four differences in the infectious clone are indicated below the running sequence. The protein sequence translated from the DNA appears above the nucleotide sequence. The first 34 amino-terminal residues were determined by Copeland and Oroszlan and positions 10–34 match our sequence. The arrow at the end of the third line indicates the region of the carboxy terminus of p15E. The rest of the amino acid sequence is that of the R protein. The numbered oligonucleotides (25, 42, 57 and 98B) represent those corresponding to AKV virus and are shown in detail in Fig. 6. The underlined region downstream from the R coding region is the origin of plus-strand DNA synthesis. The regions marked IR_L and IR_R are the inverted terminal repeats which flank the LTRs. Within the LTR we recognize a 17-base long palindrome (underlined) and three direct repeats (DR 1, 2 and 3) which lie just upstream from the promotor Hogness box (p) for the 5′ end of the viral transcript(*). Further down the molecule is the poly(A) addition signal for the 3′ end of the transcript.

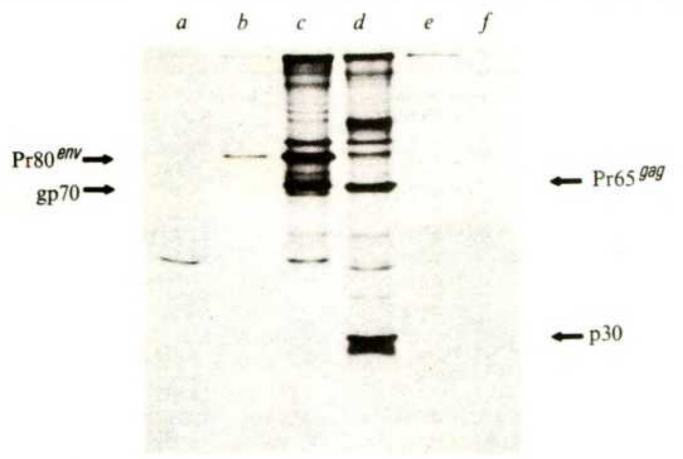

Fig. 2 Antibody to synthetic R peptide precipitates Pr80^{env}. Log-phase SCRF 60A cells, which produce a virus indistinguishable from Mo-MuLV[18], were grown in Eagle's minimal essential medium (MEM) with 10% fetal calf serum. The cells were labelled at 37 °C at 2×10^6 cells ml^{-1} for 2 h with ^{35}S-methionine (940 Ci mmol^{-1}, 100 μCi ml^{-1}) in Hank's balanced salts with 10% Eagle's MEM. Cells were chilled, washed with 0.15 M NaCl, 10 mM sodium phosphate *p*H 7.5, extracted with 0.15 M NaCl, 10 mM sodium phosphate *p*H 7.5, 1% NP40, 0.5% sodium deoxycholate, 0.1% SDS, 2% Trasylol for 20 min at 0 °C, then sonicated and spun at 12,000*g* for 5 min. The lysate was pre-cleared by reacting with 20 μl of normal rabbit serum and 20 μl of normal goat serum for 30 min at 0 °C, followed by the addition of formalin-fixed *Staphylococcus aureus* for 30 min and centrifugation for 15 min at 12,000*g*. Portions of the lysate were reacted with 5 μl of normal rabbit (*a*), rabbit anti-synthetic R pentadecapeptide (*b*), goat anti-gp70 (*c*), goat anti-p30 (*d*), normal goat sera (*e*), or anti-gp70 hybridoma (no. R1-16G07, ref. 19) (*f*) culture media for 1 h at 0 °C. Complexes were collected with *S. aureus* and after two washes with 500 mM LiCl, 100 mM Tris, *p*H 8.5, dissolved in loading buffer cleared of *S. aureus*, and loaded on an 11% SDS-polyacrylamide gel. The gel was soaked in Enhance (NEN) for 90 min, H$_2$O for 60 min, dried and exposed to film. The bands indicated have been identified previously in this laboratory and by others[20].

confirming that we are observing the *env* precursor. To rule out the possibility that these were two distinct molecules with a fortuitous correspondence in molecular size, we did two experiments. First, when the lysates are pre-cleared with anti-R sera, the 80-kilodalton radioactive target for anti-gp70 sera is removed. Conversely, clearing the lysate with anti-gp70 sera removes the R determinants. Second, proteolytic peptide fingerprinting of the two 80-kilodalton molecules precipitated by anti-R and anti-gp70 shows them to be identical (Fig. 3). Thus, we have identified the 80-kilodalton band as the complete *env* gene polyprotein product containing gp70, p15E (as shown by others) and R determinants.

Using different gel electrophoresis conditions, we were able to detect a protein of estimated molecular size 12 kilodaltons specifically precipitated by anti-R serum (Fig. 4). We tentatively identify this small protein as R although positive identification awaits N-terminal amino acid analysis. Also, we have observed, by indirect immunofluorescence, R protein determinants on the plasma membrane of SCRF 60A cells (to be published elsewhere), a result made more significant by the fact that the anti-R serum does not precipitate gp70 or p15E. Our experiments do not indicate at what time the p15E-R cleavage occurs and it is possible that the true gp70 membrane anchor is the 22-kilodalton protein containing p15E and R peptides. In that case, the proteolytic cleavage which generates p15E and R occurs during their isolation. We have not observed a 22-kilodalton protein with R determinants.

The R gene is present in another virus

Pederson and Haseltine[11] determined the nucleotide sequences of the large ribonuclease T$_1$ fragments of AKV virus, an endogenous leukaemia virus of AKR mice. By computer search we identified several of these fragments as having partial homologies to skeins of our Mo-MuLV sequence. Our defined order makes a reasonable match with the order obtained experimentally by Pederson, Crowther and Haseltine (personal communication). The matches within the R-region are indicated in Fig. 1 and detailed in Fig. 5. From these alignments we note first the matched fragments are not wholly conserved, which perhaps warns us as to what to expect from future comparisons of sequences of related viruses, and second, that matches within the R-region indicate that AKV probably encodes an R protein much like that of Mo-MuLV. Specifically, (1) none of the AKV differences introduces nucleotides which indicate a premature translational stop, (2) several (9) AKV/Mo-MuLV nucleotide differences are in third positions in triplets and do not alter the coded protein sequence, (3) some nucleotide differences do change R-protein amino acids, but the replacements tend to be conservative or synonymous (as indicated in Fig. 5), such as phenylalanine to tyrosine in spot 98B, Asn-Gln-Arg to Lys-Gln-Gln in spot 25, or Met to Leu in spot 57. All these substitutions are rated as positive correlations by the Dayhoff mutation matrix[13]. Additionally, a preliminary sequence obtained by Herr (personal communication) through 211 nucleotides of the R-region of AKV shows an open reading frame containing 51 nucleotide differences with our Mo-MuLV sequence. These 51 differences make only six amino acid alterations, all of which are synonymous. These observations indicate that the R-protein sequence is highly conserved in the two viruses.

Comments about the R protein

The entire amino acid sequence of the R protein does not correspond closely to any protein sequence in ref. 12. Some subregions of R, however, are reminiscent of subregions of known proteins such as dehydrogenases and proteases, perhaps

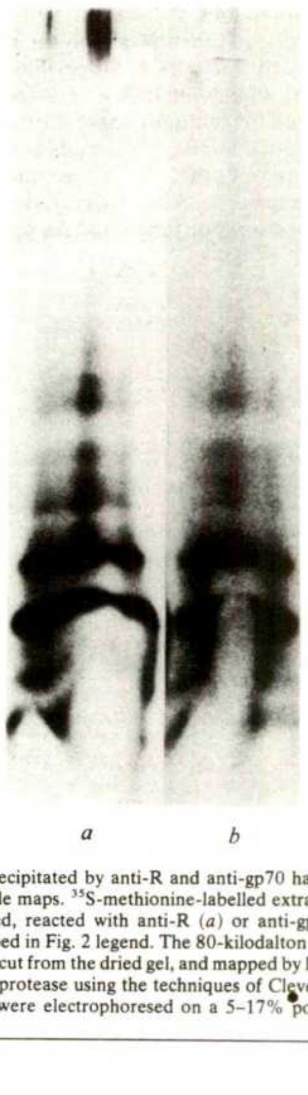

Fig. 3 Pr80^{env} precipitated by anti-R and anti-gp70 have the same one-dimensional peptide maps. ^{35}S-methionine-labelled extracts of SCRF 60A cells were prepared, reacted with anti-R (*a*) or anti-gp70 (*b*) sera, and analysed as described in Fig. 2 legend. The 80-kilodalton band precipitated by each serum was cut from the dried gel, and mapped by limited proteolysis with *S. aureus* V8 protease using the techniques of Cleveland *et al.*[21]. The reaction products were electrophoresed on a 5–17% polyacrylamide gel.

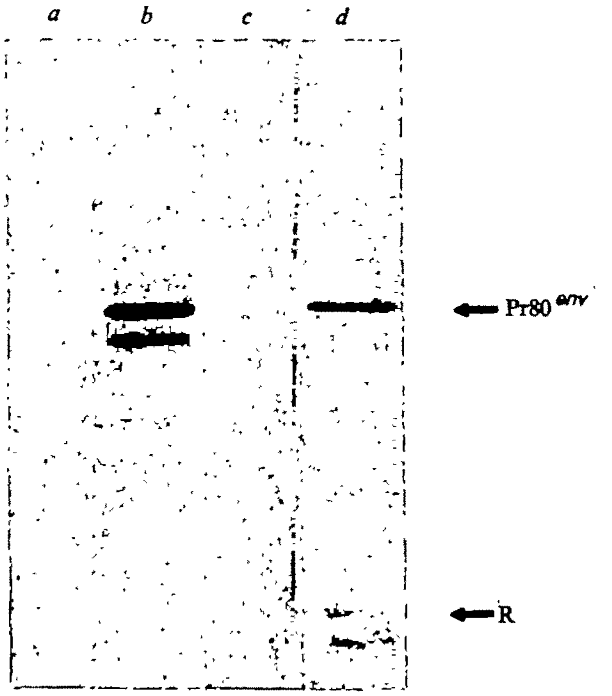

Fig. 4 Detection of the R protein. A ^{35}S-methionine-labelled lysate of SCRF 60A cells (as described in Fig. 2 legend) was divided into four equal portions and immunologically precipitated with normal goat (*a*), goat anti-gp70 (*b*), normal rabbit (*c*) or rabbit anti-R (*d*) serum, collected with *S. aureus* and electrophoresed on a 5–17.5% SDS–polyacrylamide gradient gel. The lower band in lanes *c* and *d* is usually seen with any normal rabbit serum and is thus not considered specific.

implicating domains of the R protein in nucleotide binding or protein–protein interactions.

The R protein might function simply as a structural viral protein. In this regard, the very hydrophobic domain between positions 32 and 61 suggest that R is inserted into cellular or viral membranes where it might serve to anchor other viral proteins. As mentioned above, we already have evidence from fluorescence microscopy that R is present in the plasma membranes of infected cells. Alternatively, the R protein might be involved in other sorts of functions. As originally noted by Fisher[14], genes and their regions of action seem to cluster. The R-region lies between the p15E coding region and the origin of positive-strand replication and LTR. It is, therefore, possible that R functions in replication or transposition (integration).

Fig. 5 Comparison of the R gene in two viruses. The oligonucleotide sequences determined by Pederson and Haseltine[11] for AKV were matched by computer to our Mo-MuLV sequence. Those matches within the R-region are shown, Mo-MuLV above AKV, with the corresponding translated amino acids. The numbers in the margin are those used by Pederson and Haseltine. Differences between the nucleotides are underlined. In fragment 98B, the phenylalanine codon in our cDNA sequence was a tyrosine codon in the infectious clone and is a tyrosine in AKV. The X in fragment 98B is an unsolved position for AKV[11].

The carboxy-terminal R pentadecapeptide (LTQQFHQLKPIECEP) was prepared and its acid hydrolysate was shown to be of correct composition. It was shown to be pure by TLC on both silica and cellulose in nBuOH/EtOAc/HOAc/H_2O (1:1:1:1) and electrophoresis in pyridine acetate, *p*H 5.6, on Whatman 3MM. The sample was visualized by reaction with ninhydrin reagent. It was conjugated to KLH through the cysteine sulphydryl. 63 μl of 15 mg ml^{-1} *m*-maleimidobenzoyl-*N*-hydroxysuccinimide ester[14–17] in *N,N'*-dimethylformamide was added dropwise with stirring to KLH (10 mg ml^{-1}) in 10 mM potassium phosphate, *p*H 7.0. After stirring for 30 min, the mixture was filtered and applied to a Sephadex G-25 column (0.1 M phosphate, *p*H 6.0). The activated protein (2.3 ml) was mixed with 0.1 ml of the R pentadecapeptide (10 mg ml^{-1} in 0.1 M potassium phosphate, *p*H 7.3, 5 mM EDTA) and the solution adjusted to *p*H 6.5, stirred for 4 h at room temperature and chromatographed on Sephadex G-100 (0.1 M ammonium bicarbonate, *p*H 9.5). The conjugated protein was collected and used directly for immunization of female New Zealand White rabbits (1.5–2.5 kg) or adult female G_{IX}^- mice (except mouse 1, which was BALB/c) as follows: Rabbits: 1 ml to hind footpads and subcutaneously at multiple sites along the back. Schedule *a*: 1 mg per kg in complete Freunds's adjuvant (CFA, 1:1), days 0, 7 and 14; blood days 21 and 28. Schedule *b*: 200 μg per rabbit in CFA on day 0; 50 μg per rabbit in incomplete Freund's adjuvant (ICF, 1:1) on day 7; 50 μg per rabbit in alum (4 mg per rabbit) intraperitoneally on day 14; bleed days 21 and 28. Schedule *c*: as schedule *b* except initial injection was 50 μg per rabbit. Mice were immunized intraperitoneally (schedule *d*) with 35 μg in CFA (1:1) on day 0, 35 μg with 500 μg alum intraperitoneally, day 14; bled day 21. ^{125}I-36-mer (5×10^6 c.p.m.) in immune precipitation buffer (0.15 M NaCl, 10 mM sodium phosphate *p*H 7.5, 1% NP40, 0.5% sodium deoxycholate, 0.1% SDS, 2% Trasylol) was incubated with 5 μl serum for 1 h at 0 °C, with formalin-fixed *S. aureus* for 30 min, then centrifuged for 15 min at 12,000*g*. Pellets were washed once in buffer, twice in 500 mM LiCl/100 mM Tris *p*H 8.5, then counted. *S. aureus* in the absence of serum bound, 528 c.p.m.

On the other hand, the R protein could have a role in viral transformation. A problem of the leukaemia viruses has been that, although they transform lymphoid tissues, they carry no apparent transforming genes. As a transforming protein, R could act directly or could interact with another protein. In either case, two important points must be explained: First, although they replicate in virtually all cell types of the mouse, these viruses only transform specific cells. Second, changes in the gp70 protein, which is encoded upstream from the R protein, are highly correlated with leukaemogenicity of various viruses, notably those called MCF (ref. 15). Therefore, we imagine either that gp70 and R interact directly (perhaps through disulphide linkage) and have, in the Moloney case, a T-cell-specific action or that gp70 triggers some cell-type-specific event which renders the T cell sensitive to the leukaemogenic effect of the R protein. What would cause the virus to maintain this gene is unknown.

The finding that Moloney and AKV, two viruses which cause T-cell lymphomas, have closely related R proteins, does not clarify the problem of specificity. We are now studying the R-region of other viruses such as Friend erythroleukaemia virus, which causes a disease of a different cell type, and a non-pathogenic xenotropic virus to determine whether the R protein is related to the pathogenicity and/or target tissues of the viruses.

We thank David Katz, Russell Doolittle and John Elder for helpful discussions, and Winship Herr, Stephen Oroszlan and William Haseltine and their collaborators for providing results before publication. This research was supported by a grant from the Pitman-Moore Company, Washington Crossing, New Jersey.

An extraordinary new celestial X-ray source

P. C. Gregory* & G. G. Fahlman†

* Physics Department
† Department of Geophysics and Astronomy, University of British Columbia, Vancouver, British Columbia, Canada V6T 1W5

The discovery of an extraordinary new X-ray source detected during a guest observer programme carried out with the Einstein X-ray Observatory is reported here. The object, designated G109.1 − 1.0, was found using the imaging proportional counter detector (IPC) on 17 December 1979. The IPC is sensitive to X-ray photons with energies between 0.1 and 4.5 keV. A longer exposure (3.6×10^3 s) IPC picture of a 1° field of view centred on the SNR was obtained on 8 July 1980 and is shown in Fig. 1. The picture shows a clear semicircular arc with an angular diameter of 36 arc min which appears to be the outer shell of the SNR. The resolution of the picture is 1 arc min. At the exact centre of the curvature of the shell is a strong compact source which we designate GF2259 + 586. The X-ray coordinates of GF2259 + 586 are RA = 22 h 59 min 02.5 s and dec = 58° 36′ 38″. The 1 arc min accuracy of the coordinates is limited by systematic calibration errors in the IPC detector. Emerging from the east side of the central source is a jet-like structure which curves northwards in another continuous arc smoothly joining the outer shell. On closer inspection, the jet appears to bifurcate with a second component continuing radially outwards from the central compact source. This very unusual structure has parallels with the W50 SNR with its central X-ray source SS433 and jet (F. D. Seward, personal communication).

The western half of the circular shell appears to be completely absent with the exception of a weak X-ray source located at 19 arc min from the central source and coincident in position with the bright Sharpless H II region[1] S152, which has an angular diameter of 2 arc min. The S152 X-ray source does not show up in Fig. 1 because of shadowing by a detector support rib, but does appear in the earlier exposure of 12 December. We note that S152 and GF2259 + 586 are accurately aligned along the axis of the X-ray jet. The Palomar red and blue prints fail to show any nebulosity associated with the X-ray shell. There are, however, two very faint filaments each ~2 arc min long located well inside the southern part of the shell at a distance of 12–13 arc min from the central source. Within the 1 arc min (radius) X-ray error circle of GF2259 + 586 there are about 50 possible optical counterparts to the limit of the Palomar red print, the brightest of which has a V magnitude of ~15. Also on the western side, adjacent to S152, is a second Sharpless H II region S153, which has an angular diameter of 5 arc min and is 17 arc min from the central X-ray source.

Radio emission was first detected[2] from this region (CTB 109)[2] in 1960 at 960 MHz. Their measured flux density of 75 Jy combined with a later integrated flux density measurement of 40 Jy at 3,200 MHz by RaghavaRoa *et al.*[3] indicate a nonthermal spectrum. The value of the spectral index $\alpha = -0.52$ (S proportional to ν^{α}) is typical of a SNR. One of us (P.C.G.) has obtained a differential radio map of this region at 6 cm with the NRAO 91-m telescope as part of a survey for variable sources in the galactic plane. The 6-cm map corresponds fairly closely with the X-ray emission including the jet-like feature but unfortunately there is a gap in the observations at the location of the central X-ray source. A scan through this location at 2.8 cm in June 1980, with the Algonquin Radio Observatory 46-m telescope, failed to detect a discrete radio source to a limit of 100 mJy. The 6-cm radio data indicate that the jet-like feature continues for a short distance west of the central source. There also seems to be emission extending to the north-west and there is strong radio emission from S152 and weaker emission from S153. On the western side there is no clear radio evidence for the continuation of the circular shell. The source has also been mapped at Westerbork at 50 cm. (V. A. Hughes, personal communication).

Although the true nature of the source is not entirely clear, certain aspects of the morphology suggest we may be dealing with a SNR. If so, a distance may be obtained by using the relationship of Clark and Caswell[4] between radio surface brightness and distance. The derived 408-MHz surface brightness (Σ) of 1.4×10^{-20} W m^{-2} Hz^{-1} s^{-1} using an angular diameter of 36 arc min falls close to a change in the slope of the Σ-D relationship. From their equations we arrive at a distance of 3.6 ± 0.4 kpc. Note that Crampton *et al.*[5] obtained a distance of 3.6 kpc for S152 and a distance of 4 kpc for S153. On the Palomar blue print S152 exhibits a curved tail which extends back towards GF2259 + 586. This and the alignment mentioned above suggest a possible relationship between the two objects. Hence the distance estimate is not dependent entirely on the SNR assumption.

At a distance of 3.6 kpc, the linear diameter of the shell is 38 pc, comparable to the Cygnus Loop and the Vela SNR[6].

A low energy cutoff is observed in the X-ray spectrum obtained from the IPC pulse height analyser (PHA) as expected for a ~3.6-kpc distance. However, actual spectral fits must await further IPC calibration analysis. One estimate of the X-ray absorption can be obtained from the reddening of the central stars of S152 and S153 which have $E(B - V) = 1.25$ and 0.75

0028-0836/80/440805—02$01.00

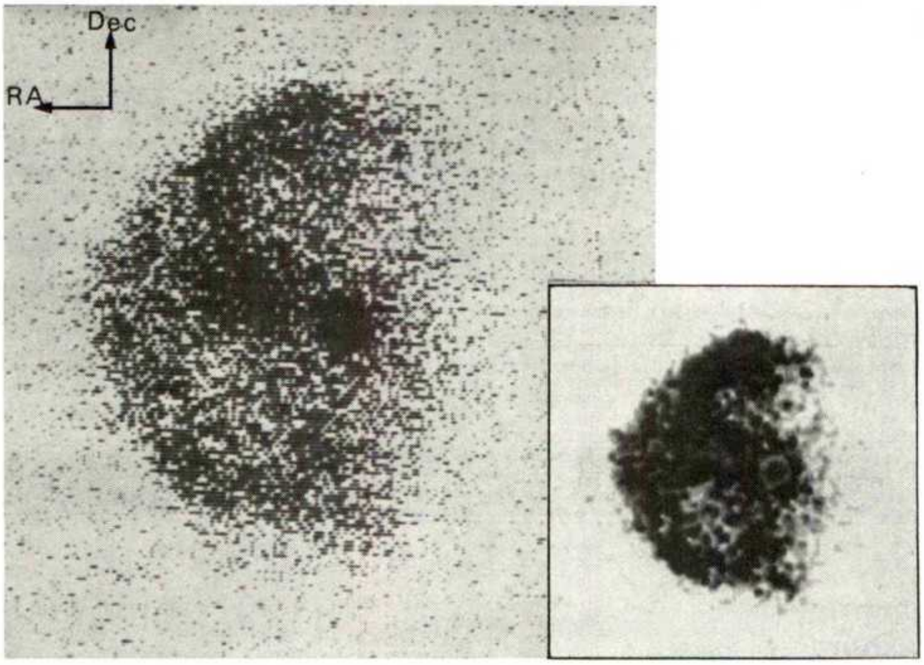

Fig. 1 IPC picture of a 1° field of view centred on G109.1–1.0. The inset shows the central core of the same object with better definition.

respectively[5]. These values can be converted to column densities of 0.85 and 0.51×10^{22} cm^{-2}, respectively, using the relationship of Ryter *et al.*[7]. We regard these as upper limits because of the possibility of dust in the H II regions themselves. Adopting a value of $N_H = 0.3\times10^{22}$ cm^{-2}, we estimate that the luminosity of the SNR, excluding the central source, is 2.7×10^{35} erg s^{-1}. If N_H is as high as 0.5×10^{22} cm^{-2} the corresponding luminosity is 4.9×10^{35} erg s^{-1}. Applying the theory of adiabatic blast waves as described in ref. 6, we find that the age of SNR is ~12,000 yr. The ambient interstellar density is ~0.1 cm^{-3} and the energy released in the supernova explosion is 3.8×10^{50} erg. The current shockwave velocity is predicted to be 600 km s^{-1}. The derived parameters are very similar to the Cygnus Loop and Vela SNR. By analogy with the Cygnus Loop we expect that the optical filaments noted earlier will have a much lower velocity than the predicted shock velocity.

If indeed this is a SNR, it is unusual because of its strong compact central source and jet-like feature which emerges on the eastern side of the central source. The PHA spectrum of the central source appears harder than the spectrum of the shell. Assuming thermal emission with $kT = 4$ keV, the corresponding luminosity of the central source is 3×10^{34} erg s^{-1}. The luminosity is uncertain by a factor of two but is of the same order as the X-ray emission from SS433. The most striking characteristics of this source are: (1) the semicircular shell which suggests a SNR; (2) a compact central X-ray source; and (3) a large-scale jet. These are also conspicuous features of the unusual object SS433 and its associated SNR, W50. Consequently, these two objects may be members of a new class of SNR. On the other hand, there are obvious differences in the morphology of the two objects. The spiral-like structure of the conspicuous X-ray jet and the hint of a similar feature to the south suggest that we may not be observing a SNR shell at all. The appearance may be the result of two jets which are being ejected from the central source and wound by rotation to give a shell-like structure. Alternatively, large-scale magnetic fields may be responsible for the observed geometry.

We thank Fred Seward of the Smithsonian Astrophysical Observatory for assistance. This research was supported by grants from the Canadian National Science and Engineering Research Council.

Note added in Proof: One of us (P.C.G.) recently obtained VLA observations of the source at 20 cm and 6 cm. A weak compact radio source was found 2 arc min from GF2259+586 but there is no optical counterpart to the limit of the Palomar Sky Survey.

Diffuse X-ray emission from the jets of SS433

F. Seward*, J. Grindlay*, E. Seaquist† & W. Gilmore†

* Harvard-Smithsonian Center for Astrophysics, Cambridge, Massachusetts 02138
† Department of Astronomy, University of Toronto, Toronto, Ontario, Canada M5S 1A1

The discovery of strong, variable emission lines[1], which are Doppler-shifted[2] from SS433, led to the development of a kinematic beam model[3-5] which explains the principal features of the time varying optical spectrum. In this model two opposed jets of material moving outwards from the central star at 0.258*c* precess with a period of 164 days, about an axis inclined 80° (or 20°) to the line of sight of the observer. The locus of the two beams forms a cone with an opening half angle of 20° (or 80°) (in the model an ambiguity exists between the inclination and cone angles, as the optical data alone cannot distinguish between the two possibilities). A 13-day period observed in the velocity of the 'stationary' lines from this object[6] shows that the system is binary. However, other models exist which also account for the

0028-0836/80/440806—03$01.00

time varying optical spectrum. For example, one model suggests that the Doppler-shifted emission lines originate in a ring of material orbiting a solitary massive black hole[7]. We now report the detection of large-scale X-ray 'jets' from SS433. The X-ray emission is diffuse, extending at least 30 arc min from SS433, and is exactly aligned with both SS433 and the bulges of the shell of the huge supernova remnant (SNR) W50. This detection now (1) directly confirms the existence of jets related to SS433, (2) shows the link between SS433 and W50, proving that SS433 is galactic, (3) establishes a minimum age of the jet phenomenon of ~10³ yr, and (4) offers an explanation of why W50 is so much larger than any other known SNR in at least one dimension. The morphology of the diffuse X-ray emission is strikingly similar to that of radio lobes of many extragalactic sources; either *in situ* heating or particle acceleration is required to explain the appearance of the diffuse X-ray emission.

The SS433 observations were made with the Einstein X-ray Observatory[8] using the high resolution imager (HRI) in April 1979, and the imaging proportional counter (IPC) during the period 5–22 October 1979. The HRI observations show that the compact central source is unresolved (⩽3 arc s) and has position (±5″) of RA(1950) = 19 h 09 min 21 35 s, dec(1950) = +04° 53′ 54.9″. This position is coincident with the optical and radio position of SS433 (ref. 9). The IPC observations were made in a series of 2,000-s observations so as to monitor variable X-ray and radio emission. Two simultaneous X-ray and radio flares were observed and will be described elsewhere[10]. Figure 1 shows the sum of all these short observations for the energy range 0.5–3 keV and with a total integration time of 17,000 s.

The morphology of the diffuse X-ray emission reveals several important points. To show the diffuse features in the 1° field more clearly, the data in Fig. 1 have been smoothed giving the contours shown in Fig. 2, which is somewhat distorted by the vignetting correction applied. The two diffuse features are aligned with the central source. A straight line passing through the centres of both diffuse features and the central source goes through position angle 98°—nearly identical to the position angle of the bulges of the shell of W50 (ref. 11) and also closely aligned with the position angle of extended small-scale (arc s) radio emission[12–14] Note that diffuse emission, including the radio features observed by Geldzahler *et al.*[11], is not detected elsewhere inside the remnant, nor from that portion of the shell which crosses the upper north-west portion of our field.

The detection of the extended X-ray emission thus directly confirms for the first time that diametrically opposed jets originate from SS433 and travel nearly a degree across the sky to the eastern and western extremities of W50 where they collide with the SNR shell and cause the observed bulges. Clearly, there is significant interaction along the way between the jets and the SNR W50. The validity of the 'beambag' hypothesis for the morphology of W50[15] is now confirmed. The X-ray data are quite consistent with 'beam models' involving twin processing jets and the ambiguity in these models between the inclination of the precessing axis and the opening half angle of the cone is removed. The X-ray morphology and the optical requirement that the angle between beam velocity and observer never be <60° fix the cone half angle at 20° and the inclination at 80°. If the beam velocity is ~0.258*c* across the whole remnant, this phenomenon has continued for at least ~10³ yr, assuming the distance is 3.7 kpc (refs 16, 17).

Examination of Figs 1 and 2 shows that the diffuse feature in the west appears to be stronger than that in the east. If real, this may be related to the asymmetries between the east and west halves of W50 as shown in the radio map of Geldzahler *et al.*[11] and may be due to slight long-term changes in the balance of the jets and/or different properties of the medium surrounding SS433. However, the most significant morphological feature of the observed diffuse emission is that the brightness increases outward from SS433, forming rather elongated lobes, somewhat reminiscent of the appearance of radio-emitting lobes in radio galaxies. It is not clear whether or not the diffuse emission is completely absent near the star. The angle subtended by this emission at the position of SS433 is significantly less than the full 40° cone angle expected if the outflowing gas followed a purely ballistic trajectory. Both characteristics indicate that the flow is influenced and confined by an external medium in the SNR. The interaction with this medium by some *in situ* process is probably the cause of the excitation in the lobes. To investigate this point further, we examined the physical state of the gas responsible for the X-ray emission.

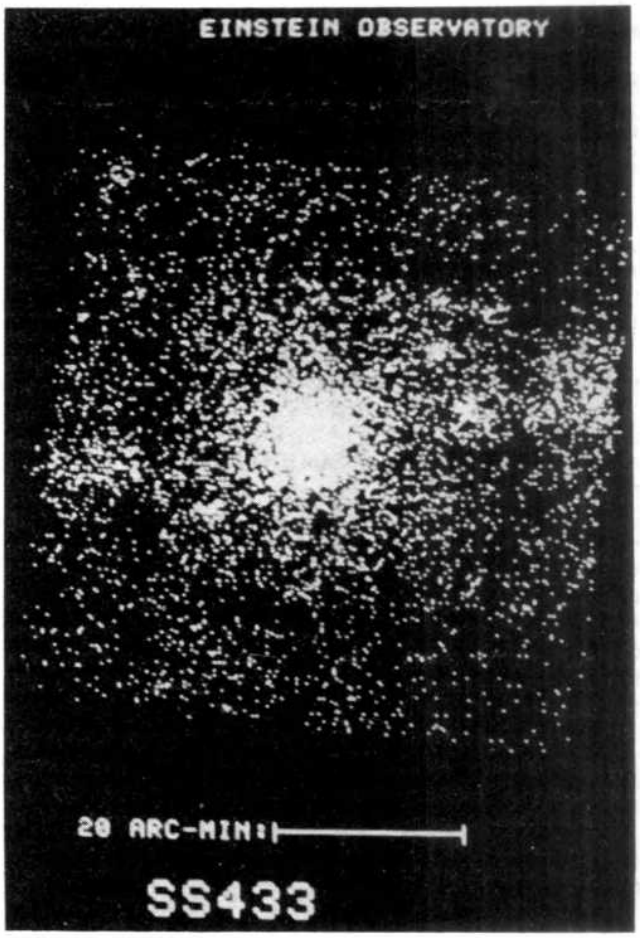

Fig. 1 X-ray emission from the central region of W50. The field of view is 1° × 1°. The bright central source is SS433. Diffuse X-ray emission is observed from a narrow region extending from east to west and roughly aligned with the central object.

The X-ray flux from the point source, SS433, is ~2×10^{-11} erg cm^{-2} s^{-1}. The X-ray flux from the diffuse source is ~3×10^{-12} erg cm^{-2} s^{-1}. At a distance of 3.7 kpc, these convert to luminosities of ~10^{35} and ~10^{34} erg s^{-1}, respectively. A factor of ~2 correction for low energy absorption (as expected for a ~3.7 kpc distance) has been applied. This is apparent in the X-ray spectra for both SS433 and diffuse emission, but actual spectral fits must await further IPC calibration analysis.

We consider two processes by which the beams might produce X-ray emission. First, the diffuse X rays could be produced thermally by hot plasma sustained by kinetic energy from particles in the beams. A possible mechanism for such heating is a shock generated by the beams interacting with the ambient medium (W. Tucker, personal communication). For an assumed X-ray spectral temperature of 10^7 K, the derived electron density is ~10^{-1} cm^{-3} and the total thermal energy contained in the plasma is 1×10^{49} erg. If the plasma has been built up over 10^3 yr, the required energy input for heating is 3×10^{38} erg s^{-1}, comparable in magnitude to the kinetic energy flow in the beams computed from the spectroscopic data[15]. Only 3×10^{-5} erg s^{-1} of this energy is required to account for the energy radiated as diffuse X rays. We conclude that the beam kinetic energy is sufficient to account for this plasma, and that a significant fraction of the beam kinetic energy might be dissipated in heating the plasma.

A second possibility is that the diffuse emission, which is detected at ~0.5–3 keV and may thus be relatively hard, is synchrotron radiation. The *in situ* production of relativistic particles by beams in regions distinct from a central compact source is clearly suggestive of the type of processes that have been invoked for double-lobed radio galaxies and QSOs. A self-consistent synchrotron model for the X-ray emission would require a magnetic field $B\approx10^{-5}$ G, 3×10^{42} electrons with Lorentz factors $\gamma\approx10^{8}$ and energy-loss lifetimes of $\sim10^{3}$ yr. Such electrons must have a total energy content of $\sim3\times10^{44}$ erg to account for the X-ray emission. Because the electron lifetime is comparable with its expected residence time in the beam (if $v\approx0.285c$), each relativistic electron radiates a significant fraction of its energy during the period of transit to the edge of the SNR.

As no clear radio counterpart to the X-ray beams is discernible above the radio background of the SNR, a lower limit of $\alpha\approx-0.8$ ($S\propto\nu^{\alpha}$) may be set for the spectral index α of the beam emission between the X-ray and radio region. Note that if $\alpha\approx-0.6$, similar to that in the radio for SS433 itself, the minimum energy in the form of relativistic electrons is 10^{47} erg, and could be as high as 3×10^{48} erg if the (unobservable) protons are included.

Regardless of which process is occurring, the internal co-moving energy density (or pressure) computed for the beams is within an order of magnitude of that resulting from relativistic particles and magnetic fields external to the beam and contained within W50, as known from the observed radio emission (see ref. 15). Thus, the beam may be confined laterally by the external medium within W50.

We have emphasized agreement with the kinematic jet model which is the model in best agreement with most data. Note that the X-ray data alone do not exclude other models. An accretion disk around a black hole, for example, could supply the high velocity material observed optically and also an axis of rotation along which escaping material might flow to form opposing 'jets' responsible for the diffuse X-ray emission.

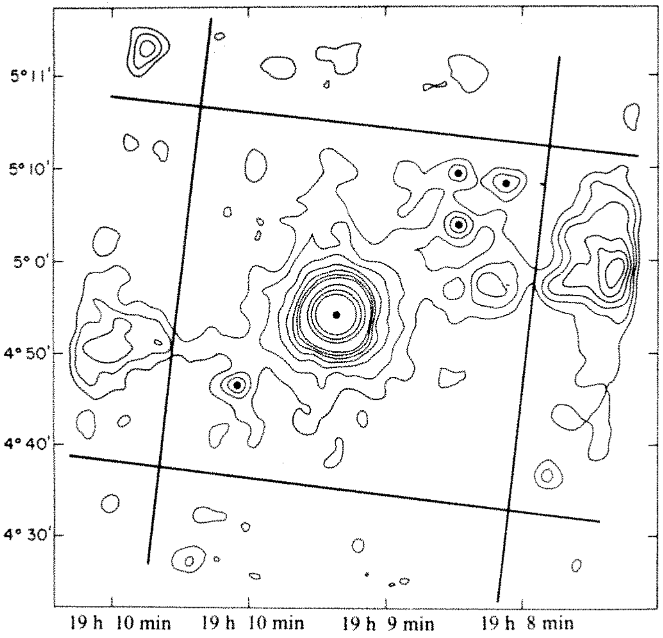

Fig. 2 Contours of constant X-ray brightness derived from data shown in Fig. 1. A correction has been made for vignetting in the telescope. Bars show detector window supports which shadow the diffuse emission. The positions of four other unidentified sources in the field are indicated. Contours showing diffuse emission are linear in increments of 5×10^{-15} erg cm^{-2} s^{-1} arc min^{-2}. Contours close to SS433 have larger increments and only show the instrument response to a strong point source.

Finally, we return to the above noted similarities between SS433 and mechanisms believed to occur in radio galaxies[5]. The similarity is in morphology but is seen in different spectral regions. In SS433, X-ray emission is seen and in the radio galaxies only radio emission is detected, that is, the ratio of X-ray to radio luminosity is very different. This fundamental spectral difference could be due to the enormous difference in size scale between the phenomena of SS433 and radio galaxies, although the primary acceleration processes may be the same. Given the same initial particle energy spectrum and assuming the X rays in the SS433 beams to be synchrotron in origin, the different ratio of X-ray to radio luminosity in these objects may be due to a different ratio of radiative lifetime to residence time in the emitting volumes. In radio galaxies, the particle residence times may be sufficiently long that we now predominantly see the radiation from the lower energy particles. In SS433, however, the radiative to residence times may be comparable; hence, we see more X-ray radiation.

This research was supported by NASA contract NAS 8-30751 and by the Einstein Guest Observer Program.

Light from electron avalanches and background rejection in X-ray astronomy

O. H. W. Siegmund, P. W. Sanford, I. M. Mason, J. L. Culhane & R. Cockshott

Mullard Space Science Laboratory, University College London, Dorking, Surrey RH5 6NT, UK

We have developed the parallel plate imaging proportional counter to register images of cosmic X-ray sources in the focal planes of X-ray telescopes[1,2]. An important factor determining the sensitivity of such an instrument, particularly for extended source studies, is the background count rate induced in the detector by the interaction of charged particles such as cosmic rays. This background in wire anode proportional counters can be reduced by applying risetime discrimination to the charge pulse[3]. We report here that a modified version of the parallel plate imaging proportional counter has been constructed as shown in Fig. 1*a*, to investigate the application of risetime discrimination to the scintillation pulses caused by the electron avalanche process[4]. We show that efficient background event rejection (>90%) is achieved and discuss an application of this system for X-ray astronomy.

An X-ray absorbed in the region between grid and the thin window produces a localized ionization cloud. The electrons in this cloud drift to the grid under the influence of a small electric field. A high electric field exists between the grid and the anode, accelerating the electrons to energies at which a Townsend avalanche occurs[5]. Light is emitted as a result of the ionizations and excitations which take place in this avalanche.

Fig. 1 *a*, Imaging scintillation proportional counter. *b*, Experimental configuration.

Figure 1*b* shows the experimental configuration used to investigate the risetimes of light pulses induced by X-ray and cosmic ray events. Light pulses are detected by an EMI 9558QB photomultiplier, which has an S20 photocathode and a minimum risetime of ~15 ns. The signals from the photomultiplier are then amplified and shaped to give a bipolar pulse. A measure of risetime is now obtained from the time interval Δt between the leading edge and crossover of the bipolar pulse. The risetime spectrum in terms of Δt was then calibrated against true risetime by direct observation of the photomultiplier signals by a fast oscilloscope (~3 ns minimum response).

The risetime spectra in Fig. 2 were obtained for Al K X rays (1.487 keV) and ^{60}Co γ rays over a limited pulse height band (1.2–1.8 keV). ^{60}Co was used because because it provides a reasonable simulation of 'in-flight' background for risetime discrimination systems[9]. Note that the events with risetimes faster than ~10 ns are due to noise.

For the gases used in this study the size of the electron cloud on reaching the grid is dominated by diffusion[2]. For Ar (90%)/CH$_4$ (10%) the maximum size (FWHM) of the electron cloud produced by an X-ray photon of a few keV is ~0.7 mm (ref. 6) (for a drift region 3.5 mm deep and a drift field of 300 V cm^{-1}). If the time development of the scintillation pulse is determined by the drift of the electron cloud across the grid, an estimate of the pulse risetime may be obtained by dividing the cloud size by the drift velocity. In Ar (90%)/CH$_4$ (10%) the drift velocity for the field of 300 V cm^{-1} is ~5 cm μs^{-1} (refs 6–8), giving a maximum pulse risetime of 14 ns. As this is comparable with the 15 ns minimum time response of the photomultiplier all the X-ray risetimes are centred on this value (Fig. 2). More recent investigations with a faster photomultiplier (EMI 9818 QBM, ~2 ns minimum response) have shown that the maximum risetime is ≲14 ns.

Relativistic charged particles such as cosmic rays or Compton electrons resulting from γ-ray interactions produce an extended track of low specific ionization in the drift region. Such particles may, therefore, give rise to energy pulses in the range of the X rays to be detected and will consequently contribute to the background. The scintillation pulses from these events will have risetimes up to a maximum given approximately by the total drift depth divided by the drift velocity. For a drift space of 3.5 mm and a drift velocity of 5 cm μs^{-1}, a maximum pulse risetime of ~70 ns results (Fig. 2). Both risetime distributions in Fig. 2 are consistent with the above estimates.

Figure 2 shows that charged particle rejection may be achieved by using risetime discrimination on the light pulse in a similar manner to that used for the charge pulse in proportional counters. Figure 3 demonstrates the ^{60}Co γ-ray rejection efficiency as a function of the X-ray rejection efficiency. It is possible to reject 91% of the γ-ray events for a loss of only 5% of the X-ray events. This represents a significant improvement over present parallel plate proportional counters[2] in which only ~50% of the γ-ray events may be rejected using charge pulse risetime discrimination. For X-ray astronomy this will result in a significant increase in instrument sensitivity. The sensitivity of an X-ray telescope of a fixed area is determined by the diffuse X-ray background, the cosmic ray background and the spatial resolution of the instrument (in the case of point sources). Rocket flight experience with a similar detector allows us to

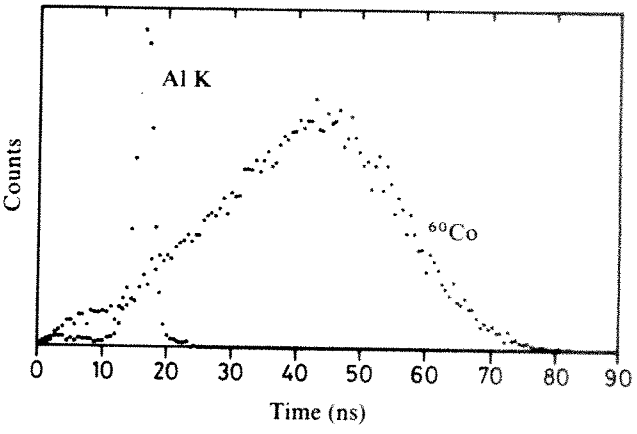

Fig. 2 Risetime spectra for a Al K X rays and ^{60}Co γ rays.

estimate the cosmic-ray background expected in flight. Taking an effective mirror area of 500 cm^2 for the range 0.1–2 keV we find that the count rate per pixel from the diffuse X-ray background is ~50% of the cosmic ray rate at low magnetic latitudes. Hence rejection of 90% of the cosmic ray background will allow the telescope sensitivity to be determined by the diffuse X-ray background, and independent of latitude variations in cosmic ray background, which can be as much as a factor of 3. This is especially important for studies of extended sources because the signal-to-background ratio is independent of the detector pixel size.

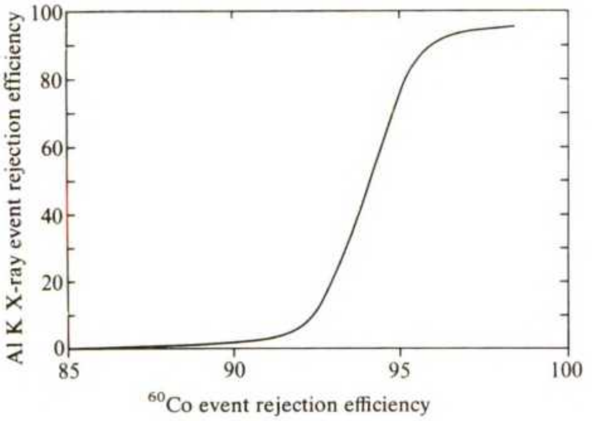

Fig. 3 ^{60}Co background rejection efficiency for risetime discrimination.

Note that for a geometrical X-ray telescope mirror area of 1,000 cm^2, a third magnitude star would result in 2×10^5 individual photon events s^{-1} in the photomultiplier, after attenuation by the counter window and anode. Most of these events will not be registered if a discriminator is used with a threshold set at a few photoelectrons equivalent pulse height. The background light from stars should not generally present a problem, however, because the density of stars brighter than third magnitude is only 2.5×10^{-3} deg^{-2}.

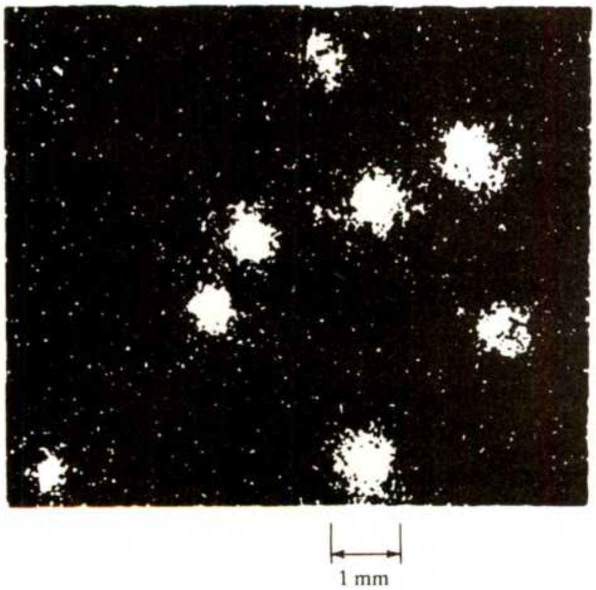

Fig. 4 Scintillation flashes produced by individual ^{55}Fe X rays in Ar (90%)–CH_4 (10%).

An investigation of the spectral distribution characteristics of the light emitted by Ar (90%)/CH_4(10%) has shown that there are two main emission bands centred on 750 nm and 420 nm, both bands having FWHM of ≤50 nm. The ratio of the intensity of the band at 750 nm to that at 420 nm is about 14 : 1. At a charge gain of 5×10^4 in Ar (90%)/CH_4 (10%) using Al K X rays a total of the order of 10^4 photons are produced for each X-ray photon event. Because the main emission band at 750 nm is reasonably narrow it should be possible to reduce the starlight background by factor of 15 using a narrow band filter transmitting between 700 and 800 nm.

Because most of the scintillation emission occurs within the last mean free path of the electrons in the avalanche region, it is possible to locate individual X-ray events from the scintillation pulse using a fibre optic faceplate and a transparent anode deposited on its surface. Figure 4 shows the localized flashes produced with Ar (90%)/CH_4 (10%) under irradiation by Mn K X rays (5.9 keV), recorded on film by means of an image intensifier. We are developing an optical detection system which will enable the centroid of each flash to be determined electronically. This work should lead to the development of a detector whose positional resolution is limited only by diffusion of the primary electron cloud in the drift space.

We thank Professor R. L. F. Boyd for helpful discussions, and H. Goddard and L. Goddard for construction of the detector. This work was supported by the SRC.

Distribution of cosmic-ray electrons in the Galaxy

M. R. Issa, P. A. Riley, A. W. Strong & A. W. Wolfendale

Department of Physics, University of Durham, South Road,
Durham DH1 3LE, UK

Although it seems that cosmic-ray electrons in the range 100–300 MeV are mostly generated in sources within the Galaxy (extragalactic electrons are kept out by the 2.7 K relict radiation) their distribution is not known. Studies of electron synchrotron radiation in the region of hundreds of MHz indicate that the synchrotron emissivity varies with position, generally decreasing as the galacto-centric distance, *R*, increases, but such dependence could be in either the electron flux, I_e, or the magnetic field strength, *H*, (emissivity $\propto I_e H^2$) or both. We examine here the distribution of I_e itself from studies of the γ-ray flux produced by electrons interacting in the interstellar medium by way of the dominant bremsstrahlung mechanism.

Using γ-ray data to find the distribution of cosmic rays has long been considered; for example, Dodds *et al.*[1] have reviewed the distribution of a mixed proton–electron component from analysis of γ rays above 100 MeV towards the galactic anticentre. Here, SAS 2 satellite data[2–4] is used in the energy range 35–100 MeV coupled with information on the distribution of target gas in the Galaxy.

In this energy range, the 1σ radius of the angular resolution function of the SAS 2 telescope for individual photons is 6°. Fichtel *et al.*[2] presented their data in the form of a number of photons observed in bins of equal solid angle (6.06×10^{-4} sr), each covering 2.5° in longitude, together with the relative sensitivity of the telescope for each bin. The above energy range is useful because the contribution to the γ-ray intensity from protons and heavier nuclei is small. Proton-induced γ rays come mainly from π^0 decay and the resulting γ spectrum has a peak at about 70 MeV ($m_\pi c^2/2$) whereas the spectrum of γ rays from electron bremsstrahlung falls continuously with increasing γ-ray energy. The overall spectral shape of γ rays indicates that π^0 and e-production do not become equal until ~170 MeV, leading to the conclusion that only ~10% of cosmic γ rays in the energy range 35–100 MeV result from π^0 decay. For γ rays in this energy range the corresponding electron energy is between about 70 and 300 MeV.

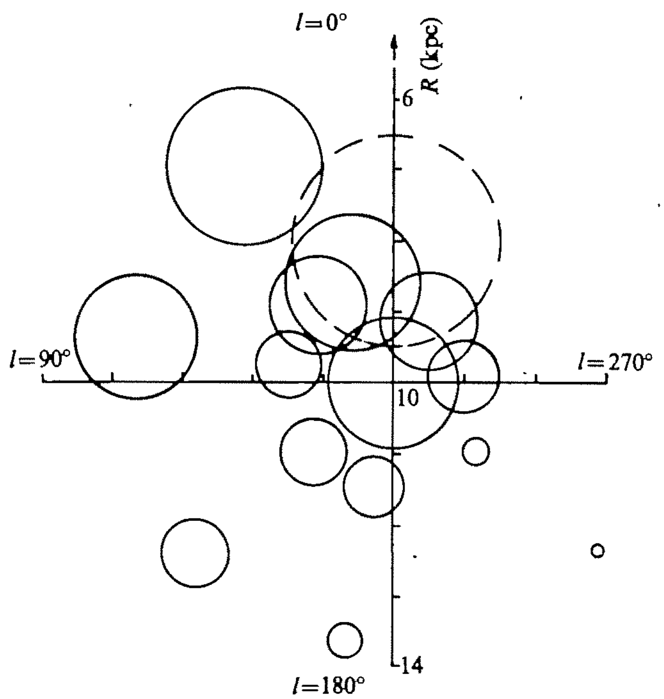

Fig. 1 Plan view of the Galaxy showing the intensity of cosmic-ray electrons in the region of several hundred MeV as a function of position in the local region. The electron intensity is proportional to the radius of the circle. Uncertainties in intensity are typically 30%. For absolute intensities see Fig. 2. The centres of the circles are the average positions to which the intensities refer; the positions are necessarily imprecise (uncertainty ~30% of distance to the Sun). The dotted circle relates to an attempt to allow for the contribution of discrete sources; the uncertainty is greater than for the other intensity estimates. The vertical scale is the distance from the galactic centre, *R*.

Previous analyses[5–7] have studied facets of this problem (although not in the present energy range) but here we examine the problem using recent data on gas densities and taking full recognition of various experimental factors (for example, the angular resolution function of the telescope). The object is to answer the specific question: how are energetic electrons distributed in the Galaxy?

We divide the γ-ray data into bands of longitude and latitude and for each find the value of $q/4\pi$ in the expression $I_\gamma = (q/4\pi)N_H + I_b$, where N_H is the volume density of target gas and I_b is the background (or more specifically, the component uncorrelated with the gas). q is proportional to the average electron intensity along the appropriate line of sight and, as a first approximation, can be taken to be proportional to $I_e(l, b, r)$ where r is the distance along the line of sight to a point $z(\frac{1}{2})$ above the galactic plane, $z(\frac{1}{2})$ being the half-thickness of the gas layer.

We have not tried to remove the contribution of 'discrete' sources from the data because we believe that many are due to molecular clouds irradiated by the ambient cosmic ray flux. As the sources CG184−5 and CG263−2 have been unambiguously identified with the Crab and Vela pulsars, however, data from within a few degrees of these sources are not used in this analysis.

This approach has several problems, the most important being that, of the gas constituents, only the atomic column densities are available for most of the range of l and b (here we adopt the Berkeley measurements[8]). The important H_2 column densities are readily available in restricted regions only, for example, $10° < l < 82°$, $b = 0°$ (±1°) (refs 9, 16) and from indirect analyses using galaxy counts[10–12] at $|b| > 10°$. The low counting statistics involved in the γ-ray results mean that a large area of the sky must be considered to obtain results with sufficient accuracy to be useful and such a wide coverage is not yet available in the case of the H_2 column densities. The H_2 column densities are, nevertheless, too large to be ignored completely. Gordon and Burton[9] presented measurements of the 2.6-mm line of CO which suggest that locally the surface densities of H I and H_2 (in atoms cm^{-2}) are about the same but their data for the local region (within 2 kpc of the Sun) may be too high, for two reasons. First, the quoted value for the local region is an average round the Galaxy at $R \sim 10$ kpc and most of the weight for the actual value comes from regions very remote from the Sun. The second point is that the formaldehyde results[13], Copernicus UV measurements[14], the analysis of Blitz and Shu[15] and our Galaxy count results favour values of N_{H_2}/N_{HI} in the range 0.25–0.5. The lack of detailed knowledge of the H_2 column density in the directions being studied can, however, be at least partially overcome if the correlation between H I and H_2 column densities can be shown to be small.

General arguments suggest poor correlation, mainly the fact that the molecular hydrogen occurs largely in dense clumps and the well-known observation that the thickness of the H_2 layer is only half that of the atomic hydrogen layer. A more detailed analysis gives the following. Galaxy count studies show a negligible correlation for the range $60° < l < 240°$ but a significant correlation for $10° < l < 60°$ (all for $|b| = 10$–$20°$). This negligible correlation for $60° < l < 240°$ would also be expected to apply for latitudes below 10°, largely because in the outer Galaxy the amount of H_2 decreases rapidly with increasing galacto-centric radius. Thus, we believe that the q-values derived from an I_γ, N_{HI} analysis give a good representation of the trend of I_e and R here, that is for $R \gtrsim 9$ kpc (we assume that the sum is at $R = 10$ kpc).

In the inner Galaxy the correlation between H I and H_2 causes more difficulty, but even here it is not insurmountable. Inspection of the CO and H I data at $b = 0°$ (summarized by Burton and Gordon[16]) show that both follow the same general decrease over the range $l = 10$–$65°$. However, large variations in the column densities of both components also occur on a smaller scale ($\Delta l \sim 1$–$5°$). These smaller-scale variations are sometimes of the order of 50% of the overall decrease in the range $l = 10$–$65°$ and the variations in CO seem uncorrelated with those in H I. If the longitude range is split into the two ranges $l = 10$–$35°$ and $l = 35$–$65°$, to be considered separately, then the smaller-scale variations are found to be large enough compared with the overall variation in column density to treat the H I and H_2 column densities as being effectively uncorrelated. The limited statistical accuracy of the data and the fact that the angular resolution is several degrees means that a rather large range of latitude must be considered (we take various regions, mainly with $|b| < 5.6°$ and $|b| = 2.4–12.8°$); thus, the contribution of H_2 will be much smaller than that at $b = 0°$ and the correlation effect even smaller. Considering $|b| < 12.8°$ the values of $(q/4\pi)$ are 3.4 ($l = 10–65°$), 3.8 ($l = 10–35°$), and 2.8 ($l = 35–65°$) × 10^{-26} s^{-1} sr^{-1} atom^{-1}. These indicate that there is very little correlation in this range, as correlation would cause the q value for $l = 10–65°$ to be bigger than for the divided ranges.

The data are analysed by plotting I_γ against N_{HI} (from ref. 8) and finding the maximum likelihood estimators of $q/4\pi$ and I_b in the expression $I_\gamma = (q/4\pi)N_{HI} + I_b$. If N_{H2} is uncorrelated with N_{HI} then the mean contribution of H_2 to the γ-ray flux in the region being considered will appear as a component of I_b, leaving $q/4\pi$ as the γ-ray emissivity of the atomic hydrogen gas. The present analysis differs from that of Fichtel *et al.*[6] in including the angular resolution of the SAS 2 telescope and in the more detailed analysis of the data in each longitude and latitude range.

Figure 1 shows the relative values of I_e; the radii of the circles are proportional to $q/4\pi$ at the position in the galactic plane (relative to the Sun) represented by their centres. The distance from the Sun to which each measurement of $q/4\pi$ refers is taken to be the distance along the line of sight to a point $z(\frac{1}{2})$ above the galactic plane. The goodness of fit of the lines to the data points gives an estimate of the uncertainty in the value of $q/4\pi$ and this is roughly 30%. Figure 1 shows a dispersion of intensities about a smooth dependence on galacto-centric radius such as corresponds to the estimated individual errors except for the intensities in the quadrant $l = 180°$ to 270° are singularly low. Such very intensities are probably real, however, and no doubt relate to the dearth in likely cosmic ray sources in this region (such as H II regions, and OB associations). The low values in general in the direction of the anticentre are particularly firm in view of their lack of contamination by the effects of molecular hydrogen.

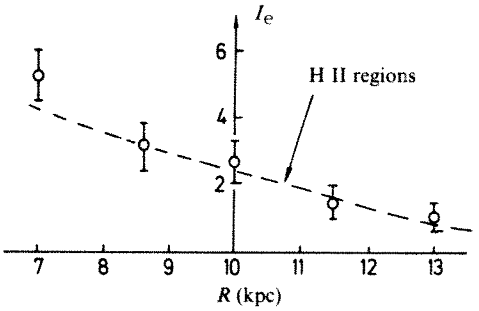

Fig. 2 Average intensity of cosmic-ray electrons as a function of galacto-centric radius, R, for the region covered by Fig. 1. I_e ($R = 10$ kpc) $\simeq 8 \times 10^3$ m^{-2} s^{-1} sr^{-1} GeV^{-1}. The dotted line is the average distribution of the number density of H II regions above a fixed threshold[15]. H II regions are not necessarily the sources of the electrons: many other astronomical objects have similar radial distributions, although it is interesting that the dearth of electrons at $R < 2$ kpc is mirrored by a deficit of H II regions (this is a difficult region in which to see the other objects) and the same situation arises for the region l, 180°–270°.

The data can be combined, assuming radial symmetry, to give the average radial distribution of electron intensity in the vicinity of the Solar System (within a few kpc of the Sun). Figure 2 shows the result.

The distribution of electrons nearer to the galactic centre than shown in Figs 1 and 2 can be studied using the unfolding technique to give the radial distribution of γ-ray emissivity; this is then divided by the gas density to give the electron intensity. Such unfoldings of the γ-ray data have been performed[17,18] and assume cylindrical symmetry of the γ-ray emissivity of the galactic disk to derive its radial distribution from the variation of the flux with galactic longitude. The method suffers because of large uncertainties in the amount of molecular gas in the inner Galaxy. Here, as no sophisticated analysis is possible, the earlier results are very doubtful.

New data on gas densities[19,20] have renewed interest in this method, however, at least for the central region of the Galaxy ($R \leq 2$ kpc). These data give a much higher mass of gas than previously suspected (and account for its non-observation previously). Specifically, Liszt and Burton[19] quote a mass of at least $10^9 M_\odot$ and Linke *et al.*[20] favour $8 \times 10^9 M_\odot$. These masses are high enough to derive important conclusions even allowing for some uncertainty in their magnitude.

We have made a new determination of the emissivity versus galacto-centric radius using the γ-ray line flux from Fichtel *et al.*[4] in the range 35–100 MeV. The γ-ray emissivity averaged within $R = 2$ kpc is $\sim 10^{40}$ γ's (35–100 MeV) kpc^{-2} s^{-1} (an essentially upper limit which does not depend at all sensitively on the unfolding assumptions), and the electron intensity required, using a mass of $8 \times 10^9 M_\odot$, is only 4% of the local value. Such a small value is difficult to explain in terms of exclusion of electrons from molecular clouds insofar as the gas seems to be rather smoothly distributed[17] rather than in clumps which could conceivably have associated excluding magnetic fields. If the gas data are correct it suggests that the electron intensity is very low (the arguments here relate to a region much larger than the 300-pc ring very close to the galactic centre for which different arguments apply[21]). Evidence on the deficit of likely sources of energetic electrons at $R < 2$ kpc is hard to come by; however, some data on H II regions (which are indicators of energetic phenomena) show a similar deficiency below 2 kpc (ref. 20). The most important feature is probably that not only are sources infrequent here but that diffusive motion is so small and the space is not filled with particles propagating from elsewhere.

Clearly there are significant variations in the intensity of cosmic-ray electrons over the Galaxy. A fall off at $R > 10$ kpc and a reduction by at least an order of magnitude, compared with the local intensity, for $R < 2$ kpc seem particularly firm.

We thank Professor W. B. Burton and Dr J. L. Osborne for useful discussions and Professor P. Thaddeus and Dr A. A. Stark for helpful correspondence.

The dynamic expansion and contraction of the jovian plasma sheet

J. W. Belcher & R. L. McNutt Jr

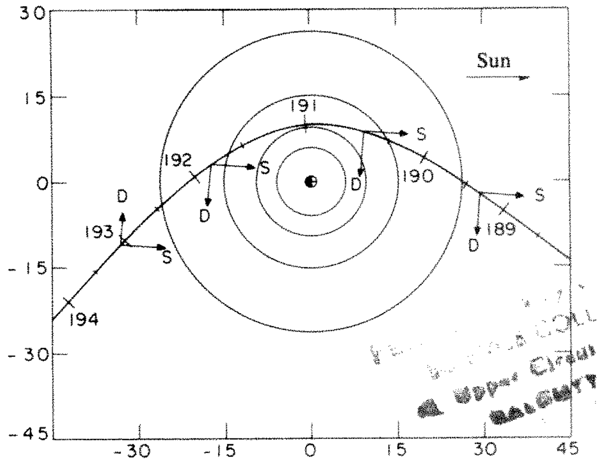
Department of Physics and Center for Space Research, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

We report here that near noon in the magnetosphere of Jupiter, plasma is observed to flow away from the equatorial current sheet. The motion reverses near dusk, with a subsequent infall of plasma towards the sheet on the nightside. We associate this motion with the compression of magnetic flux tubes on the dayside and their subsequent expansion on the nightside due to the solar wind interaction with Jupiter. Such compression and expansion may be sufficiently rapid that the plasma in the sheet cannot reach quasi-static equilibrium. Dynamic motions at transonic velocities ensue.

The plasma instrument on board the Voyager spacecraft consists of four modulated-grid Faraday cups which measure positive ions and electrons with energies per charge in the range 10–5,950 V (ref. 1). Three of these cups are arranged in a cluster whose symmetry axis normally points towards the Earth. The fourth cup (the D cup) is situated so that its axis is perpendicular to the symmetry axis of the main cluster. The trajectory of Voyager 2, and the orientation of the sensor normals at various points along that trajectory, are shown in Fig. 1; the Voyager 1 trajectory and sensor orientations are qualitatively similar. Plasma flow in the jovian magnetosphere has a tendency to co-rotate with the planet, that is, to move azimuthally at the rotation rate of the planet. The D cup is orientated so that azimuthal flow moves almost directly into that cup on the inbound leg of the trajectory. Near closest approach, strictly co-rotating flow would move into the field of view of the main sensors, and after closest approach out of the field of view of all sensors.

The response functions[2] of the Voyager Faraday cups are broad, with 30% response at an angle of incidence of 60° to axes of cups in the main cluster, and 30% response at an angle of 40° to the side sensor axis. Over much of the inbound trajectory, there is at least one sensor for which the plasma flow velocity is within ~20° of the sensor normal. If, in addition, the plasma is reasonably supersonic (Mach $\geqslant 3$), the response function can be taken as unity. In such a situation, the analysis of the positive ion data from that sensor is relatively straightforward, although complicated by the fact that the jovian magnetospheric plasma consists of an admixture of many ionic species (H^+, S^+, S^{2+}, S^{3+}, O^+, O^{2+}, Na^+, SO_2^+). Such single sensor data have been exhaustively analysed since the Jupiter encounters for heavy ion densities and temperatures, as well as for the velocity component along the sensor axis[3–5]. However, only for a brief time near closest approach, and during isolated spacecraft manoeuvres, is the unit response assumption valid for more than one sensor. To obtain all three components of the plasma velocity, we must use information from at least three sensors; because two of the three are usually significantly oblique to the flow, it is necessary to use the full response functions of the sensors. The complete determination of the velocity is more complex and time consuming, and at present can only be done on a limited basis. We discuss some quantitative results from this analysis below.

First, however, we take advantage of the symmetry properties of two of the main cluster sensors with respect to the jovian equatorial plane to obtain some qualitative results about the plasma velocity component perpendicular to that plane. These qualitative results are quantitatively verified by our more sophisticated analysis below. When the attitude of the spacecraft is referenced to the star Canopus, the axes of the A and D cups are essentially in the jovian equatorial plane. The axes of the B and C cups, however, are inclined to that plane in a nearly symmetrical fashion, at angles of 18.6° south and 15.3° north, respectively, for Voyager 2. We compute the flux density in a given cup by taking the total current due to positive ions with energies per charge from 10 to 5,950 V, and dividing by the proton charge and the effective area of the sensor. Figure 2 shows the flux density of the B cup minus the flux density of the C cup, divided by the sum of the flux densities in the B and C cups for a portion of the Voyager 2 trajectory. Because of the orientation of the cups, this difference will be positive for flow towards the north and negative for flow towards the south. Figure 2 also plots the distance of the spacecraft above the magnetic dipole equatorial plane. We indicate at various points the local time, and the distance of the spacecraft from Jupiter, with perijove at 10.1 jovian radii (R_J) (9 July 1979 at 2230 h). We have only plotted data in Fig. 2 when the fluxes in the B and C sensors are high enough to allow a significant comparison, and when the spacecraft was on Canopus. Unfortunately, this means that we can use little data past 1400 h on 10 July 1979.



COLLEGE
Upper Circular Road
CALCUTTA

Fig. 1 The Voyager 2 trajectory projected onto the jovian equatorial plane. The line labelled S is the projection of the symmetry axis of the main cluster of Faraday cups, and the line labelled D is the projection of the D cup axis. The A and D cup axes are essentially in the jovian equatorial plane, with the A cup axis ~110° from the D cup axis. The B and C cup axes are inclined ~17° south and north of that plane, respectively, ~75° from the D cup axis. Tic marks along the trajectory are shown every 12 h, with day of year at the beginning of the day (day 190 is 9 July, 1979). The orbits of the four Galilean satellites are also shown. Distances are given in R_J.

Crossings of the magnetic dipole plane are reasonably accurate markers for crossings of the jovian current sheet, especially inside $20R_J$. From the Voyager 2 data in Fig. 2, and from similar plots of Voyager 1 data, it is clear that in the dayside jovian magnetosphere near noon, there is a marked tendency for plasma flow to be northward when the spacecraft is north of the magnetic dipole plane, and southward when the spacecraft is south of that plane—thus, the flow is away from the current sheet. This pattern is the same as that observed in Pioneer measurements of the anisotropies of MeV protons in the dayside middle magnetosphere[6,7]. The amplitude of the B–C difference decreases to zero with decreasing radius and increasing local time towards dusk. In the dusk to midnight sector, the B–C

0028-0836/80/440813—03$01.00

difference again increases with increasing radius and increasing local time towards midnight. However, in this sector the plasma flow tends to be northward when the spacecraft is south of the magnetic equator, and southward when it is north of the equator—that is, the flow is now towards the current sheet.

The flow pattern can also be seen in a detailed inspection of the positive ion spectra from the various sensors. Figure 3 shows a low-resolution scan of the positive ion flux density near the crossing of the magnetic equatorial plane near $20R_J$ on Voyager 2 inbound (see Fig. 2). The flux density spectrum in the D sensor is an unresolved superposition of H^+, O^{2+}, S^{3+} and S^{2+} (refs 4, 5). At this time, the B and C sensor normals are ~73° and ~67° from the rigid co-rotational flow velocity, with the D sensor normal only ~12° from that velocity. From these spectra, we conclude qualitatively that the flow velocity is mostly azimuthal at this time because the D sensor flux is much higher than fluxes in the main sensor. Moreover, the flow velocity must lie near the equatorial plane because of the near equality of the fluxes in the B and C cups. In contrast, Fig. 4 shows a low resolution scan of the positive ions during a dayside excursion of the spacecraft to $\sim 3.3R_J$ below the magnetic equatorial plane. The B and C sensor fluxes are comparable with those in the D sensor even though the sensor orientation is qualitatively the same as for the spectra in Fig. 3. This implies a significant component of velocity radially towards the planet during this interval. In addition, the C cup flux is larger than the B cup flux, implying a southward component of flow and thus a flow away from the current sheet. We also note that the main sensor is orientated such that there would be slightly more purely azimuthal flow into the C cup than the B cup on the inbound leg, and vice versa on the outbound leg. Thus even in the absence of any north/south flow, we qualitatively expect to see a negative signature in $(B-C)/(B+C)$ inbound and a positive signature outbound. In fact, the differences in Fig. 2 oscillate about a negative average value inbound and a positive average value outbound, as expected.

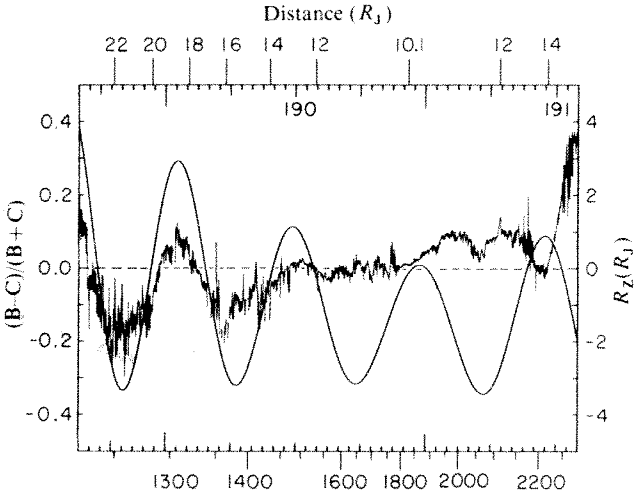


Fig. 2 The difference between the B and C cup fluxes divided by the sum of those fluxes, as a function of time during the Voyager 2 encounter, from 1600 h on 8 July, 1979 (day 189) to 1400 h on 10 July, 1979 (day 191). A positive value for this difference indicates northward flow. Also shown is the distance of the spacecraft above a magnetic dipole plane. Interior tic marks give spacecraft time at one hour intervals, with day of year given at 1200 h. We also indicate values of the local time and the radial distance from Jupiter.

This qualitative information on flow patterns is borne out by quantitative analysis of detailed measurements of the positive ion distributions in the various sensors. This analysis is essentially done in stages using an integration code which includes the full sensor responses. For example, we quote results obtained by Voyager 2 near 2009 h on 8 July 1979 (Fig. 4). The spacecraft was near noon, $21.6R_J$ from Jupiter and $-3.3R_J$ below the magnetic dipole plane. An analysis of the proton peak in the B, C and D sensors yields a density of 0.12 cm^{-3} and a thermal speed of 120 km s^{-1}. In a cylindrical coordinate system, where the z-axis is the rotation axis of Jupiter, the radial component of the proton velocity was -167 km s^{-1}, the azimuthal component was 264 km s^{-1} and the z-component was -95 km s^{-1}. These non-azimuthal velocity components should not be taken as typical, since for quantitative analysis, we must at present choose the most pronounced examples of the phenomenon. The azimuthal component here is slightly less than the 270 km s^{-1} velocity expected for rigid co-rotation[3]. In this interval, the plasma was flowing southward (away from the current sheet), in agreement with Fig. 2, and was also flowing radially towards Jupiter, a feature which cannot be deduced from Fig. 2. An analysis of spectra near midnight (at 1300 h on 10 July, 1979) yields similar results, except that the flow is now northward (towards the current sheet) and away from Jupiter.

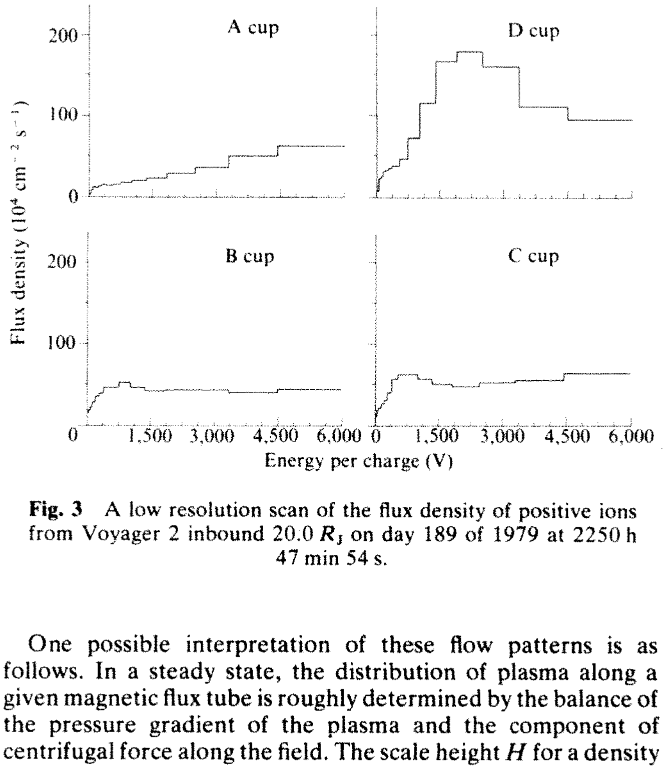

Fig. 3 A low resolution scan of the flux density of positive ions from Voyager 2 inbound 20.0 R_J on day 189 of 1979 at 2250 h 47 min 54 s.

One possible interpretation of these flow patterns is as follows. In a steady state, the distribution of plasma along a given magnetic flux tube is roughly determined by the balance of the pressure gradient of the plasma and the component of centrifugal force along the field. The scale height H for a density distributed in this way is the product of the sound speed C_s, the rotation period of the planet[8] and dimensionless factors of the order of $1/2\pi$. If this static situation is perturbed we still expect a quasi-static density distribution as long as the perturbation time scale is long relative to the dynamic time scale $2\pi H/C_s$. If the perturbation is short relative to this time scale, the plasma cannot adjust in a quasi-static fashion, and plasma motions with velocities up to C_s and beyond can result.

The dynamic time scale for the jovian plasma sheet is thus some fraction of the order of unity of the rotation period of the planet. However, the plasma sheet is perturbed on time scales of this order due to the compression of the dayside magnetosphere by the solar wind. Plasma will tend to move away from the plasma sheet as it moves into the dayside magnetosphere, because of both the compression and the decreasing component of centrifugal force along the field. Because of the rapid time scale, the adjustment of the plasma density distribution along the field line will not be quasi-static, and bulk motion along the field and away from the sheet can ensue. This motion will lead both to a north/south flow and a flow towards the planet on the dayside, as observed. At decreasing radial distances, the

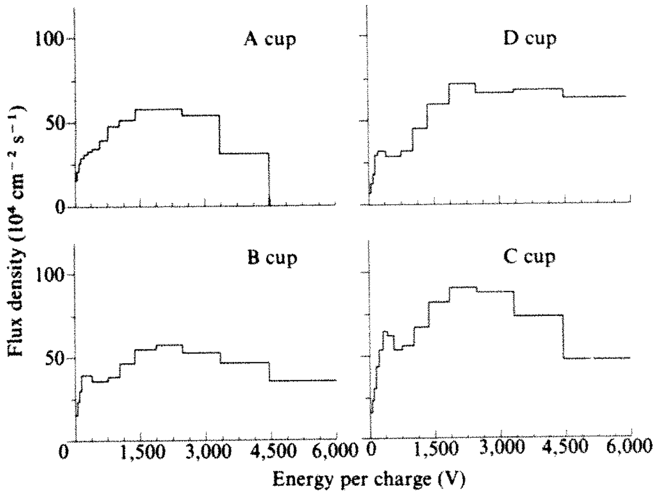

Fig. 4 A low resolution scan of the flux density of positive ions from Voyager 2 inbound 21.6 R_J on day 189 of 1979 at 2009 h 11 min 55 s.

perturbation associated with the solar wind is smaller and leads to a perturbed flow whose amplitude decreases with decreasing radial distance near noon, also in accord with observations (Fig. 2 and ref. 7). Past noon, the magnetic flux tube will begin to expand and move to larger distances. The expansion of the flux tube and the increasing component of centrifugal force will lead to a reversal of the plasma flow near dusk, and cause an infall of material at transonic (or supersonic) velocities in the nightside current sheet.

We note that this picture is very different from what would be expected from a quasi-static expansion and contraction of the plasma sheet due to the solar wind interaction. A quasi-static process would produce a sheet which was thickest at maximum compression (noon), and thinnest at minimum compression (midnight). Any small velocities associated with such a quasi-static process would be zero at noon and midnight, and maximal at dawn and dusk. In contrast, the dynamical velocity pattern described above, especially its phase, arises only in the absence of quasi-static equilibrium. The possibility of such a pattern depends on the fact that the solar wind interaction tends to perturb a given flux tube on the same time scale as it takes the plasma to come to static equilibrium.

These observations and our interpretation of them have two obvious implications for both theory and observation of the jovian magnetosphere. First, irreversible processes such as internal shocks or effective viscosities will lead to a net heating of the plasma as it expands away from and collapses towards the plasma sheet (that is, a fluid analogy of the acceleration mechanism of Goertz[9]). Second, theoretical models of the plasma sheet which assume quasi-static equilibrium, and interpretations of data based on such models, must be re-examined.

We thank H. S. Bridge and S. Olbert for discussions. This work was supported in part by NASA contract 953733.

Note added in proof: It has been suggested that the solar wind perturbation is slow enough to allow quasi-static solutions. This reasoning is based on a comparison of the solar wind perturbation time scale to the quasi-static equilibration time scale. Here we attempt to clarify our argument. In a plane parallel atmosphere,

$$\rho\frac{\partial \mathbf{v}}{\partial t} = -\nabla p - \rho g$$

where **v** is the plasma velocity, ρ the mass density, p the pressure, and g the gravitational (real centrifugal for Jupiter) acceleration. Taking a time derivative and using mass conservation

$$\rho\frac{\partial^2 \mathbf{v}}{\partial t^2} = +\rho C_S^2\frac{\partial^2 \mathbf{v}}{\partial z^2} + g\rho\frac{\partial \mathbf{v}}{\partial z}$$

where we have assumed that g and **v** are in the z direction, and we are only keeping terms of interest for order of magnitude (we have dropped many other terms). Assuming an $\exp(i(kz - \omega t))$ dependence for **v**, we have

$$\omega^2 = C_S^2k^2 - igk = k(kC_S^2 - ig)$$

The static or quasi-static solution is obtained by setting ω^2 to zero and obtaining $k = +ig/C_S^2$ and thus an $\exp[-z/H]$ falloff, with $H = C_S^2/g$. This solution will be valid as long as $\omega^2 \ll C_S^2k^2$, or $\omega \ll C_SH$. Thus, the angular frequency of any sinusoidal perturbation should be compared to C_SH to determine if the response of the system will be quasi-static.

At Jupiter, C_S/H is the angular rotation rate of the planet ($2\pi/10$ h), to factors of the order of unity ($\sqrt{2/3}$). The angular frequency of the solar wind perturbation is ($2\pi/10$ h). The similarity between these two frequencies is the basis for our contention that the quasi-static situation may not obtain. We have been rather sloppy in this derivation, but the overall conclusion remains even in a more careful consideration.

Io control of jovian radio emission

Michael D. Desch

Department of Physics and Astronomy, University of Maryland,
College Park, Maryland 20742

The stimulation by Io of some fraction of the jovian decametre-wavelength radio emission was recognized in 1964[1]. Since then many observations have indicated that strong Io control is limited to frequencies between about 22 and 40 MHz (refs 2–4). At lower frequencies, that is 8–10 MHz, the degree of Io modulation declines markedly[5]. Recent low-frequency RAE 1 satellite[6], Voyager 1 (ref. 7), and groundbased[8] studies have shed some doubt on the conclusion that Io control predominates only at high frequencies. Data from the Earth-orbiting RAE 1 satellite[6] revealed a strong dependence of emission detection probability on Io orbital phase at frequencies in the range 6.5–2.2 MHz. These apparently conflicting results lead to two different conclusions: (1) Io control decreases markedly in the 10–20 MHz regime but reappears near 6 MHz, or, (2) observations above 8 MHz require[5] that the emission intensity be taken into account. We demonstrate here that the latter is the case and offer a reinterpretation of these data which is consistent with the recent low-frequency satellite and groundbased results.

Figure 1 shows the results of a two-year survey conducted at 26.3 MHz. These observations, a preliminary analysis of which was reported earlier[9], are unique in that they were made with an extremely sensitive antenna array consisting of 640 half-wave dipoles. Thus a large volume of very weak emission was detected for the first time. We divide the data into two approximately

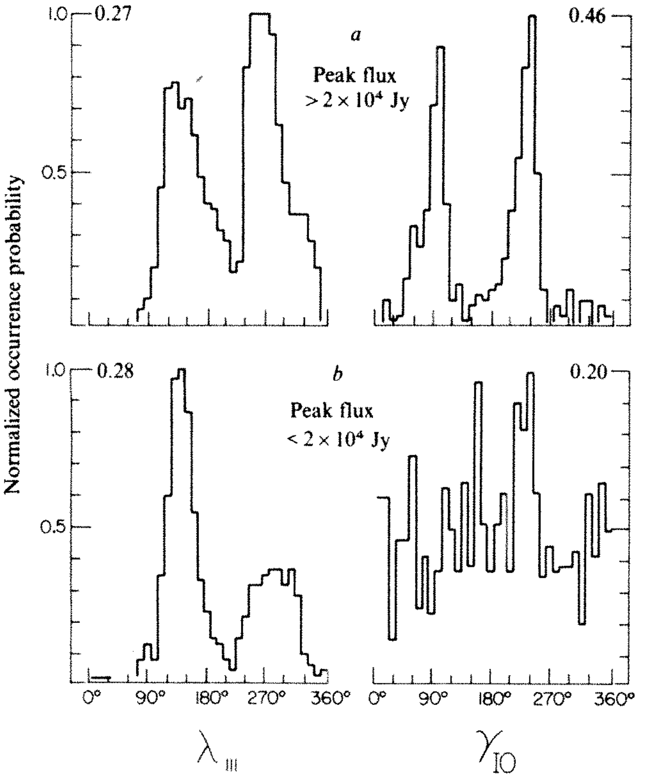

Fig. 1 A total of 151 h of 26.3-MHz jovian radio emission in which the occurrence probability is plotted as a function of the System III central meridian longitude (CML, 1965) and the geocentric phase of Io (γ_{Io}). In each case the data are divided into two components. One component (*a*), consisting of 83 h of activity is comprised of storms which exceeded a threshold intensity of 2×10^4 Jy (2×10^{-22} Wm^{-2} Hz^{-1}). The weaker component (*b*), consisting of 68 h of activity is made up of storms which did not exceed this same level. The observing period extended from 16 April, 1973 to 1 March, 1975 and contained 997 h of interference-free monitoring. The weak emission, while displaying strong modulation in CML, exhibits virtually no control by Io.

equal parts, one consisting of radio storms whose peak intensity exceeded a certain threshold and one component which did not exceed this threshold. Both the strong and weak components are plotted as separate functions of the System III (1965) central meridian longitude (CML) on Jupiter and the geocentric phase of Io (γ_{Io}). As anticipated from previous studies, the high intensity component (*a*) displays strong Io control, having occurrence probability peaks at the expected Io phase locations of 90° and 240°. The weak emission (*b*), however, shows no preferred Io phase. Instead it exhibits random fluctuations as a function of γ_{Io} and is, therefore, considered to be Io-independent emission. This latter result was entirely unexpected because large amounts of Io-independent emission had previously been observed only at relatively low frequencies, for example at 18 MHz and below. Reliable identification of these low-level Jupiter events is assured as can be inferred from the histogram (Fig. 1*b*) which shows the emission plotted as a function of CML. It displays the same dependence on CML as does the high intensity component.

Thus from the above observations alone it seems that there is not necessarily a strong frequency dependence to Io control. We hypothesize that, phenomenologically at least, Io control is a flux-dependent rather than a frequency-dependent phenomenon. We test this hypothesis by performing the same analysis as above at lower frequencies, where Io control is supposed to weaken and eventually disappear.

The results of such an analysis at 18 and 10 MHz are presented in Figs 2 and 3, respectively. The plots are identical in format to Fig. 1. In agreement with the 26.3 MHz results, there is strong Io control evident at both 18 and 10 MHz when the high intensity emission is isolated. The occurrence probability peaks are centred on the classical 90° and 240° Io-phase positions; only the relative amplitudes of the peaks differ. Note also that, just as was evident at 26 MHz, the low intensity emission is independent of Io phase. This is particularly striking at 18 MHz where the statistical reliability of the data is greatest. Both data sets retain modulation in the System III coordinate at both intensity levels, the absence of which might imply significant mistaken identification of Jupiter events.

We have shown that by isolating the high intensity radio emission at 26, 18, and 10 MHz the dependence of Io control on frequency disappears to first order. The explanation for apparent Io control in previous studies is now evident if one recalls that Jupiter's flux density spectrum peaks at ~8 MHz and falls off steeply at higher frequencies[10]. Thus, at the higher frequencies the radio emission is relatively weak and only the most intense, that is Io-controlled, events are detectable by the conventional low-gain radiometers. The weak, predominantly non-Io-controlled emission at these same high frequencies is generally undetectable, except by large antenna systems. On the other hand, at low frequencies, that is those nearer to the 8-MHz spectral peak, both the strong Io-controlled and weak non-Io emission can exceed the radiometer detection thresholds, leading to the specious conclusion that Io control has diminished. The apparent correlation between frequency and Io control is thus seen to result from a selection effect owing to the admixture of increasing amounts of non-Io emission as the observing frequency (and hence relative antenna detection threshold) is

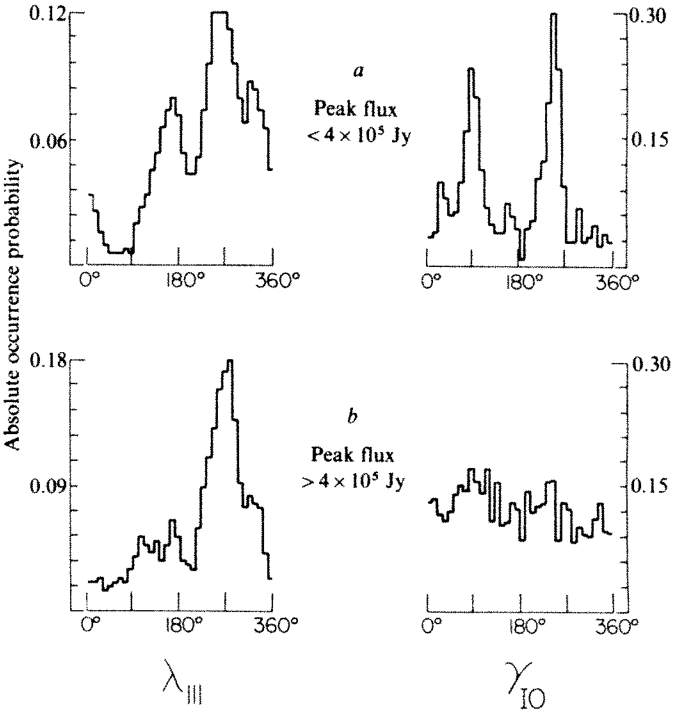

Fig. 2 A total of 491 h of 18-MHz jovian radio emission, organized as in Fig. 1, with high and low intensity components represented by *a* and *b*, respectively. Each component contains approximately equal amounts of activity. The intensity threshold in this case is 4×10^5 Jy. Observations were made at the University of Florida Radio Astronomy Observatory between 7 May 1964 and 8 May 1967, totalling 4,280 h of actual monitoring. As at 26 MHz, Io strongly modulates the high intensity emission, but the low intensity emission seems free of any Io control.

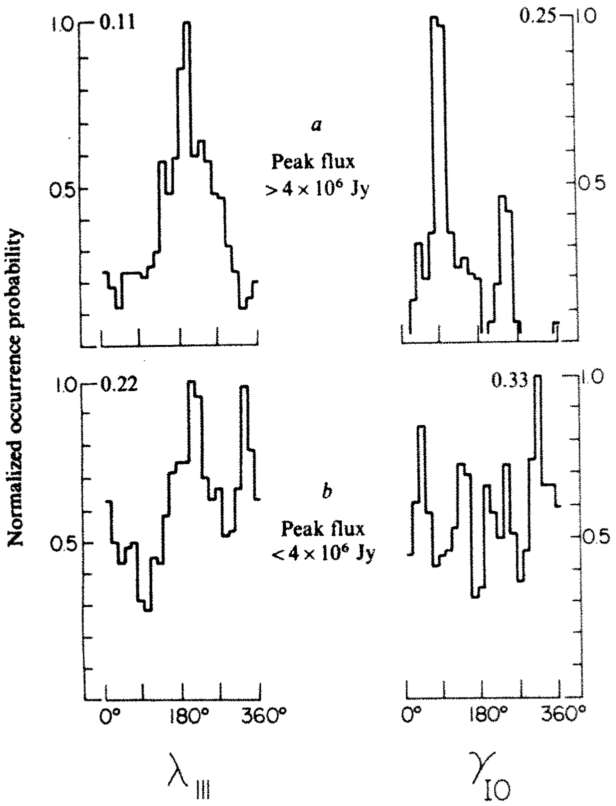

Fig. 3 A total of 138 h of 10-MHz jovian radio emission, organized as in Fig. 1. Here the low intensity component contains approximately three times as much activity as the high intensity component. The total observing time was 758 h. The observations at 10 MHz were made at the Maipu Radioastronomical Observatory in Chile in exceptionally good observing conditions between 18 May 1963 and 20 January 1964. The flux density threshold was set at 4×10^6 Jy. Qualitative agreement with the results at both 18 and 26 MHz is clear. Io modulation is evident in the case of the high intensity emission but nonexistent in the case of the relatively weak emission.

reduced. Primarily because the aforementioned low-frequency RAE 1 satellite observations were made with a relatively insensitive radiometer, it is not surprising that strong Io control was observed.

These results bear directly on the question of the radial extent of the Io-controlled source region. Those theories[11–14] which specifically address the problem of the stimulation mechanism itself generally postulate emission at or near the local electron gyrofrequency. Based on this assumption, an Io-controlled source location can be inferred from the Pioneer-modelled ambient magnetic field[15] and, most importantly, from the observed frequency range of the Io-controlled emission. The present study infers a contiguous Io-controlled source region which, rather than being limited to the near-surface planet, extends out several jovian radii along the Io flux tube. Detailed satellite studies are now being made to define more precisely the spatial extent of the source.

Si-rich Fe–Ni grains in highly unequilibrated chondrites

Ermanno R. Rambaldi, Derek W. Sears & John T. Wasson*

Institute of Geophysics and Planetary Physics, and Department of Chemistry, and * Department of Earth and Space Sciences, University of California, Los Angeles, California 90024

Some Fe–Ni grains in the Bishunpur L3 chondrite have Si contents in the range 1.3–4.5 mg per g (mole fractions of 0.003–0.009); the only previous report of Si in ordinary chondrite metal is a lower limit of 0.7 mg per g for metal in the Leighton H4 chondrite[1]. The Bishunpur Si contents are 1.1–4 times that found in a large metal grain in the Murchison CM2 chondrite[2]. As whole-rock systems both meteorites have high degrees of oxidation and consist of unequilibrated, essentially unmetamorphosed mineral assemblages. Thus the Si was not introduced into the metal during metamorphic reheating, but rather during nebular condensation[2]. Grossman *et al.*[2] calculated that the Si mole fraction of 0.0024 in the Murchison grain required a total nebular pressure $\geq 10^{-5}$ atm, which is higher than that generally inferred for the CM formation location. We show here that improvements in the Si activity coefficients and plausible constraints on the nucleation of mafic silicate condensates allow Si mole fractions of 0.003 at nebular pressures of $<10^{-6}$ atm. Thus such chondrites could have formed over a wide range of distances from the Sun.

Bishunpur is one of the three most unequilibrated chondrites[3–5] (Krymka and Semarkona are the others), and thus best preserves the record of processes occurring in the portion of the primitive solar nebula where the ordinary chondrites formed. Our data were obtained by electron microprobe; experimental details and Bishunpur's opaque phases are reported elsewhere[6]. All observations were made on polished thin sections 2359-1, 2359-2, and 2359-3 loaned by the Smithsonian Institution. Contrary to previous suggestions[2], we did not find that fluorescence of Si in adjacent silicates was a problem: (1) Si was below our detection limit of 0.4 mg per g in all metal grains except those listed in Table 1 and in two others having variable Si contents apparently reflecting the presence of Si-rich inclusions; (2) the problem is least where it is expected to be greatest, as regions of the Si-bearing metal that abut silicates have Si contents below our detection limit.

Figure 1 shows photomicrographs of three of our eight Si-bearing metal grains. Figure 1*a*, using transmitted light and partially crossed polars, shows an FeS–metal aggregate which is embedded in an olivine grain in the matrix (no. 39 in Table 1). The olivine grain, possibly a fragment of a chondrule, contains numerous opaque inclusions and it also displays undulatory extinction indicating distortion by shock. Not resolvable in this photomicrograph is a Ca–Al-rich glass having low Na and Fe concentrations. Such glass enriched in refractories is relatively common adjacent to Si-bearing metal, indicating that refractory materials are preserved within these chondrules. The large opaque inclusion is shown by reflected light in Fig. 1*b*. Its outer region is FeS and other minor phases and the interior is metal with a Ni content in the kamacite range. The sulphide gives the impression of having formed by corrosion of a metal grain.

Another FeS–metal assemblage (no. 19 and Table 1) is embedded in an olivine pyroxene chondrule that also contains

0028-0836/80/440817—04$01.00

two other Si-bearing metal assemblages and numerous small, uncorroded, spherical metal grains (Fig. 1*c*). We cannot detect Si in the uncorroded grains and the Si content of the corroded grain drops below the detection limit at those places where there is no FeS shield (upper right corner, near the dark embayment on lower right). Both the Si-bearing metal and the surrounding FeS contain numerous inclusions too fine to analyse. Some metal grains were not free enough of inclusions to be suitable for analysis. The areas whose compositions are listed in Table 1 were uniform in Si though an occasional point showed a high Cr content, perhaps reflecting the presence of $FeCrO_4$ or $FeCrS_4$. The Si we determined is probably in solid solution in the Fe–Ni, but we cannot completely rule out the presence of uniformly distributed submicroscopic grains of Si-rich phases such as perryite, $(Fe, Ni)_2(Si, P)_5$. As such a phase would have formed by low-temperature exsolution, its presence would not complicate the following discussion of how the Si was originally introduced into the metal.

Figure 1*d* shows the only Si-bearing metal that was not enclosed by olivine (no. 78 in Table 1). It is located in a thin layer of opaque, amorphous matrix with large porphyritic chondrules on either side. The entire assemblage is 480×320 μm, thus its area is about quadruple that of the largest of the grains embedded in olivine. The metal grains are more-or-less randomly distributed within the sulphide. They show little variation in Ni, Co, and Si, but Si drops below the detection limit at grain edges. As in the other assemblages, there is a Ca, P and Cr-rich layer between the metal and the sulphide. Unlike the grains within chondrules, this assemblage does not have a rounded outline, nor does it have the inner metal, outer sulphide configuration. Despite the differences, the compositional and petrological evidence indicates that this grain assemblage is genetically related to those found inside chondrules. It may have been freed of silicates before the chondrule melting process, or it may have been a fragment broken out of a chondrule. The preservation of reduced Si despite its siting in the matrix can probably be attributed to its large size.

Table 1 shows the compositions of the six Si-bearing Fe–Ni grains for which precise data could be obtained, and the Fe/(Fe+Mg) ratios in the host olivine. All grains are Cr-rich, but there is no correlation between Cr and Si or between these and other compositional parameters including olivine composition. One relevant observation is Cr zoning; Cr increased in concentration towards the grain edge. This implies that Cr was being reduced and diffusing into the grain before diffusion ceased. A possible interpretation is that Si was the agent reducing the Cr. All Ni concentrations are in a relatively restricted range of 34–40 mg per g, a composition that falls within the α stability field at temperatures between 550 and 1,100 K.

Summations in the FeS around the metal grains are often <980 mg per g reflecting the presence of the numerous fine inclusions mentioned above; even in areas of essentially pure FeS (Fe+S >980 mg per g), Ca, Cr, P and Si totalling 8–33 mg per g are observed.

Clearly, the FeS shell has either introduced the Si or preserved Si that entered the Fe–Ni at higher temperatures. As FeS cannot reduce silicates to Si, and because the only observed evidence for an oxidation–reduction reaction involves Si oxidation, we conclude that the latter is correct. We can think of two mechanisms by which the FeS shell could preserve the reduced state of Si during the mild metamorphism experienced by Bishunpur. It could either act as a barrier to diffusion of oxidant or Si, or it could act as a reducing buffer which consumed any oxidant (Fe^{2+}) released by the surrounding silicates. The reducing agent might have been $(Fe, Ni)_3P$ or Cr^{2+}. Diffusion at the low metamorphic temperatures experienced by Bishunpur probably limited any oxidant generation to very small amounts.

In unequilibrated chondrites the metal inside chondrules is significantly less equilibrated than the metal in the matrix[4]. Thus it is not surprising that seven of the eight Si-bearing grains that we observed are inside chondrules or inside olivine fragments that may have originated as chondrules. As the chondrules were either completely molten or high-degree partial melts, their temperatures at formation were surely $\gg$1,250 K, the FeS–metal eutectic temperature, it follows that the Si-bearing metal–FeS assemblages were also molten. It therefore seems probable that the concentric geometry (FeS as an exterior shell) and corroded appearance were produced during solidification and a very brief period of annealing. As the Si was not oxidized by FeO from the silicates during this process, it follows that the chondrules cooled very rapidly following formation.

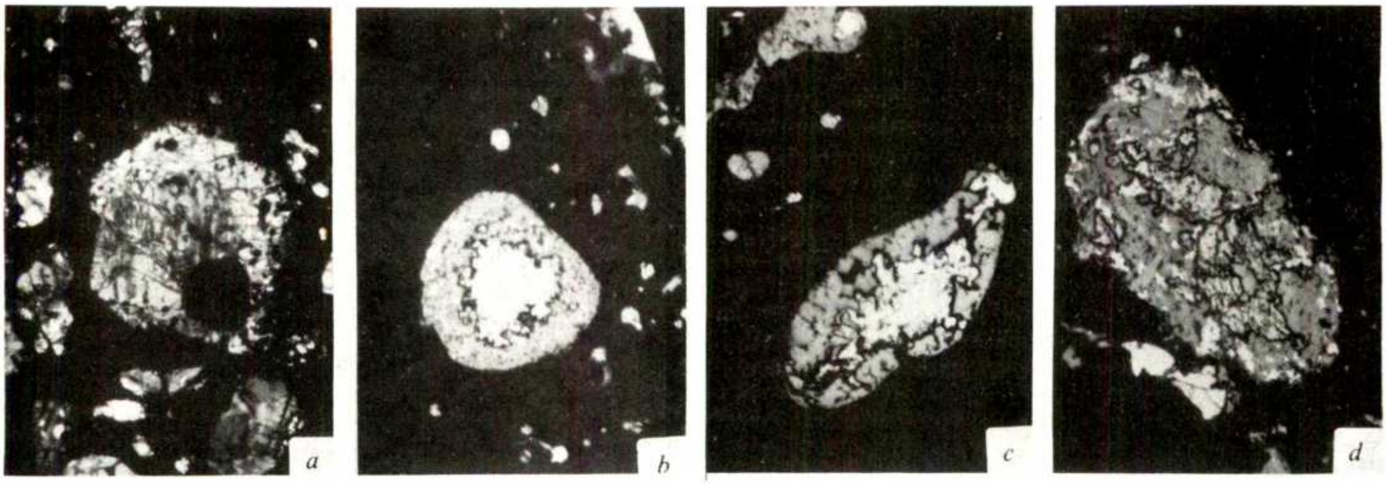

Fig. 1 Cr, Si-rich Fe–Ni grains in Bishunpur. *a*, Transmitted light photo showing a 760×950-μm olivine crystal. The olivine displays undulatory extinction, probably indicating shock, and it contains numerous glassy inclusions of variable composition, but all strongly enriched in Ca and Al. The small opaque inclusions are mainly metal; the large one (190 μm) is shown by reflected light in *b*. The white area is metal (no. 39 in Table 1) and the outer rim consists of FeS. The irregular outline of the metal suggests that the sulphide formed by corrosion of the metal. *c*, Reflected light view of a 97×310-μm metal–sulphide assemblage (no. 19 in Table 1) inside a chondrule. In the interior, the Si content is constant (3.7 mg per g) but drops below the detection limit near edges which are not coated in FeS. A fine-grained FeS-rich material, located between the metal and sulphide, is rich in Ca and P. The outer sulphide is relatively inclusion-free and contains Ca, Cr and minor P and Si. *d*, A large 320×480 μm metal–sulphide assemblage (no. 78 in Table 1) surrounded by a thin layer of matrix and sandwiched between two large porphyritic chondrules. In contrast to the other grains, the metal (white, irregular) is randomly distributed in the sulphide. The Si content drops below the detection limit at the edge of each metal grain.

Table 1 Compositions of Si-bearing metal and adjacent olivine in the Bishunpur L3 chondrite

Grain	Points	Fe (mg per g)	Co (mg per g)	Ni (mg per g)	Si (mg per g)	Cr (mg per g)	Olivine (mol % Fa)	Petrographical setting
19	5	954	4.6	38	3.7	8.6	3.6	Separate grains in chondrule
20	3	933	4.5	40	1.3	10.0		
27	3	941	4.2	36	2.9	6.7		
39	5	948	8.0	40	2.0	2.0	1.4	Olivine fragment
62	6	950	6.4	36	1.6	5.2	—	Chondrule
78	6	946	6.5	36	3.4	6.2	—	Matrix

The 250×360-μm metal grain from the Murchison CM chondrite[2] contained 1.2 mg per g Si; there is no indication that it was surrounded by a sulphide shell. Considered as whole-rock chemical systems both Bishunpur and Murchison are highly oxidized. In Bishunpur ~50% of the Fe is present in the +2 state as oxides; in Murchison about 75% is in the +2 and +3 state as oxides. At equilibrium Fe-rich silicates or magnetite will readily oxidize Si. The large amount of oxidized Fe and the highly unequilibrated nature of both chondrites are strong evidence that the Si-bearing metal did not form by reduction during metamorphism.

The more plausible mechanism for producing Si-bearing metal is to produce it during the condensation of the cooling solar nebula. In an unfractionated nebula the Si activity in Fe–Ni will be controlled by reactions of the sort

$$2\mathrm{MgSiO_3(s)} + 2\mathrm{H_2(g)} = \mathrm{Si(s)} + \mathrm{Mg_2SiO_4(s)} + 2\mathrm{H_2O(g)} \qquad (1)$$

if condensed silicates are the source of the Si. If gaseous SiO is the source of the Si the appropriate reaction is

$$\mathrm{SiO(g)} + \mathrm{H_2(g)} = \mathrm{H_2O(g)} + \mathrm{Si(s)} \qquad (2)$$

The chief hindrance to the accurate calculation of Si mole fractions during nebular condensation is the inadequacy of available activity coefficient (γSi) data[7]. Sears[8] used the function determined by Sakao and Elliott[9] at temperatures of 1,373–1,623 K:

$$\log(\gamma_{\mathrm{Si}})\alpha = 1.19 - \frac{7{,}070}{T} - \left(6.30 - \frac{18{,}300}{T}\right)X_{\mathrm{Si}} \qquad (3)$$

A study by Sakao *et al.*[10] yielded log γ values about 0.15 more negative. Grossman *et al.*[2] used the Sakao–Elliott function and one covering the temperature range 873–1,273 K obtained by Roberts[11], we have not used the latter because it does not cover the range of condensation temperatures for Fe–Ni. The Sakao–Elliott data were obtained for Ni-free α (body centred cubic) phase. The Fe–Ni that condenses from the nebula has the γ structure (face centred cubic) and a Ni content >50 mg per g. We cannot predict the effect of Ni, but there is evidence that $(\gamma_{\mathrm{Si}})_\gamma$ is lower than $(\gamma_{\mathrm{Si}})_\alpha$. Wai and Wasson[12] reported that Si concentrations in the γ phase of the Tucson iron are 1.3–1.5 times higher than those in the coexisting α phase. However, equilibrium was not achieved in Tucson. (There is no definite γ phase in other highly reduced meteorites that are more equilibrated than Tucson; Keil[13] found phases having 91–98 mg per g Ni in the Fe–Ni in EH Adhi-Kot and EL Hvittis, but the low Ni content of these grains leaves doubt that they are really γ.) The observed $\mathrm{Si}_\gamma/\mathrm{Si}_\alpha$ distribution ratio is probably a lower limit of that prevailing at the equilibration temperature of ~1,000 K; a plausible guess is that $(\gamma_{\mathrm{Si}})_\gamma$ is about three times lower than $(\gamma_{\mathrm{Si}})_\alpha$ at 1,000 K. Because γ should approach unity with increasing temperature, we will assume that the $\mathrm{Si}_\gamma/\mathrm{Si}_\alpha$ distribution ratio drops to 2 at 1,500 K. $\log(\gamma_{\mathrm{Si}})_\gamma - \log(\gamma_{\mathrm{Si}})_\alpha$ usually follows an $A + B/T$ relationship over moderate temperature ranges, so that equation (3) can be written:

$$\log(\gamma_{\mathrm{Si}})_\gamma = 1.24 - \frac{7{,}600}{T} - \left(6.30 - \frac{18{,}300}{T}\right)X_{\mathrm{Si}} \qquad (4)$$

the absolute change of log γ_{Si} is assumed to be the same for γ and α metal.

Figure 1 shows the nebular condensation of Si for two models: (1) the thick curves show the metal compositions if Fe–Ni and mafic silicates condensed heterogeneously as soon as temperatures fell low enough to make the condensates stable; and (2) the thin curves show the compositions if metal condensed heterogeneously, but the mafic silicates condensed homogeneously with amounts of required undercooling[14]. The thermodynamic data set is the same as that used by Sears[8], with the exception of the Si activity coefficient.

We suggest that the second model is the more appropriate one for the low-pressure regions of the nebula in which ordinary and carbonaceous chondrites formed. Evidence[15] indicates that CM chondrites formed at solar distances ≥2 AU where nebular pressures were probably $\leqslant 10^{-5}$ atm, and ordinary chondrites at ~1–3 AU at pressures $\leqslant 10^{-4}$ atm. Although Blander and Abdel-Gawad[14] and Blander[16] argued that at low nebular pressures ($\leqslant 10^{-4}$ atm) nucleation inhibitions should result in Fe–Ni nucleating at temperatures well below those at which enstatite and forsterite condense, the opposite must have occurred for the Si-rich grains. If supersaturation of metal led to condensation of Fe as silicates or FeS, subsequently condensed metal should have had a Ni/(Fe+Ni) atom ratio well above the solar ratio of 0.054; but the Murchison ratio (0.064) is only slightly higher, the ratios in Bishunpur (0.030–0.038) distinctly lower. Moreover, there is no way to condense metal having high Si contents after Si has largely (≥99%) condensed as silicates. If the nebula had a 'solar' $p\mathrm{H_2O}/p\mathrm{H_2}$ ratio of $\sim 5 \times 10^{-4}$, the Si concentration in subsequently condensed metal will be orders of magnitude lower than that observed in Bishunpur and Murchison. Thus, although we cannot rule out the condensation of other metal grains after silicate condensation, the evidence indicates that these Si-bearing grains condensed earlier than the bulk of the silicates. It has been proposed that refractory metal grains such as those embedded in refractory inclusions in CV chondrites could have served as condensation nuclei for Fe–Ni (ref. 17).

The carbonaceous and ordinary chondrite groups contain large quantities of Fe-rich silicates that probably either formed by direct condensation or by reaction of gaseous Fe with precondensed $\mathrm{MgSiO_3}$. Direct condensation avoids the need for mass-transport of Mg out of and Fe into these silicates, and may be more likely. Direct condensation implies a high degree of supercooling both for metal and silicates, consistent with our conclusion that most of the silicate condensation occurred at temperatures well below the equilibrium condensation temperature for Fe–Ni, and not inconsistent with the condensation of a minor amount of the metal at high nebular temperatures.

Figure 2 shows mole fractions of Si in Fe–Ni at nebular pressures of 10^{-4}, 10^{-5}, and 10^{-6} atm based on these alternative models. The positions are marked where $\mathrm{Mg_2SiO_4}$(Fo), Fe–Ni(M), and $\mathrm{MgSiO_3}$(En) become stable if equilibrium holds, and the point where silicate liquid (L) becomes stable in the constrained equilibrium model of Blander and Abdel-Gawad[14]. The heavy curves depict the Si/(Fe+Ni+Si) trajectories in equilibrium conditions. Maximum mole fractions reach 0.006, 0.002 and 0.001 at 10^{-4}, 10^{-5} and 10^{-6} atm, respectively. The results at 10^{-4} and 10^{-5} atm seem to agree with those of Grossman *et al.*[2]. The light curves show the Si mole fractions for metal grains condensing heterogeneously (in equilibrium conditions) while the condensation of the major silicates has not occurred because of nucleation constraints; the extensions of these curves below the estimated silicate nucleation temperatures (L) are shown dashed. If our second model is correct, then the Si/(Fe+Ni+Si) ratios of 0.012, 0.007 and 0.003 are reached before silicates condense at nebular pressures of 10^{-4}, 10^{-5} and 10^{-6} atm, respectively. If this is the correct model for the formation of Si-bearing grains, the Murchison grain could have formed at nebular pressures of 10^{-6} atm or slightly lower.

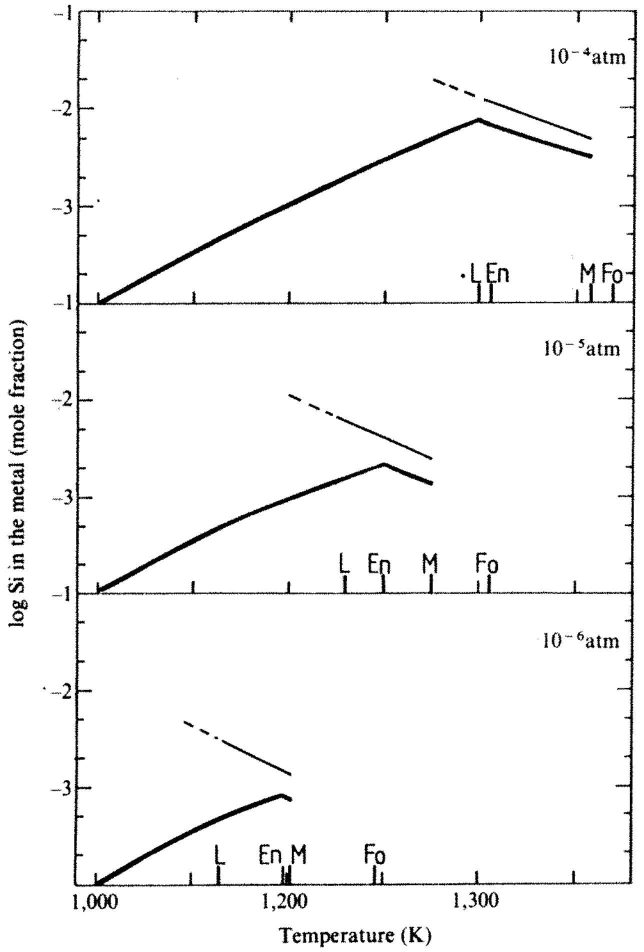

Fig. 2 Mole fraction Si in Fe–Ni condensing in a cooling nebula of solar composition at total (pH_2) pressures of 10^{-4}, 10^{-5} and 10^{-6} atm. The heavy curve shows the Fe–Ni composition if both Fe–Ni(s) and Mg_2SiO_4(s) condensed according to simple thermodynamic equilibrium. The light curve shows the Si content of the metal if the metal condenses according to the equilibrium calculations but silicates condense only after 70–85 °C of supercooling. Also indicated are the nucleation temperatures of Mg_2SiO_4(Fo), Fe–Ni(M), $MgSiO_3$(En) and a silicate liquid (L).

Is it reasonable that high Si contents could be preserved after mafic silicates start to condense? In some cases the Si was oxidized by H_2O(g) and entered silicates that nucleated on the surfaces of the metal grains. On the other hand, uncondensed SiO(g) is a more readily available source of Si, and rapid formation of silicates around a metal grain could remove the metal from contact with the gas and preserve its Si content, just as the refractory-rich metal grains are preserved in the inclusions of CV chondrites[17,18].

Studies of highly unequilibrated chondrites have taught us that if a phase can form in certain solar-nebula conditions it will probably eventually be found in these remarkable meteorites.

Dead Sea Scroll parchments: unfolding of the collagen molecules and racemization of aspartic acid

Stephen Weiner*, Zina Kustanovich†, Emanuel Gil-Av† & Wolfie Traub‡

* Isotope Department, † Organic Chemistry Department, ‡ Structural Chemistry Department, Weizmann Institute of Science, Rehovot, Israel

The parchments of the Dead Sea Scrolls were prepared from the skins of animals, mainly sheep and goats[1,2]. They were copied and hidden between the beginning of the first century BC and AD 70[3]. Since then and until their discovery in the late 1940s by local Bedouins, they were located in caves close to the northwestern shore of the Dead Sea[4]. Having been handled by various intermediaries for periods of up to 8 yr, most of the intact scrolls are housed in the Israel Museum, Jerusalem. We have examined small pieces ($\leq$25 mm^2) from these scrolls, together with random fragments without any writing, to study some of the chemical changes which have occurred in the past 2,000 yr or so. Using X-ray diffraction and racemization analyses, we found that a major degradative change is due to the unfolding of the collagen molecules to form gelatin and that the degradation generally occurred many centuries ago.

Inspection of these parchments clearly differentiates lighter and darker areas (Fig. 1). The latter are generally located close to the edges and are obviously less well preserved. Under the scanning electron microscope, the damaged edges are generally seen to be more massive and gel-like than the better preserved areas, in which fibres can usually be identified. The IR spectra of Dead Sea Scroll fragments show a marked decrease of the 3,330-cm^{-1} amide A band absorption as compared with modern parchments, consistent with the interpretation of a loss of collagen structure[5].

We have developed a technique using X-ray diffraction to determine semiquantitatively the relative proportions of collagen and gelatin in parchment (Fig. 2). Only very small samples (a few mm^2) are required. The method is non-destructive and contaminating inorganic minerals generally do not interfere. In parallel, we have determined the ratios of the left-handed (L) and right-handed (D) isomers of aspartic acid, present in scroll fragment hydrolysates. Living tissues are generally composed of L-amino acids only. After death, conversion to the D-configuration slowly occurs to form eventually equilibrium mixtures of D- and L-isomers. Conditions influencing this process include the ambient temperature, the time elapsed, the pH, the protein amino acid sequence and the molecular conformations[6–8]. Thus, measurements of the D/L ratio may provide additional insight into the rates and conditions in which the chemical changes have occurred. Aspartic acid

Fig. 1. The Thanksgiving Scroll soon after unrolling.

undergoes racemization relatively rapidly[9] and is, therefore, well suited for this study.

The collagen to gelatin indices (C:G) and the ratios of D- and L-aspartic acid (D/L Asp) of the samples, are listed in Table 1 and plotted in Fig. 3. The C:G indices of Dead Sea Scroll parchments fall between the values for fresh rat tail tendon collagen and gelatin. On hydrolysis, both collagen and gelatin yield a small amount of D-aspartic acid, with gelatin showing more of the D form. Most of the scroll parchments, however, contain more D-Asp than is generated during the analytical procedure. The general distribution of the data in Fig. 3 shows that samples enriched in collagen contain only small amounts of D-Asp, whereas those enriched in gelatin have a range of D-Asp concentrations from insignificant to ~30%. In some cases, dark, poorly preserved edges were compared with lighter, better

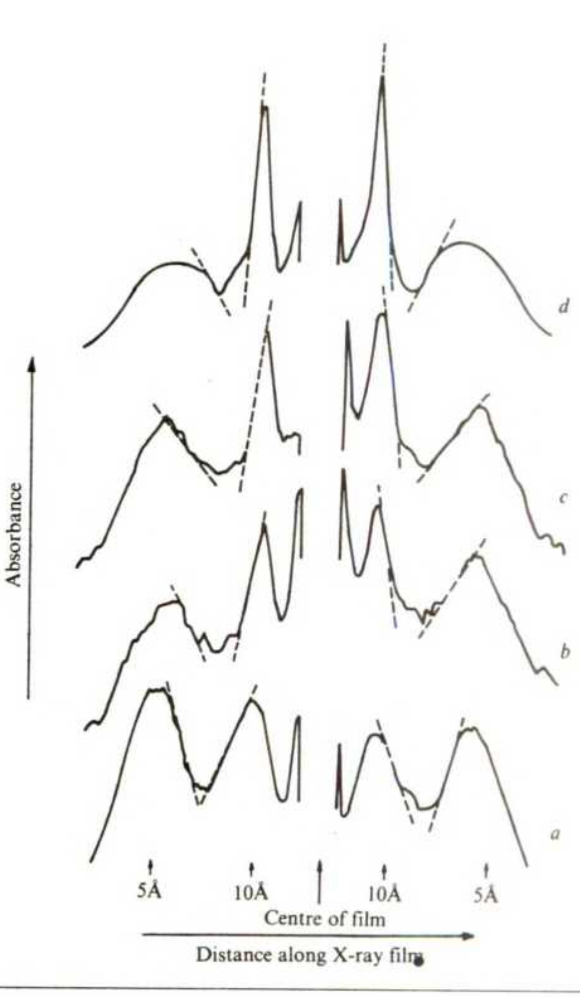

Fig. 2 Optical densitometer traces of X-ray diffractograms of collagen, gelatin and Dead Sea Scroll parchments. *a*, Gelatin; *b*, random fragment 32; *c*, random fragment 35; *d*, collagen. The parchment surfaces were mechanically cleaned and then X-rayed in a Debye–Scherrer camera for 8–24 h depending on the size of specimen. Optical densitometer traces through the centre of the film were made using a microdensitometer (Joyce, Loebl, model MKIII B) in standard conditions (slit width, 0.8 mm; sensitivity, 8; chart speed, 7; 0–1.0 absorbance wedge). The C:G indices were estimated by dividing the sum of the slopes for the 10-Å peak by the sum of the slopes for the 5-Å peak (the 10-Å peak is both higher and narrower in collagen than in gelatin, whereas the 5-Å peaks are quite similar for the two materials and provide an internal standard for each photograph, so that the C:G index does not depend on experimental conditions such as specimen size and exposure time). The standard deviation on repeat preparations of two samples (32 and 35; Table 1) is 0.4, but is probably much larger in samples composed predominantly of collagen, due to the difficulty of estimating the slope of the 10-Å peak. The results are not very dependent on exposure time, unless the film is either very light or very dark. Relatively fast scanning on the densitometer and a wide slit effectively results in a trace with minimal interference from the sharp mineral lines. The C:G index values are on a relative scale. Interpolation between collagen and gelatin curves indicates that 25, 50 and 75% collagen compositions correspond to ~1.4, 2.8 and 5.0, respectively, on the C:G scale.

Table 1 C:G index and D/L Asp of the samples analysed

Sample no.	Sample description	C:G	D/L Asp	Sample location and notes
1	Collagen	10.2	0.05, 0.04	Washed and dried rat tail tendon collagen
2	Gelatin	0.7	0.08, 0.09	Rat tail tendon denaturated at 100 °C for an hour in water

§ Ref. 17.

preserved areas from the same scroll. It was generally observed that the better preserved samples are enriched in collagen and contain less D-Asp (see, for example, samples 7 and 8; 9 and 10; 16 and 17; 20 and 21; 27, 28 and 29). In some cases, samples located within 1 cm of each other have D/L Asp ratios which span almost the entire range encountered (Table 1; Fig. 3).

Using different skins in one scroll and/or various parchment preparative treatments could conceivably influence the C:G index and the D/L Asp ratios. The first panel of the War Scroll, although uniformly darker than the other panels, is not significantly different from the rest of the scroll with respect to the two parameters measured (Table 1). The Isaiah Scroll had been repaired by the addition of a patch of parchment in one corner. In this case, the patch is enriched in collagen and contains more D-Asp than the main scroll parchment, which curiously shows no significant concentrations of D-Asp. Note also that the Temple Scroll, which has a light appearance and is relatively pliable, has surprisingly high concentrations of gelatin and D-Asp.

The unfolding of collagen to gelatin seems to be one of the major chemical changes which these parchments have undergone. The dark borders have suffered more than the light interior sections (Fig. 1). Furthermore, during unrolling it was observed that the inner sheets were better preserved than the outer sheets[10], suggesting that an external environmental agent, probably water, influences the conversion of collagen to gelatin. Collagen is more stable in drier conditions[11] and the low relative humidity in the area of the caves was probably a major factor responsible for the preservation of these materials. The micro-environment around the inner portions of the scrolls themselves was probably particularly dry as the outer layers probably trapped incoming water vapour. Extreme dryness also reduces the racemization rate of amino acids[12]. Fungal and bacterial activity may also have been absent for this reason. The sharp boundaries observed between light and dark areas are generally paralleled by marked variations in C:G proportions and D/L Asp ratios. This suggests that major water-accumulation events occurred sporadically during limited periods. Continual exposure to humidity would result in gradual variations in these two parameters due to a slowly expanding area in which collagen is unfolding.

It is easier to envisage racemization reactions and the consequent incorporation of D-amino acids occurring in gelatin, which has a largely disordered structure, than in the regular conformation of collagen. Indeed, the dominance of negative slopes for the connecting lines of Fig. 3 shows that, for different pieces of the same scroll, significantly higher proportions of D-Asp correspond to higher proportions of gelatin. Thus, the time of formation of gelatin from collagen should influence the ultimate D-Asp content measured. Some of the samples have accumulated considerable amounts of D-Asp (see Table 1 and Fig. 3). As fossil organic materials generally require hundreds

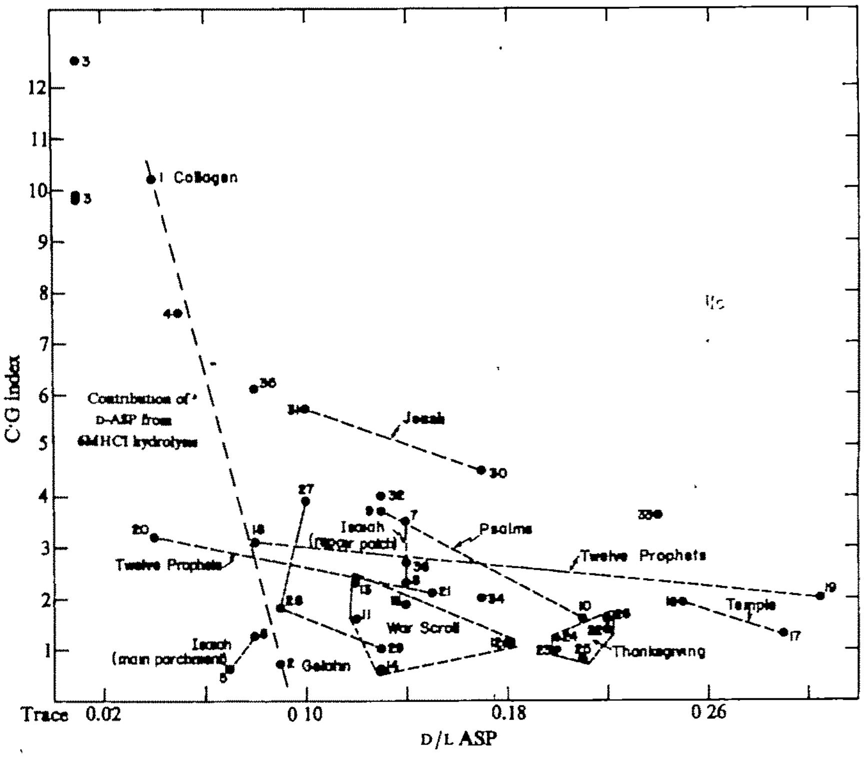

Fig. 3 The index plotted against D/L Asp of the samples analysed. For racemization analyses, ~2–5 mg of parchment were used. The parchment surfaces were mechanically cleaned, soaked in double distilled water for 2–3 h at room temperature and then transferred to 0.5 M acetic acid for 4 h at room temperature to remove the more soluble contaminants. The samples were hydrolysed in redistilled 6M HCl *in vacuo* at 150 °C for 40 min. Amino acid compositions of the random fragments closely resemble the amino acid composition of collagen. After extensive drying, the hydrolysates were derivatized to *N*-trifluoroacetyl isopropyl ester as described previously[15]. The samples were dissolved in ether and passed through a silica column (Merck, 200 mesh) in a Pasteur pipette. The aspartic acid enantiomers were separated by gas–liquid chromatography using a stainless capillary column coated with *N*-lauroyl-L-valine *t*-butylamide[16]. To confirm the identity of the D-Asp peak some of the samples were also chromatographed on the corresponding D-valine phase, which showed the expected peak reversal. Where large amounts of D-Asp were found, trace amounts of D-alanine and occasionally D-leucine, were also observed. The relative proportions of D- and L-Asp were measured by peak height. the reproducibility of the analyses is 5–10%. However, a significant portion of this variability may be due to sample heterogeneity. The ratios have not been corrected for the amounts of D-Asp generated during hydrolysis.

or thousands of years to accumulate significant amounts of D-Asp[6–8], it is reasonable to assume that most of the parchment fragments must have suffered collagen to gelatin denaturation many centuries ago, rather than in the comparatively short period since their removal from the caves. A careful visual comparison of photographs of scrolls taken soon after being unrolled 30 yr ago (Fig. 1) with the same scrolls in January 1980, revealed no noticeable differences in the distribution of light and dark areas. As at least the scroll fragments excavated by archeologists were found to be buried beneath sediments[4], the early damage may be due to the lack of a protective covering for some time after the scrolls were deposited in the caves or even, in part, be due to handling by the original readers. A corollary of our arguments might be that samples with relatively high gelatin but low D-Asp contents, such as the Isaiah scroll (see Fig. 3), were damaged more recently. However, this presupposes a more or less constant rate of racemization unaffected by differences in preparative treatments and microenvironmental conditions for different portions of the scrolls. The lower gelatin but higher D-Asp contents of the repair patch (see Fig. 3), which has presumably been attached to the Isaiah scroll for the past 2,000 yr, suggests that such factors probably do affect the rate of racemization.

Our study shows that the transformation of collagen to gelatin is one process which causes significant deterioration of the parchment. Optimal preservation conditions, which minimize the rate of transformation, should be established. As a guideline, the minimal melting temperatures of Dead Sea Scroll collagen[13], about 22 °C, and a relative humidity of 65% (above which uptake of moisture by collagen increases very rapidly)[14] should not be exceeded. The C:G index can be used in this regard to monitor any possible further deterioration, as well as to perform long-term simulation experiments.

Compared with various fossil materials, on which age determinations by racemization were made, parchment is a relatively well defined proteinaceous material. Nevertheless, our data show a wide range of D/L Asp ratios for different scrolls emanating from the same period and often even for different parts of the same scroll. Before attempting age determinations of parchment by the D/L Asp ratio, we need to understand better the mechanism of the changes involved and to develop an appropriate sampling procedure.

We thank Ms R. Yekutielli, for help and advice, also Drs A. Veis, M. Broshi and Y. Klibansky for assistance. This study was partly supported by a US–Israel Binational Science Foundation grant to S.W. and a grant by the Stiftung Volkswagenwerk to E.G.

High winter concentrations of SO_2 in the Norwegian Arctic and transport from Eurasia

Kenneth A. Rahn*‡, Einar Joranger*, Arne Semb* & Thomas J. Conway†

* Norwegian Institute for Air Research, Lillestrøm, Norway
† Graduate School of Oceanography, University of Rhode Island, Kingston, Rhode Island 02881

Since July 1977, the Norwegian Institute for Air Research has been studying trace gases and aerosols in the atmosphere at Bear Island, an Arctic site located at 74° N and 19° E. Although Bear Island lies well north of the Arctic Circle, the warm Norwegian Sea gives it an annual mean temperature of −1.8 °C, considerably warmer than at many other Arctic locations (Barrow, Alaska, for example, is 350 km farther south but has an annual mean of −12.2 °C). In summer, Bear Island is surrounded by open water; in winter there is open sea to the south and west and pack ice to the north and east. Atmospheric samples are taken 20 m above mean sea level and 2 m above local ground: high-volume filters are taken three times a week and analysed for various elements by atomic absorption, neutron activation and wet chemistry; sulphate and sulphur dioxide are measured daily by a method similar to that of Johnson and Atkins[1], using low-volume (16 m^3) prefilters for sulphate and KOH-impregnated afterfilters for SO_2. The collection efficiency of this method for SO_2 has been tested extensively[2]. Results for the high-volume samples have been reported[3]; here we discuss the SO_2 data, which seem to indicate that during winter there is efficient transport from Eurasian midlatitudes, due at least in part to long atmospheric residence times in and around the Arctic.

During summer, Bear Island has a narrow temperature range (typically 0–10 °C at noon) and persistently low concentrations of SO_2 (at or below the detection limit of 0.2 μg m^{-3}). For example, from May to October 1978 there were only 10 days with SO_2 concentrations >0.4 μg m^{-3}. During winter, however, the weather becomes more variable (temperatures range from 0 to −30 °C); SO_2 concentrations (and those of aerosol) often become much higher. For example, from November 1977 to April 1978 there were 65 days with SO_2 concentrations $>$ 0.4 μg m^{-3}. Concentrations of SO_2 are also highly episodic in winter, with about three to five irregularly spaced pulses per month. Pulse duration can vary from one day to more than a week. Between pulses, SO_2 concentrations are at the summer values, whereas daily mean concentrations in pulses reach 1–6 μg m^{-3}. Figure 1 records SO_2 concentrations from mid-December 1977 to mid-April 1978. *c* indicates probable contamination by the local diesel generator, deduced from wind observations every three hours.

Three of these pulses were associated with warm air from the south (0 to −5 °C), but 10 were associated with colder air (−10 to −30 °C). Wind direction during the cold-air episodes was typically northeastern at the surface and N–NE at 1,500-m elevation (which eliminated the possibility of local contamination from the north-west causing the high SO_2 values); wind speed was often high (>10 m s^{-1}) during cold-air episodes. During the period of Fig. 1, nearly every pulse of cold air at Bear Island had high SO_2 concentrations.

There is considerable evidence that this 'Arctic' SO_2 is derived from distant pollution sources, probably the Eurasian midlatitudes. (1) There is no correlation between the presence or elevation of local temperature inversions and SO_2 (or aerosol) concentrations, as would be expected if local sources dominated. With E–NE winds, there may be either ground-based temperature inversions or near-adiabatic profiles to a few hundred metres with an inversion above that. With W–SW winds there are usually surface-based inversions. (2) Aerosol species such as sulphate, vanadium and lead usually peak at the same time as SO_2, and have high enough concentrations (2–4 μg m^{-3}, 1–3 ng m^{-3} and 5–10 ng m^{-3}, respectively) to suggest that they have come directly from polluted areas. Of these, at least

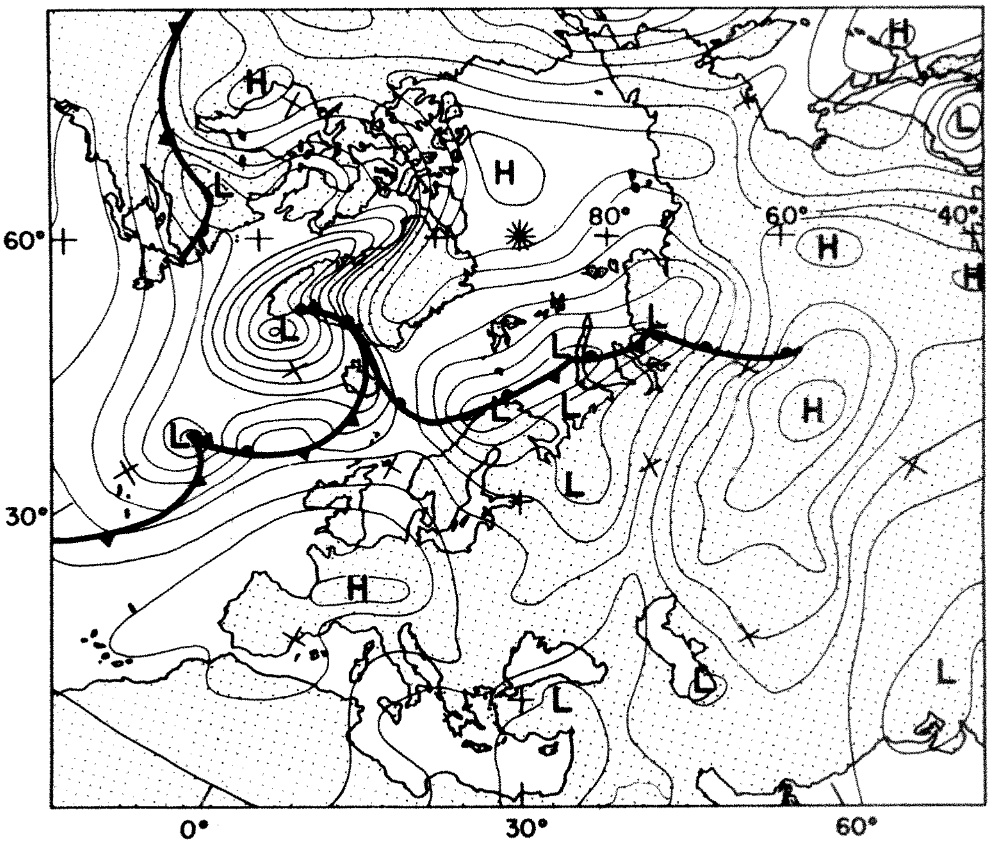

Fig. 2 Simplified surface synoptic situation for 10 March 1978, typical for cold-air episodes of SO_2 at Bear Island. H, High pressure; L, low pressure.

[illegible] Library [illegible] College [illegible] Chemistry [illegible]

vanadium has its main pollution sources in midlatitudes[4]. Occasionally, however, peaks of aerosol are not accompanied by peaks of SO_2. (3) Preliminary trajectory analysis indicates that during cold-air episodes, air flows to Bear Island around the eastward and northward sides of one or more low-pressure centres located over or just north of Scandinavia and the western USSR. A typical surface synoptic situation, for 10 March 1978, is shown in simplified form in Fig. 2. Surface-geostrophical five-day back-trajectories (which represent air flow between the surface and 1,500 m) for five high-SO_2, cold-air days at Bear Island during winter–spring 1978 are shown in Fig. 3. These trajectories, which are only rough guides to how the air masses could have travelled, indicate that for four of the five days, the air reaching Bear Island did seem to curve cyclonically around the low-pressure system, coming first from the region between Novaya Zemlya and the Taymyr Peninsula, and before that from farther south in the western USSR. Allowing for large-scale lateral diffusion, many of the densely populated areas of the western USSR and Europe are included within travel times of roughly 5–10 days. We call this the 'return-flow' pathway from Eurasia to the Norwegian Arctic.

A similar pathway to the Arctic was proposed earlier[4,5] for aerosol. The return-flow pathway is different from the 'direct-flow' pathway, where air flows northward from Europe to Bear Island, on the eastward side of a low-pressure centre located more to the south or west, and creates a warm-air episode[3]. In Fig. 1, these two types of air flow, as determined from surface meteorological maps, are indicated by 'R' and 'D', respectively.

The reason for the different character of the trajectory of 24 January 1978, which apparently came from the north, is not clear. The general synoptic situation at that time was similar to those for the other four cases of high SO_2; consequently, we think that the high SO_2 of 24 January came ultimately from the south as well. This illustrates the uncertainties of meteorological analysis in the Arctic, where weather stations are spaced widely.

The five trajectories for days of low SO_2 came from other directions. Three originated north and east of Bear Island, one came from North America via the North Atlantic, and one even came from Scandinavia and Europe. The trajectory of 6 February, which seemed to bring very low SO_2 from Europe, is another problem. It came a few days after a strong direct episode, but with considerably weakened pressure systems by the time it had reached northern Norway. Aerosol concentrations were still one-third to one-half of their values at the peak of the episode, but for some reason, SO_2 had decreased to more than an order of magnitude below its peak.

It seems, however, that rapid transport along the return-flow pathway from Eurasia to the Arctic is insufficient to explain the high winter SO_2 there; long atmospheric lifetimes also seem to be required. Transport times from Eurasia to Bear Island of 5–10 days, initial SO_2 concentrations of 30 $\mu g\ m^{-3}$ (mean winter values for the industrialized countries of Europe[6,7], probably an overestimate for Europe as a whole), dilution of the polluted air mass by a factor of four during transport (derived from simulations of aerosol transport to Bear Island, probably an underestimate), and a final SO_2 concentration of 3 $\mu g\ m^{-3}$ at Bear Island require that mean residence times during transport be 5–10 days. If the residence time increases during transport, as is likely, an initial value of 2–5 days at the source is still needed to explain the measured SO_2 concentrations. In contrast, currently accepted atmospheric residence times for SO_2 in Europe are 1–2 days[8–11]. Thus, winter residence times for SO_2 in Eurasia would seem to be up to five times longer than annual mean values, and in the Arctic of the order of weeks.

There are good physical and chemical reasons for these long residence times. In Eurasia, the residence time for SO_2 is determined primarily by the rate of dry deposition to the surface, secondarily by precipitation scavenging, and to a still lesser extent by the rate of oxidation to sulphate. In Arctic (or cold continental) winter conditions, all these rates should be very slow, because: (1) The rate of dry deposition decreases with increasing stability of near-surface air and surface smoothness; low values have been measured over snow[12]. (2) Wet deposition of SO_2 should be small during winter in the Arctic because of the slight precipitation there, typically only 5 mm per month. (3) Heterogeneous oxidation of SO_2 in Arctic cloud droplets ought

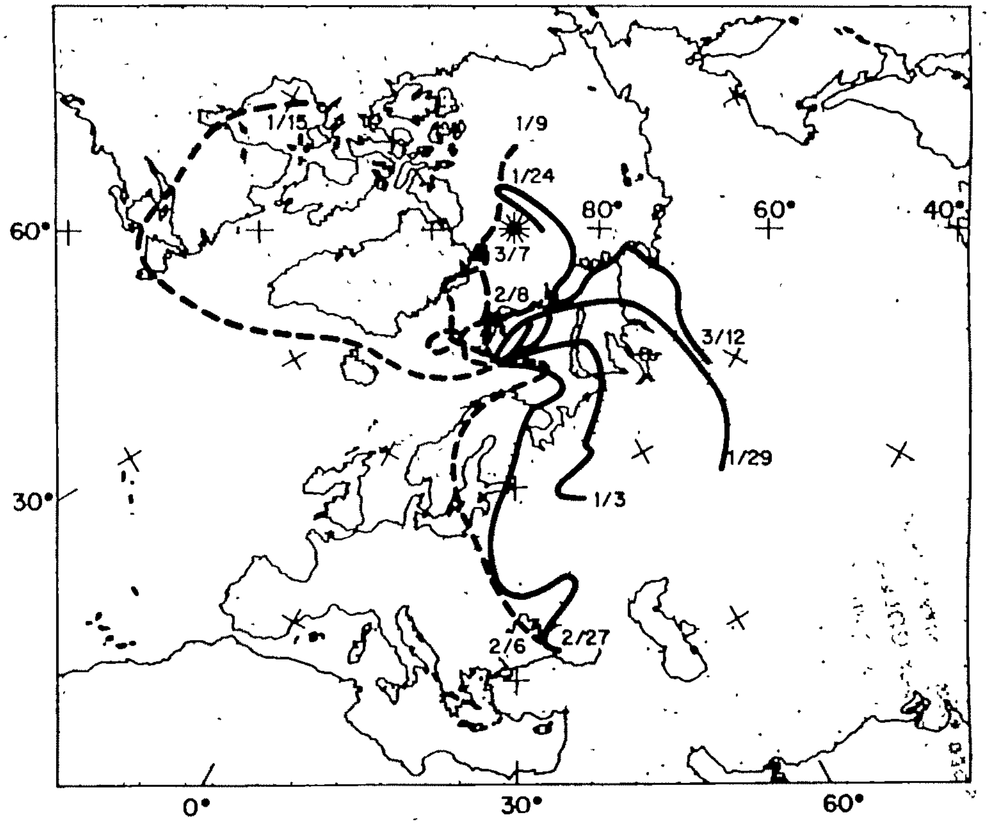

Fig. 3 Five-day surface geostrophic back-trajectories for cold-air episodes (solid line) and periods of low concentration (broken line) during winter 1977–78. Dates of arrival at Bear Island are indicated.

to be very slow because of the low temperatures, the low frequency of clouds, their restricted vertical extent, their small liquid–water content, and the meagre amounts of trace elements such as Mn and V available as catalysts (30–40 times less than in midlatitude air masses). This oxidation rate may decrease as an air mass ages, because acidity produced in the droplets limits the subsequent solubility of SO_2. (This decrease ought to be greatest over oceans and cold continents, where little NH_3 is available to neutralize the increasing acidity (C. Brosset, personal communication).) (4) Lastly, homogeneous oxidation of SO_2 by the OH radical ought to be extremely slow during the Arctic night because of the lack of direct solar radiation.

Similarly long lifetimes for aerosol in and around the Arctic have been deduced recently[4]. When combined with the long lifetimes for SO_2, they begin to explain how gaseous and particulate sulphur can be efficiently transported northward from midlatitudes during winter and dispersed over the entire Arctic.

This case illustrates just how sensitive the atmospheric rates of transformation and removal of the various forms of sulphur may be to climatic properties. In 1977 the Dubrovnik workshop on atmospheric sulphur[13] recommended that attention be given to these seasonal and regional variations for the sulphur system. Now that long-range transport of gases and aerosols through highly different climatic zones is known to be a regular feature of the atmosphere, such attention becomes mandatory, and should be extended to other species.

This work was supported jointly by the Norwegian Institute for Air Research, a fellowship to K.A.R. from the Royal Norwegian Council for Scientific and Industrial Research, the Office of Naval Research (contract N00014-76-C-0435), and NSF grant DPP77-27242. We acknowledge helpful discussions with B. Ottar and H. Dovland.

The UK wave energy resource

A. J. B. Winter

Energy Technology Support Unit, AERE Harwell,
Oxon, OX11 ORA, UK

Previous estimates[1,2] of wave energy around the United Kingdom have been made by extrapolating measurements from a few sites to the whole UK seaboard. Here directional wave spectra are used from a numerical wave model developed by the Meterological Office[3], to make estimates which are verified where possible by observation. It is concluded that around 30 GW of power is available for capture by wave energy converters: when estimates of converter spacing and efficiency are considered an average of about 7 GW of electrical power could be supplied. This resource estimate is smaller than previous ones, though consistent with them when factors such as the directional properties of waves and the likelihood that converters will be sited near coasts are included.

The first reliable wave measurements were made by weatherships at Ocean Weather Ship Station 'India' in the North-west Atlantic, 710 km west of the Outer Hebrides. The power density at this location has been estimated at between 80 kW m^{-1} (ref. 4) and 91 kW m^{-1} (ref. 2), to give a UK resource of about 120 GW (ref. 1). In 1976, the Institute of Oceanographic

Sciences[5] installed a waverider buoy 18 km west of South Uist, in 42 m of water. This has supplied the standard wave climate for evaluation of wave energy schemes[6,7], and the expected long-term average power density is 48 kW m^{-1} (ref. 6). In estimating the resource, account must be taken of the directional properties of waves: all the measurements referred to above have been of water-surface elevation at a point, and refer to the total power crossing a vertical cylindrical surface of 1-m diameter in the sea from all directions. Thus, the power density falling on a line of converters whose normal is at an angle θ to a given wave direction is $P \cos \theta$ where P is the power density measured by a non-directional instrument. Power usually arrives from a range of directions; this is referred to as a 'spread' sea. For a given orientation of a line of converters, the incident power per unit length is the integral of the product of the power flux in each directional component of the incident waves and their $\cos \theta$ factors. The ratio of this power to the non-directional power flux as defined earlier is termed the 'directionality factor', and is less than unity. The incident power density P crossing a line in the sea is then

$$P = p\delta \quad \mathrm{kW\,m^{-1}}$$

where

$$p = \int_{-\pi}^{\pi} p(\theta)\,\mathrm{d}\theta \quad \mathrm{kW\,m^{-1}}$$

is the incident power density from all directions and

$$\delta = \frac{1}{p}\int_{-\pi/2}^{\pi/2} p(\theta)\cos\theta\,\mathrm{d}\theta$$

is the directionality factor, usually integrated over waves crossing the line from one side only, as few wave energy converters absorb significant wave energy from behind. (This is not usually a significant restriction as near the coast few waves are generated travelling away from land.) If the converter line is oriented to intercept the maximum possible power (that is it faces the 'best direction'), then the directionality factor is a measure of the range of wave directions present. Off the Hebrides, for example, the best direction is close to west and the directionality factor is ~0.76.

Data used here are from the Meteorological Office depth-dependent wave forecasting model, developed by Golding[3]. In this model, surface winds over the sea are used to calculate wave spectra. Wind data are from the Meteorological Office 10-level atmospheric model, and wave fields are calculated on a 50-km grid covering the North Sea and most of the North Atlantic. The effects of energy loss and spreading mechanisms such as wave breaking, refraction and an idealized model of bottom friction are included. The resulting directional wave spectra are calculated every 30 min and archived every 12 h, and comprise spectral estimates at six frequencies (0.05–0.15 Hz) for each of 12 directions (that is, a 30° sampling interval) for every grid-point. The integrals referred to earlier have been calculated by summation over those directions. Results used here are from December 1977 to September 1979, the first two years of the model's operation. The gridpoints selected for analysis are

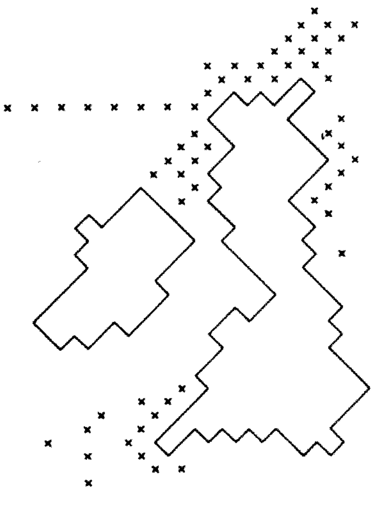

Fig. 1 The UK as it appears in the model. ×, Gridpoints where the archived wave spectra have been analysed; data for a gridpoint near OWSS 'India' have also been analysed.

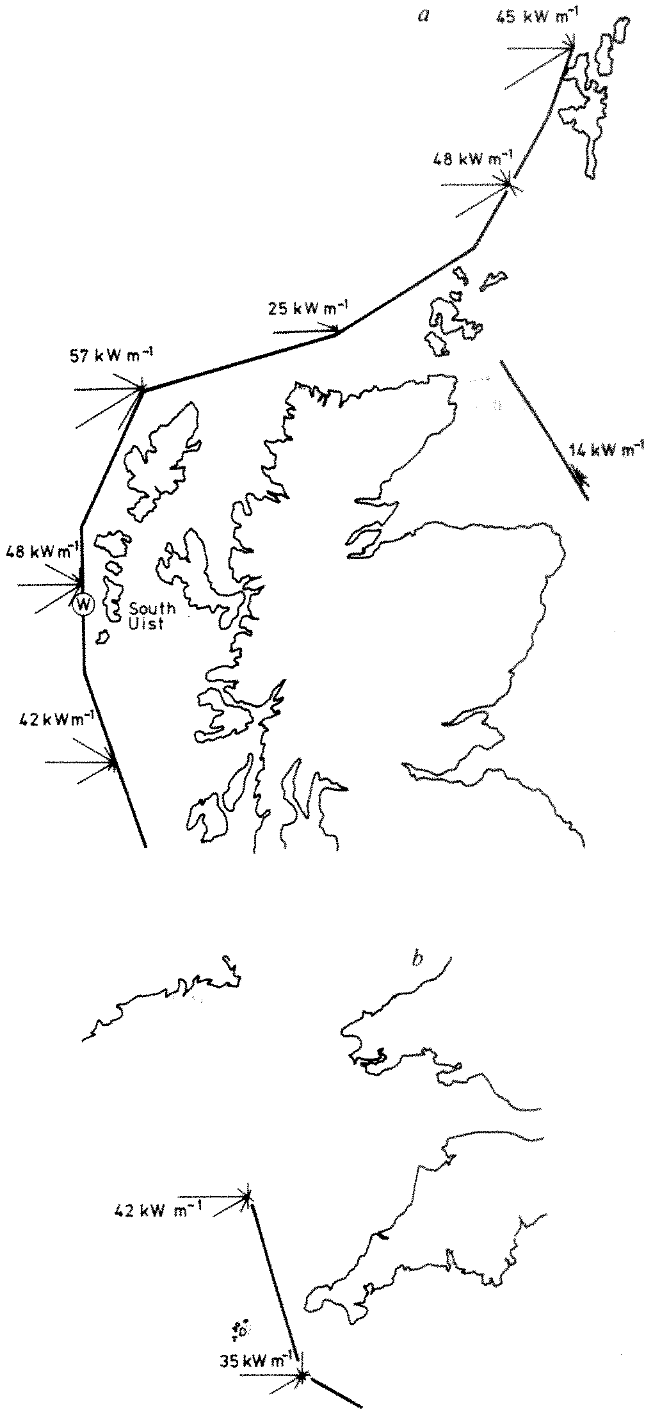

Fig. 2 *a*, Wave power at various gridpoints around the Scottish coasts. The numbers give average non-directional power density over the two years of data and the 'crows-feet' indicate the directional breakdown. The length of the direction bars in each crows-foot is proportional to the average power density arriving from a 30° sector centred on that direction. W, The location of the South Uist waverider. *b*, Wave power around the south-west of England. The heavy lines represent locations where it has been suggested that wave energy converters might be sited.

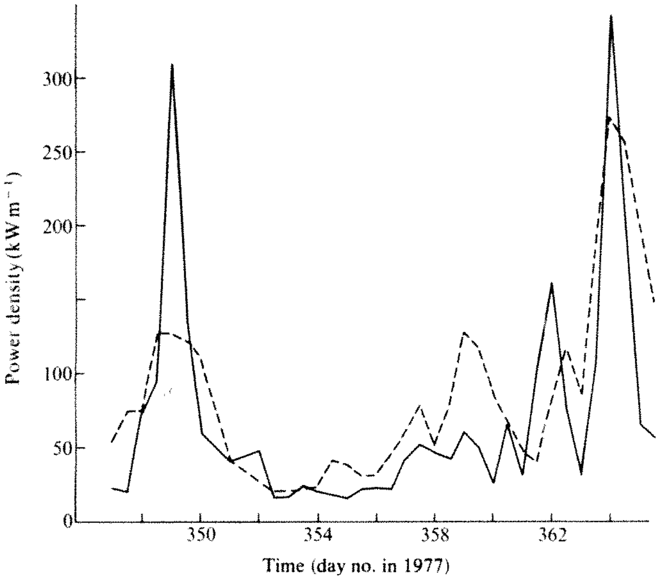

Fig. 3 Wave power density during part of 1977: measured by the waverider buoy at South Uist (solid line); results from the nearest model gridpoint (dotted line).

shown on Fig. 1. Evidently a 50-km gridpoint spacing is not fine enough to reproduce the convolutions of our coasts. To increase the accuracy of the model near the coast, the following procedure was adopted. Gridpoints were drawn on the 'real' maps (Fig. 2) at their correct positions where possible. If this was on land on the real maps (but in water in the model) or behind a real island which could not be reproduced in the model, then that gridpoint was displaced slightly when drawn on Fig. 2. In all cases, when calculating power levels the only directions used were those from which gridpoints as drawn on Fig. 2 could accept energy. This modification matches the coarse grid of Fig. 1 to the detailed coast shown in Fig. 2. It is applied after the wavefield has been computed, and does not affect refraction around headlands due to changes in bottom topography.

Figure 3 shows a time series of power for the South Uist waverider and the nearest model gridpoint, for 20 days in 1977. There are three points of interest. First, the model power levels are greater than the measured values in low-sea states, but less in high-sea states. Second, there is evidence of time shifts between the model and the waverider measurements, and finally high power levels develop sooner and die away more slowly in the model. These effects mean that when instantaneous model results are plotted against measured values they show a large scatter: this is reduced significantly if values for several consecutive time periods are averaged before being plotted. Figure 4 compares measured values and model results for South Uist. Each point represents the average power over a 2.5-day period: simultaneous observations and model results were available for 140 days in 1978. Figure 4 shows that the model gives slightly higher power levels than the waverider up to ~100 kW m^{-1}. Above this power level, the trend is reversed. The average power levels over the 140 days of the comparison were in very good agreement. The waverider measured 49 kW m^{-1} and the Meteorological Office model gave 52 kW m^{-1}. Note that the expected long-term average power level at South Uist is 48 kW m^{-1} (ref. 6), implying that the wave climate over the comparison period was representative of the long-term average. There are few other sites where direct comparisons are possible, because of the limited number of instrumental wave measurements made during 1978–79. If it is assumed that the wave climate in 1978–9 was representative of the long-term average, then the wave power at OWSS 'India' may be compared. Mollison *et al.*[2] give a weighted average power of 91 kW m^{-1} for this location: the nearest model grid point gives 96 kW m^{-1}. The Meteorological Office model is, therefore, accurate enough to determine the average power levels around the United Kingdom.

It should be emphasized that the power densities given below refer to power crossing the heavy lines in Fig. 2. For comparison, the power densities shown on various locations in Fig. 2 are omnidirectional power densities. The north-west line extends for 820 km from Islay, around the Hebrides to the Shetlands. The average power flux crossing the line is 24 GW, at a density of 29 kW m^{-1}. This value is lower than that suggested by non-directional measurements such as the 48 kW m^{-1} shown on Fig. 2*a* for South Uist: one reason is that a large fraction of the line (Cape Wrath to the Orkneys) does not face the best direction. In contrast, the section of the line around the Hebrides up to Lewis could provide 12 GW at a power density of 39 kW m^{-1}. This section faces approximately the best direction, and its directionality factor is 0.73, implying that most of the wave energy arrives from due west. The north-east line is often[4,7] drawn across the mouth of the Moray Firth, and is about 110 km long with an average power flux of 0.65 GW. The power density is only 6 kW m^{-1} and the directionality factor 0.52. These low values arise mainly from the absence of swell, which accounts for some 65% of the wave energy on the west coast[6]. Weather patterns in the North Sea are less consistent than in the North Atlantic, and the spread of wave directions is much larger in the North Sea. If the line were extended southwards by 340 km from Peterhead to Scarborough, the average power flux across the extension would be 1.9 GW, at a power density of 5.5 kW m^{-1}. The south-west line is 190 km long and the average power flux across it is 4.9 GW, at a density of 25 kW m^{-1}. This is comparable to the level off the Hebrides and supports the idea that a large fraction of the energy is received in the form of swell generated by depressions travelling across the Atlantic.

Wave power levels at OWSS 'India' are much higher than those at South Uist, close inshore. Figure 5 shows the variation of power with shore distance off the Hebrides. Curve *a* indicates total (non-directional) power density; curve *b* indicates the product of power times directionality factor, which is roughly constant over the whole range of distances. This suggests that the reason for higher power levels at OWSS 'India' is that the power arrives from a larger range of directions there, a conclusion supported by curve *c* which shows the power density arriving from directions centred on 240° ± 45°. This is actually

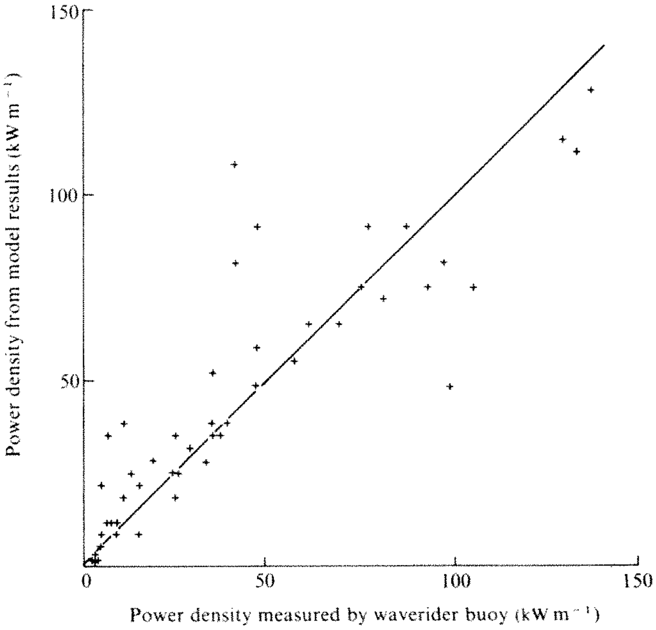

Fig. 4 Measured power densities plotted against model power densities. Each point represents the average values over a 2.5-day period, from a comparison of 140 days in 1978. The straight line has a slope of unity.

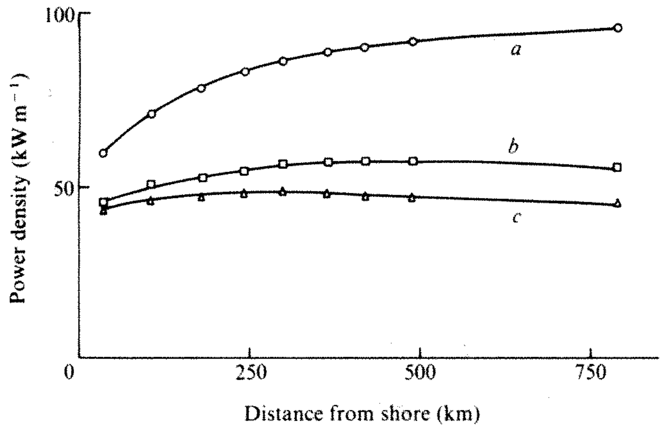

Fig. 5 Wave power as a function of shore distance, using the gridpoints extending westward from the Hebrides, shown in Fig. 1. Curves: *a*, the total power density from all directions; *b*, the product power times directionality factor; and *c*, the power arriving from directions centred on 240° ± 45°.

somewhat less at OWSS 'India' than at intermediate distances, probably because the westerly fetch for a typical depression is less there.

If ideal wave energy converters were sited on the lines shown in Fig. 2, the estimated wave energy resource would be 29 GW (annual average). Using this as an input figure, it is possible to estimate the contribution that such a scheme could make to the UK energy supply. There are two factors which would reduce the output of a large wave energy scheme. The first is that it would not be possible to install converters along the entire length of the lines shown in Fig. 2. Siting and mooring considerations imply that gaps must be left between individual converters; some parts of the lines could not be used as they intercept shipping lanes. It is difficult to quantify these factors at present. I assume here that 80% of the lines in Fig. 2 can be filled with converters.

The second factor arises from the low efficiency of converters. Most can capture 25% of the incident energy (averaged over a typical year), although it is possible that 30% can be achieved (S. Salter, personal communication). Taking values of 80% for the first factor and 30% for the second, the average power delivered would be 7 GW, ~25% of the CEGB's average power output. Siting converters further from the coast is unlikely to increase this substantially. As Fig. 5 shows, higher power further offshore comes from a larger range of directions; the power density crossing a line is largely independent of distance offshore. The suggestion that the resource could be significantly increased by deploying parallel lines of converters off the Hebrides is also debatable. Most of the wave power is in the form of swell, which would not be regenerated in a short fetch. The wind sea that might be regenerated could have a large directional spread, making capture less efficient because of the low directionality factor.

I thank Brian Golding, John Crabb and Technical Advisory Group 2 of the Wave Energy Steering Committee for helpful discussions, and the Department of Energy for permission to publish this paper.

North Pacific palaeoceanography: late Quaternary coiling variations of planktonic foraminifer *Neogloboquadrina pachyderma*

Peter R. Thompson

Lamont-Doherty Geological Observatory of Columbia University, Palisades, New York 10964

Nicholas J. Shackleton

Sub-Department of Quaternary Research, The Godwin Laboratory, Cambridge University, Cambridge CB2 3RS, UK

Intraspecific coiling variations of the planktonic foraminifer *Neogloboquadrina pachyderma* (Ehrenberg) form an important micropalaeontological technique for the palaeoclimatic interpretation of late Cenozoic mid-latitude marine sediments. In all the modern oceans, this species preferentially coils dextrally in subtropical to temperate latitudes and sinistrally in subpolar to polar latitudes[1,2]. Plankton[3–5] and surface sediment studies[6–20] of the North Pacific clearly associate sinistral populations with subarctic water masses and dextral populations with temperate-subtropical regions. Here we show that down-core ratios of sinistral to dextral coiling, when correlated with oxygen isotopes, indicate major late Quaternary southward advances of the subarctic boundary (polar front) and the Oyashio Current during oxygen isotope stages 2, 4 and 6.

Advective circulation of western boundary currents such as the Gulf Stream and the Kuroshio Current serves to transfer warm saline water (and the associated warm moist air) to temperate latitudes of the Northern Hemisphere. The Kuroshio is probably the most important ocean current influencing the climate of eastern Asia and, ultimately, of western North America. The deep-sea sediments of the north-west Pacific record the history of the major trends of this climate pattern as the responses of the marine organisms to the ambient temperature.

The planktonic forminiferal species *N. pachyderma* (Ehrenberg) is one of the most useful of such biostratigraphic tools for the interpretation of late Cenozoic marine sediments in high- and mid-latitudes. This species preferentially coils its test dextrally in subtropical to temperate latitudes and sinistrally in subpolar and polar seas[1,2]. The general plankton distribution of *N. pachyderma* is known for the North Pacific[3–5] and its occurrence in surface sediments has been mapped[6–19]. Here we describe the biogeographic distribution of the two coiling types for the northwestern Pacific from the total faunal analyses of more than 150 surface sediment samples[20] and the down-core coiling variations of 11 Quaternary piston cores (Table 1). The timing of the down-core coiling variations has been determined by correlation with the oxygen isotopic records of many of the cores and by the recognition of biostratigraphic datum levels in all of them.

Table 1 Cores used in the study

Core	N. latitude	E. longitude	Depth (m)	Isotopic refs	Palaeontological refs
V20-119	47°57′	168°47′	2736	23, 22	13, 20, 22
V21-146	37°41′	163°02′	3968	23, this work	14, 20
V28-294	28°26′	139°58′	2308	23	20

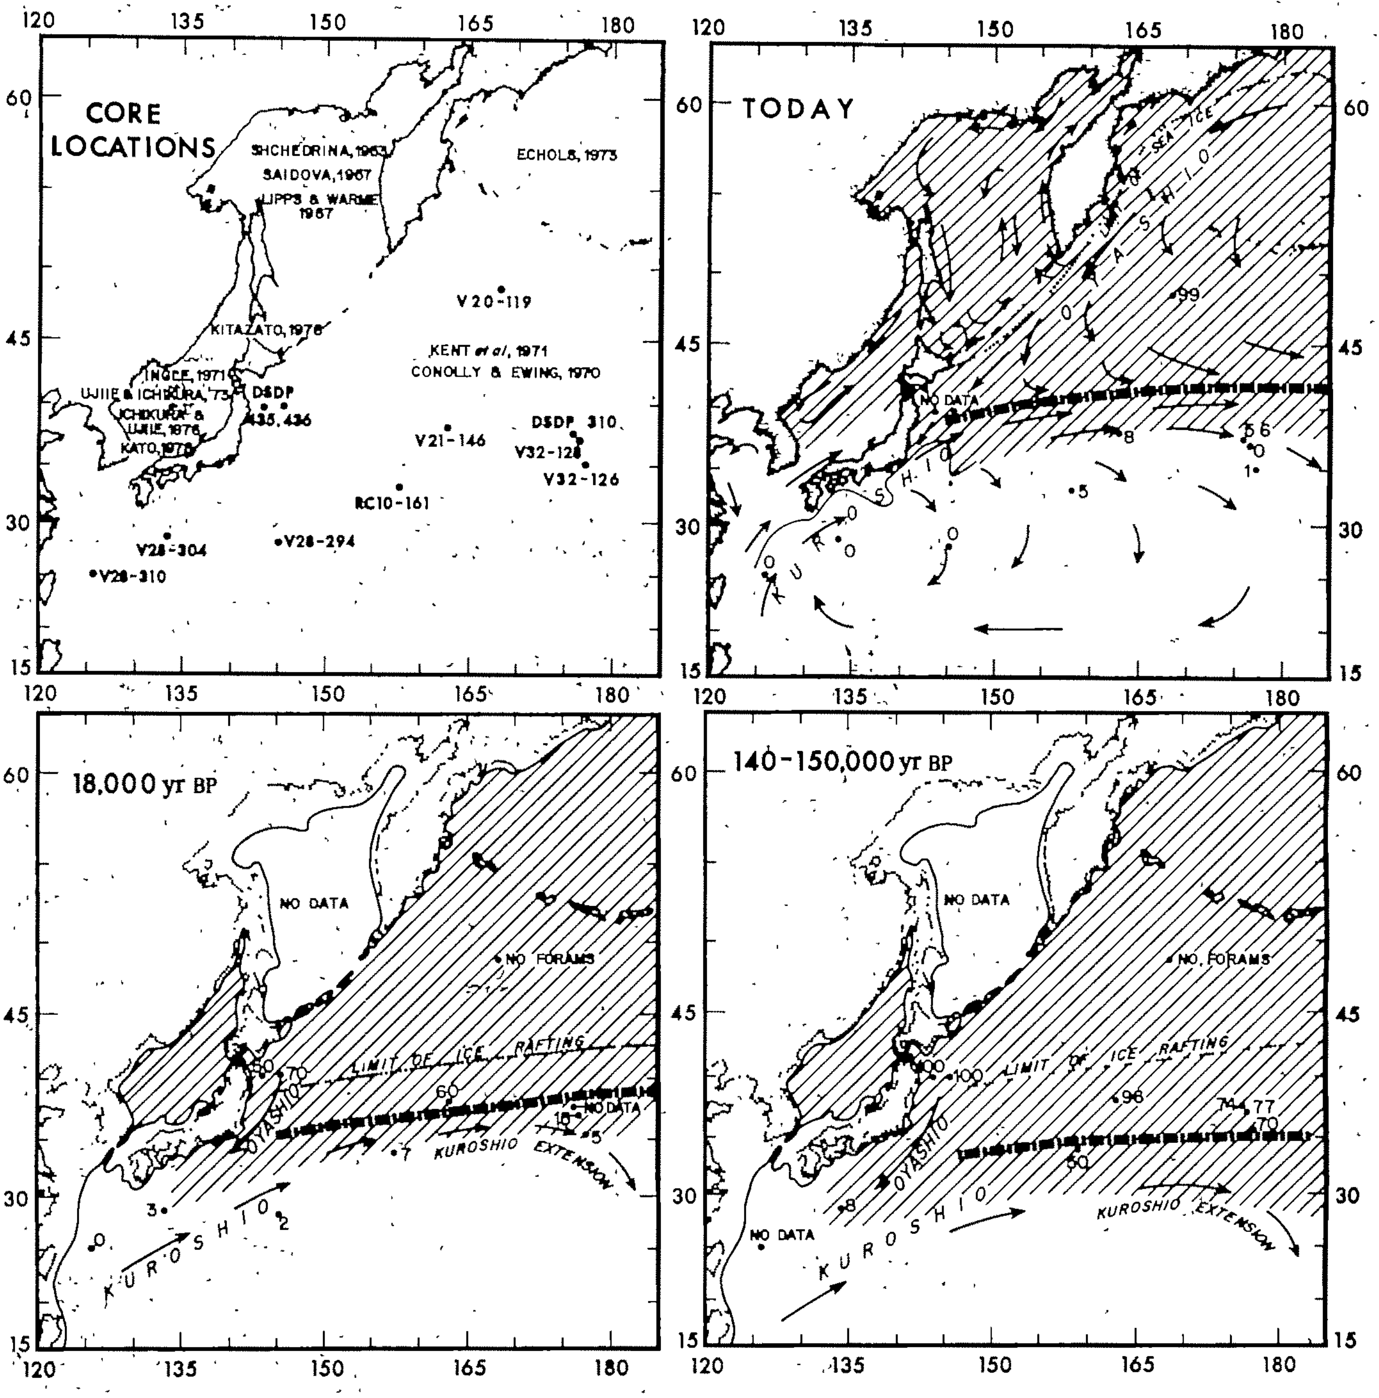

Fig. 1 Core locations and distribution of *N. pachyderma* in north-west Pacific. Upper left: core locations (see Table 1) and areas of previous study (refs 8–20, 33–36). Upper right: modern seabed percentage distribution of sinistral *N. pachyderma* relative to surface currents (arrows), position of subarctic boundary (heavy dashed line), and sea ice (dotted line). Lower left: 18,000-yr-BP position of subarctic boundary based on percentage of sinistral *N. pachyderma*, ice-rafted detritus[26] and sea-level drop of 120 m. Lower right: 140,000–150,000-yr-BP position of subarctic boundary.

The southern seabed limit of *N. pachyderma* is well defined along the western Pacific margin, where coring sites are closely spaced and the shallow depths of the locations minimize carbonate dissolution. The percentage frequencies of the species are very low at tropical sites, and frequencies do not exceed 1% south of 30° N. They account for 15–20% of the total fauna near Japan, however. Along the northern part of the Izu-Marianas Ridge and the area north of Taiwan, the dominant coiling mode is dextral. These individuals have 4.5–5 chambers in the final convolution forming a sub-rhomboidal outline; the surface of the test is non-spinose and coarsely reticulate. Dextrally coiled *Neogloboquadrina eggeri* (Rhumbler) (= *Neogloboquadrina dutertrei* of some authors) is also present in these sediments, but can be easily recognized as it has more than five chambers in the final whorl and an umbilical tooth in the apertural depression—*Neogloboquadrina pachyderma* has an apertural rim flush with the outer surface of the final chamber.

Near the confluence (about 35° N, 145° E) of the warm, saline and northward-flowing Kuroshio Current and the cold, low-salinity and southward-flowing Oyashio Current, small proportions (less than 2% of total fauna) of sinistrally coiled *N. pachyderma* first occur in surface sediments together with the more abundant dextral forms. Further east beneath the axis of the Kuroshio Extension (35–40° N, east of 155° E), central North Pacific populations are predominantly dextrally coiled and account for about one-third of the planktonic foraminiferal assemblage of the surface sediments.

North of latitude 40° N and along the continental shelf of

Japan north of about 36° N, populations of *N. pachyderma* are almost exclusively sinistral, and planktonic foraminiferal assemblages are often nearly monospecific. Individuals typically have four chambers in the final whorl, giving the shell a quadrate outline; about 1–2% of the *N. pachyderma* tests are dextrally coiled but have the quadrate, four-chambered arrangement of the sinistral type.

There is some difficulty in associating an exact temperature with the changeover from dextrally coiled to sinistrally coiled populations of *N. pachyderma.* Because of the wide seasonal contrasts of sea-surface temperatures in the western North Pacific in mid-latitudes[21], the changeover takes place where the annual range of temperature is 20 °C. There is no gradual shift of coiling direction, however, in the few sediment samples that have been recovered from this region: instead, there appears to be an abrupt switch from predominantly dextral coiling south of the subarctic boundary (polar front) to predominantly sinistral cooling north of it. Bradshaw[3] mapped the maximum plankton abundance of *N. pachyderma* (probably quadrate sinistral forms) as lying between 44 and 48° N, corresponding to an annual sea-surface temperature range of 2–15 °C. In the north-eastern Pacific between 44 and 48° N, Banerji[5] observed a change in plankton coiling directions at about 7–10 °C. These data are in good agreement with the observations of Bé[2] that the species is typically found in Antarctic seas between −1 and 8 °C, and most abundantly below 2 °C. Sea-surface temperatures in the region of dextrally coiled *N. pachyderma* have an annual range of 15–25 °C, clearly indicating two separate biogeographic populations that may be mixed only along a narrow region of the subarctic boundary.

Although temperature is a classically cited influence on the distribution and diversity of marine organisms, additional factors such as salinity, dissolved oxygen and nutrient availability, are also important. The physical boundaries for planktonic populations appear to be those of water masses characterized as large regions of fairly homogeneous properties. Thus it seems unwise to define a boundary between the coiling modes of *N. pachyderma* based on sea-surface temperature alone; rather, it is more useful (until plankton studies can be made at different seasons) to consider the coiling types as characteristic of the adjoining subarctic (sinistral) and subtropical (dextral) water masses. On either side of the subarctic boundary, coiling populations are distinct, as are the oceanographic properties of the water masses. The area of mixed coiling directions then represents a narrow transitional region where the two populations are mixed, perhaps seasonally or in response to the

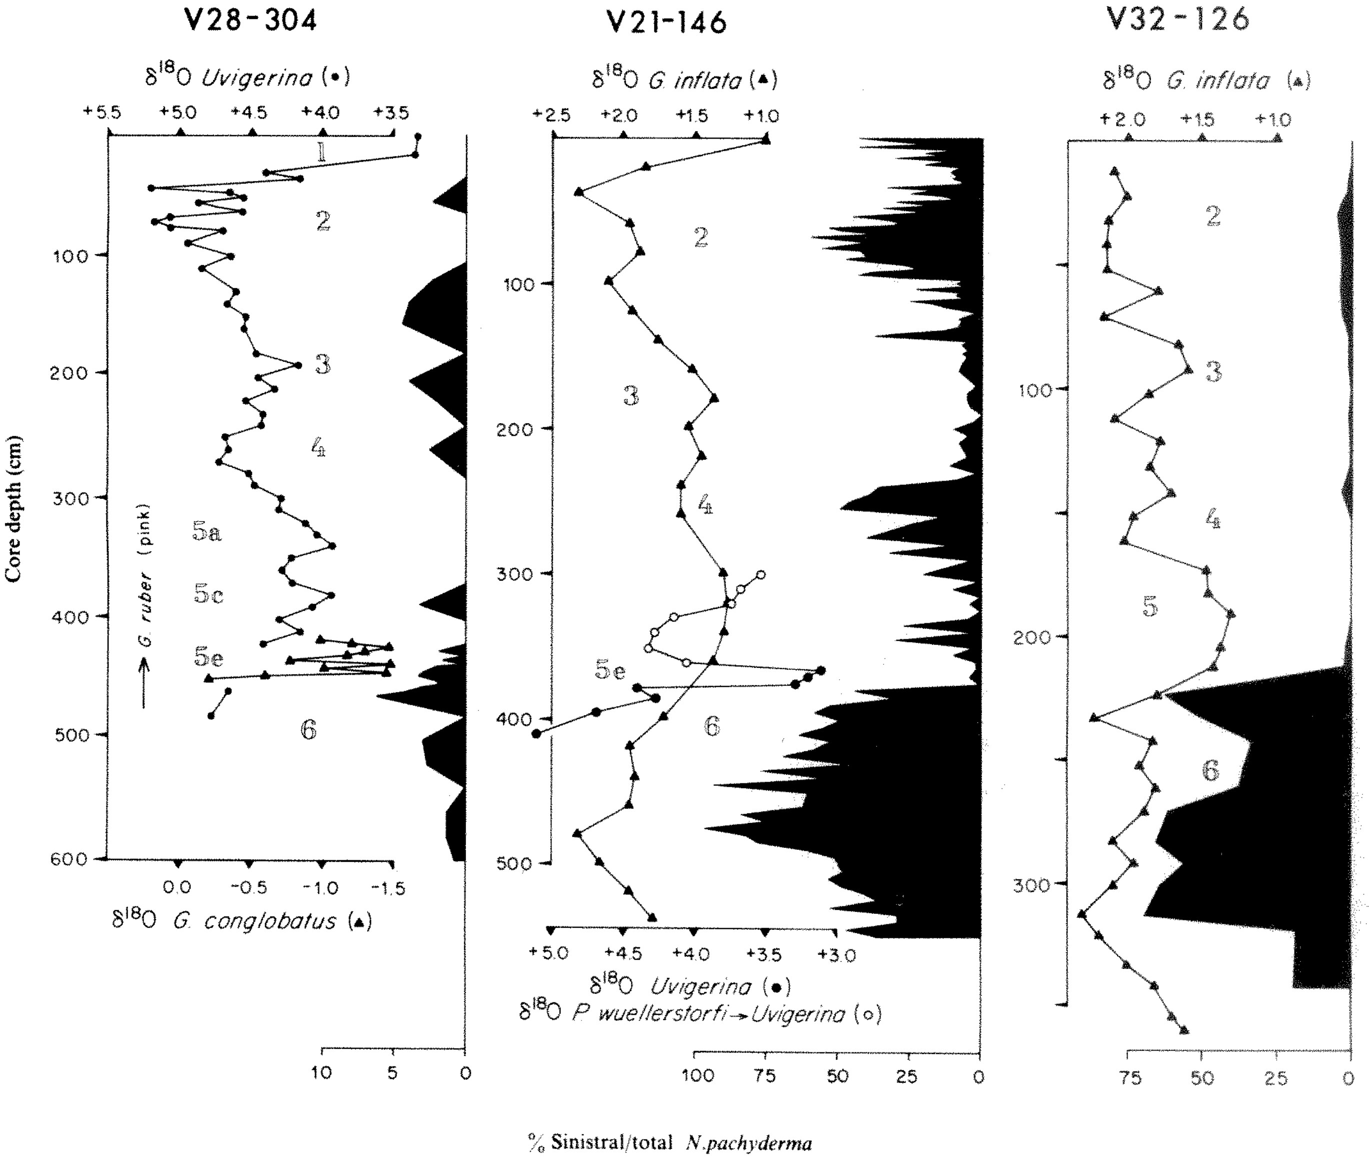

Fig. 2 Coiling ratio of sinistral to total *N. pachyderma* (shaded) versus oxygen isotopes (relative to PDB standard) for *Uvigerina* (solid circles), other benthic taxa (open circles) and planktonic taxa (solid triangles).

variable location of the many meanders and eddies along the confluence, and is further homogenized in the sediments by bioturbation over a long period of time.

Five of the six carbonate-rich piston cores (Table 1) were selected for both palaeontological and isotopic study because of their location on topographically positive features beneath the present-day axis of the Kuroshio Current and Extension; core V20-119 was retrieved from the Emperor Seamount Chain and represents a unique carbonate section available from the subarctic water mass[13]. Given the locations of the cores, we expected that down-core coiling variations of *N. pachyderma* could be interpreted as representing major fluctuations of flow within the Kuroshio gyre system, southward advances of the subarctic water mass or changes in carbonate preservation through time. (Total faunal analyses were made on plankton foraminiferal assemblages which will be described elsewhere.) Fluctuations of oxygen isotopic values are considered to monitor global ice volume[22,23] and are believed to be virtually isochronous within the time resolution of the sedimentary record.

Piston core V21-146 (ref. 14), located just north of the present southern limit of the subarctic boundary, contains the most detailed record of coiling variations (Fig. 2). The strong sinistral peaks at 70 cm (60% sinistral) and at 450 cm (96%) are associated with oxygen isotope stages 2 and 6 respectively, while dextral maxima are well defined in isotopic stages 1, 3 and 5. The topmost centimetres of the core show a return to sinistral coiling which may be interpreted as marking the period of recent climatic cooling since the Climatic Optimum at about 6,000 yr BP. Although the planktonic foraminiferan *Globorotalia inflata* was used throughout the core for isotopic analyses, benthic foraminiferal taxa were used to provide the details across the 5/6 transition, including *Uvigerina* and *Planulina wuellerstorfi* (corrected to *Uvigerina* by +0.64‰).

The piston cores located south of the present subarctic boundary [RC10-161 (Shatsky Rise)[17], V32-126, V32-128 and DSDP Site 310 (Hess Rise)[18]] are marked by dextral coiling interrupted by sinistral maxima. In these cores, the dramatic shift of the coiling dominance of *N. pachyderma* at the glacial intervals so prominant in V21-146 is not apparent. Only the major sinistral peak in V21-146 during oxygen isotope stage 6 can be widely recognized in cores south of the present polar front. The stage 2 sinistral peak seen in V21-146 is weak in the southern cores; the stage 4 sinistral peak, which is only moderate in V21-146, often cannot be located.

Along the western margin of the Pacific coast of northern Japan, DSDP Site 435 (ref. 24) has a moderate ratio of dextral to sinistrally coiled *N. pachyderma* near the top of the sequence, which gradually becomes entirely sinistral throughout the remainder of the downcore Pleistocene. Piston core V28-304, located beneath the axis of the Kuroshio south of Japan, shows very weak (< 10% sinistral) peaks (Fig. 2); the stage 6 peak can be identified only by its isotopic position. Here, the details of the 5e/6 transition were determined by analysis of *Globigerinoides conglobatus* because of the curious absence of *Uvigerina* in that part of the core. A weak sinistral peak correlated with stage 2 is present, but there are also several additional sinistral pulses during stage 3, which was expected to be dominantly dextral. Core V28-310, located south-east of core V28-304, has no isotopic record; correlation with core V28-304 using the extinction of pink-pigmented *Globigerinoides ruber* at 120,000 yr BP (ref. 25), did not reveal any sinistrally coiled *N. pachyderma* within the past 150,000 yr. Core V28-294, east of core V28-304, has a short stratigraphic record which does not extend to the pink *G. ruber* datum level and the oxygen isotope record identifies a weak sinistral peak in stage 2.

Core V20-119, from the centre of the subarctic water mass (Table 1), contains only sinistrally coiled *N. pachyderma* which vary in absolute abundance (Fig. 2) from over 70,000 tests per gramme near the top of the core to totally barren intervals. These barren sections, when correlated to the oxygen isotope record[22], are of glacial age. Although ice-rafted detritus is quite common in these same glacial sections[26], the sedimentation rate does not differ greatly from that of the interglacial intervals. Moreover, carbonate dissolution does not account for the absence of both planktonic and benthic foraminifera for there is no increase in fragmentation before or after the barren region; in any case, dissolution studies[27] indicate that carbonate dissolution is more intense in interglacial periods than in glacial stages. In this case, however, diatom abundances are increased in the glacial sections[28], suggesting a shift in the areas of diatom and planktonic foraminiferal production.

In the CLIMAP 18,000-yr-BP reconstruction[29], we noted that the sea-surface cooling at the last glacial maximum was small over most of the Pacific in comparison with the Atlantic, although in the region near the Pacific coast of Japan sea-surface temperature gradients were quite steep. The down-core distribution of sinistrally coiled *N. pachyderma* during isotopic stage 2 (as well as stages 4 and 6) supports the contention that the steepened gradient was the result of a southward advance of the polar front. In the modern ocean, the polar front overlies sediments containing 10–20% sinistral-to-total *N. pachyderma*; the water mass boundary (Fig. 1) for the past reconstructions has been drawn to correspond with such a ratio. Down-core increases in the sinistral-to-total ratio (Fig. 2) require that the subarctic boundary be moved to a location between 35–38° N during the stage 2 glacial and to about 32–35° N during the stage 6 glacial. South of Japan, core V28-304 marks the southernmost extent of the glacial advances of sinistral *N. pachyderma*, which implies drastic southward penetrations of the Oyashio Current (possibly as a submerged current[30]) along the coast of Japan. Mollusc[31] and pollen[32] records of the Pleistocene of Japan indicate a cold dry climate as far south as Tokyo. A eustatic closure of the Sea of Japan eliminated the warm Tsushima Current and glacial sections from the Sea of Japan contain only sinistrally coiled *N. pachyderma*[33–36].

The depositional centre of abundant sinistral *N. pachyderma* moved from near core V20-119 at about 50° N to about 45° N near core V21-146 during the late Pleistocene glacial advance (Fig. 2). The decrease in absolute abundances of both planktonic and benthonic foraminifera in core V20-119 and the accompanying increase of diatoms in glacial isotopic stages 2 and 6 may indicate substantial circulation changes in the subpolar gyre resulting in southward shifts in the locations of pelagic habitats. Species common to modern Sea of Okhotsk sediments such as *Globigerinita uvula* and *Turborotalita quinqueloba*[11] become prominent members of glacial faunas of cores V21-146, V32-126 and V32-128. The dominance of sinistrally coiled *N. pachyderma* at these sites is evidence for the prevalence of modern winter conditions over this area during most of the year.

In contrast, the interglacial maximum at isotopic stage 5e appears to have been somewhat warmer than today. As well as the dominance (up to 100%) of dextrally coiled *N. pachyderma* in both the tops and stage 5e of many cores (Fig. 2), there are many warm-water planktonic species in stage 5e samples, including *Globigerinoides conglobatus, Globorotalia truncatulinoides* and *Orbulina*. These species appear at low frequencies as far north as core V20-119, suggesting that the subarctic boundary may have been placed north of its present position, but the lack of foraminifera-bearing sediments precludes a firm conclusion.

We thank M. A. Hall for operating the mass spectrometer, and G. Wollin, W. Ruddiman and C. Sancetta for helpful discussions. Occurrence of hydroxamate siderophore iron chelators in soils

P. E. Powell*, G. R. Cline†, C. P. P. Reid† & P. J. Szaniszlo*

* Department of Microbiology, University of Texas, Austin, Texas 78712

Although iron is abundant in soils (1–6%), it is often unavailable to plants because its solubility is dependent on *p*H and controlled by the low solubility of ferric oxides. Iron availability to plant roots may thus depend on organic chelators which Lindsay reports would maintain an adequate iron supply by diffusion and mass flow at concentrations as low as 10^{-8} M[1,2]. Hydroxamate siderophores (HS), microbially produced, ferric-specific, iron transport molecules with stability constants[3] as high as 10^{32}, may represent the chelators which maintain these soil iron concentrations. Such peptide derivatives were shown to control iron availability in aquatic ecosystems[4], but little is known about their soil role beyond their function as microbial growth factors[5,6]. We report here the occurrence of HS in aqueous extracts of a variety of soils in concentrations (10^{-7} M–10^{-8} M after correction to 10% soil moisture) sufficient to affect plant nutrition[1,2].

Soil samples (0–10 cm deep) were collected from 57 sites representing numerous biomes and soil types. After extraction (1 : 1 H_2O : soil, w/w) at 4 °C for 1 h, samples were centrifuged, the supernatants dried (90 °C), and the residues rehydrated, filter sterilized, and bioassayed using the HS auxotrophic bacterium *Arthrobacter flavescens* JG-9. The initial survey used a diffusion plate method developed by P.J.S. as described by Estep *et al.*[7]. Nineteen survey soils, and other experimental materials, were assayed by a more sensitive turbidimetric, dilution-tube modification of the plate method. The mean values of quadruplicate samples were expressed as molar equivalents of the HS standard, desferrioxamine methanesulphonate (DFOM).

The specificity of any bioassay of complex natural substrates must be regarded cautiously. To verify the specificity of the *Arthrobacter*[8] we tested the natural chelators, citric acid, oxalic acid, 2,3-dihydroxybenzoic acid and the catechol siderophore, enterochelin, at concentrations of 4×10^{-3} M to 4×10^{-10} M. No growth stimulation was detected. A suspension of haemin was weakly stimulatory[9] in our assay and measured 7×10^{-9} M DFOM. Although the concentration of haemin in soil extracts is probably reduced during sample processing, stimulation by haemin or unknown compounds remains a possibility. The presence of secondary hydroxamates in highly concentrated soil extracts was demonstrated qualitatively by a positive Csaky test[10].

Hydroxamate siderophore concentrations in excess of 3×10^{-9} M DFOM equiv. were found in the extracts of all 57 preliminary survey soils. These soils were from grasslands, areas of mixed herbaceous vegetation, and coniferous and deciduous forests across the US. In extracts of 19 soils, representing a wide range of *p*H, diethylenetriaminepentaacetic acid-extractable iron (DTPA-Fe) and organic matter content, HS concentrations ranged from 3.4×10^{-8} to 2.7×10^{-9} M DFOM equiv. (mean, 1.2×10^{-8} M; median, 8.5×10^{-9} M). No simple relation between HS levels and either soil *p*H or DTPA-Fe was evident. However, HS concentration was directly correlated with per cent organic matter ($r = 0.868$, $n = 19$).

Significant adsorption of HS to soil surfaces was indicated by the low recovery (range, 0.3–17.3%; mean, 3.7%) of the model compound DFOM added at 1 μg per g dry wt of soil. Proof of a large reservoir of natural siderophores came from repeated extractions of an unamended soil sample (Fig. 1). The early extractions yielded nearly the same quantity of HS (~0.03 nmol g^{-1}), but yield subsequently declined to about 0.01 nmol g^{-1} per extraction. Total yield after 11 extractions was 0.18 nmol g^{-1}. DFOM added to a similar soil sample was more readily desorbed than was natural HS (Fig. 1). The decreasing yield of natural siderophores suggests that chemisorption on organic matter or migration to micropore sites occurs with time.

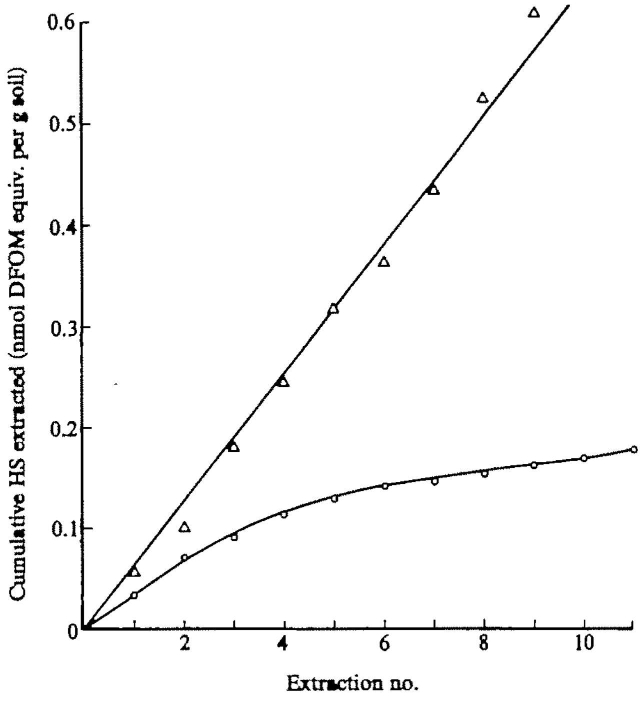

Fig. 1 Siderophore desorption (nmol per g soil) from soil (TC1) by the repeated extraction of amended DFOM at 1 μg per g dry wt soil (△) and natural HS (○).

0028-0836/80/440833—02$01 00

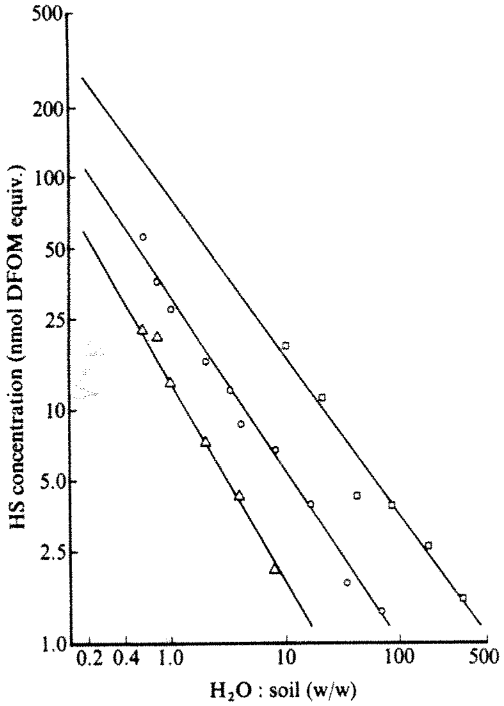

Fig. 2 Concentration (nmol) of natural HS in aqueous extracts of three soils at various H_2O : soil (w/w) ratios. (△), Soil TC9 with 2% organic matter, $\ln y = \ln 13.5 - 0.873 \ln x$; (○), soil TC1C with 10% organic matter, $\ln y = \ln 29.8 - 0.760 \ln x$; (□), Canadian sphagnum peat with 95% organic matter, $\ln y = \ln 80.2 - 0.686 \ln x$.

To estimate the solution concentrations of HS in realistic soil moisture conditions, we extracted several soils at various H_2O:soil ratios. Siderophore concentration in solution increased markedly as soil moisture decreased (Fig. 2) and was clearly a power function of per cent soil moisture. Slopes of the curves were inversely correlated with soil organic matter content, as would be expected if the chelators were adsorbed to soil organic matter. A conservative estimate of minimum siderophore concentrations at 10% soil moisture was extrapolated from the value for this 1:1 H_2O:soil extract using the slope value from sphagnum peat containing 95% organic matter (see Fig. 2 legend). Extrapolated values for 10% moisture varied from 1.7×10^{-7} M to 1.3×10^{-8} M DFOM equiv., entirely within the range theoretically necessary to maintain an adequate iron supply to roots[1,2].

The ecological significance of hydroxamate siderophores in ferric iron mobilization is apparent when their stability constants (for example, ferrioxamine B, log $K = 31$)[3] are compared with those of the less specific organic acids (for example, ferric citrate, log $K = 12$)[11], phenolates (for example, ferric p-hydroxybenzoate, log $K = 15$)[11] and several synthetic chelators. Although the synthetic chelate ethylenediaminetetraacetic acid (EDTA) has a log K of 26 for ferric iron, it cannot effectively retain iron in soil solutions above pH 6 because of competition from other cations[2].

We have shown that hydroxamate siderophores are present in a wide variety of soils in concentrations that significantly increase the availability of iron to plants. We have also presented evidence that large reservoirs of these compounds are adsorbed to soil organic matter. We believe that HS in soils perform many chelate functions previously attributed to organic acids and polyphenolic humic material.

Structure and function of mycorrhizal rhizomorphs with special reference to their role in water transport

J. A. Duddridge, A. Malibari & D. J. Read

Department of Botany, University of Sheffield, Sheffield S10 2TN, UK

Anastomosing systems of fungal rhizomorphs are found in association with mycorrhizal roots of trees in arid zones[1], in soils of temperate deciduous[2], coniferous[3] and humid tropical[4] forests, and even in mine spoils[5]. Although it is recognized that the fungus depends on the host for its carbon supply[6,7], the functional relationship between the partners has not been investigated fully. Transport of ^{32}P through rhizomorphs has been demonstrated[8], but their potential to absorb and transport water is not known. We have synthesized mycorrhizal rhizomorphs in association with pine, and preliminary experiments with tritiated water (^3H_2O) showed that the cut distal ends could absorb water which was transported to mycorrhizal roots and to seedling needles[9]. We have since developed a method for feeding ^3H_2O to the intact terminal portions of rhizomorphs in sealed vessels with negligible disturbance to the mycelial system, and we report here that mycorrhizal rhizomorphs can absorb water and facilitate its transport over ecologically significant distances. Electron microscopy shows that the rhizomorphs are differentiated structures with large central 'vessel' hyphae.

Mycorrhizas were synthesized in aseptic conditions in 250-ml Erlenmeyer flasks which contained a peat–vermiculite mixture (1:4 v/v) moistened with modified Melin–Norkrans (MMN) solution. The medium was inoculated with a disk of *Suillus bovinus* mycelium. After the fungus had become established, aseptically germinated seedlings of *Pinus sylvestris* were transferred to the flasks which were then maintained in a growth chamber. After mycorrhiza formation had been confirmed, seedlings were transferred to fresh non-sterile milled peat in Perspex chambers (15 × 17 × 1 cm) with detachable sides and base. Three seedlings were placed on the surface of the peat with most of their mycorrhizal roots visible on the upper surface. The wall was then replaced, the chambers were wrapped in aluminium foil to exclude light and replaced in the growth cabinet. Within 142 d the peat was extensively exploited by rhizomorphs, many of which formed on the wall of the chamber. A shallow Perspex cup (1 cm in diameter, 1 mm deep), its rim coated with anhydrous lanolin, and containing 4 μCi of ^3H_2O in 50 μl water, was attached to the lower surface of the chamber wall enclosing the terminal parts of a rhizomorph system. Cups were placed either near the upper peat surface and hence in close proximity to the seedlings, or at the base of the chamber at least 15 cm from the seedling needles (Fig. 1). After exposure to the isotope for 1 h the rhizomorphs emerging from the cup were cut, dissected away from the wall and peat, and traced backwards to mycorrhizal roots. They were then cut into 5-mm segments, which were placed in sealed scintillation vials

containing 1 ml of NCS tissue solubilizer (Amersham/Serle). These, together with vials containing peat, root and needle samples, were incubated at 50 °C for 48 h, cooled to room temperature, and hydrolysed with 0.4 ml of 5N HCl before radioactivity was determined by scintillation counting. Similar rhizomorphs from the chambers and from a pine plantation were cut into 2–3-mm lengths, fixed and processed for examination by transmission electron microscopy.

Within 1 h, ^3H_2O moved from both the upper (Table 1*a*) and lower (Table 1*b*) source cups, through rhizomorphs to mycorrhizal roots and shoots. In each case movement occurred to more than one of the seedlings in the chamber, indicating that, as would be expected from visual inspection of the rhizomorph system (Fig. 1), the route was irregular. Beyond the root, passage of label preferentially to young needles (plants *A* and *B*, Table 1*a*; plant *A*, Table 1*b*) suggests a polarity of movement along recently laid down conduits in the seedling. Seedling *A* (Fig. 1*a*), to which no rhizomorphs were attached, contained no label, demonstrating that water movement was dependent on the presence of a rhizomorph connection from source cup to seedling. Detection of counts in needles up to 27 cm from the source (Table 1*b*) indicates that a minimum rate of transport of 27 cm h^{-1} was obtained in these experimental circumstances. Such rates of transport, which are comparable with those frequently reported for xylem, suggest that the hydraulic conductivity of the pathway is high. It is likely that water moves through the rhizomorph along a gradient of water potential established by transpiration from the seedling.

Ultrastructural analysis reveals considerable differentiation in this type of rhizomorph. Transverse and longitudinal sections (Fig. 2) show that central hyphae of relatively large diameter, and which generally lack cytoplasmic contents, are surrounded by narrower densely cytoplasmic hyphae often with thick cell walls. These form a pseudoparenchymatous sheath around the central structures. Stages in the dissolution of transverse walls of the central hyphae, can be seen. At maturity these structures are analogous to the 'vessel' hyphae of *Serpula lacrymans*[10,11]. Their diameters are between 6 and 20 μm which, together with the absence of cross walls and cytoplasm, makes them structurally comparable with xylem vessels of higher plants. This helps to explain the low resistance to water movement through the rhizomorphs revealed by the tracer studies, and lends support to

the view that water moves apoplastically through the central vessels rather than symplastically through the narrow outer hyphae or through the cell walls. The accumulation of activity in the sheath region may reflect increased resistance to flow in this area, where presumably a considerable portion of the pathway must be through the symplast. Certain of these structural features would be expected to protect the vessel hyphae from collapse when under negative hydrostatic pressure. The parenchymatous sheath of the rhizomorph with its thick-walled members would supply external support, and the mycorrhizal sheath situated in the pathway between seedling and rhizomorph would supply a filtration resistance isolating the 'vessels' from the lowest seedling water potentials. The outer sheath of the rhizomorph also probably presents a high resistance to lateral movement of water which would explain the absence of isotope leakage into the peat (Table 1*a*).

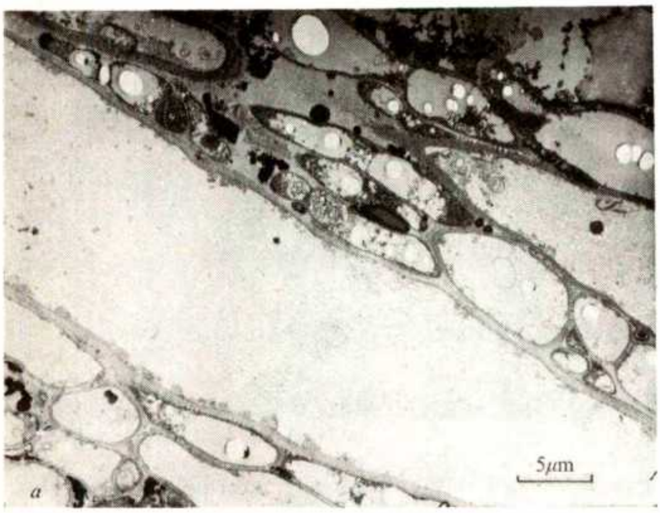

Fig. 2 *a*, Longitudinal section of rhizomorph from synthesized *Pinus sylvestris–Suillus bovinus* system. *b*, Transverse section of rhizomorph from the same system. *c*, Transverse section of rhizomorph attached to mycorrhizal root of *Pinus sylvestris* in the field. All tissues were fixed for 1.5 h in 2.5% phosphate-buffered glutaraldehyde, dehydrated in graded ethanol series and embedded in Spurr's resin.

Plants such as pine which are normally ecto-mycorrhizal have a relatively low root density compared to grasses and most other herbaceous plants[12–14]. Our observations indicate that the rhizomorphs of ecto-mycorrhizas may represent functional extensions of the root system. We have now synthesized mycorrhizas from which rhizomorphs grow to exploit moist soil while the soil around the seedling roots is allowed to dry progressively. In these circumstances seedling water balance has been maintained for several weeks by means of water transport through the rhizomorphs. During the same period control seedlings lacking rhizomorphs died.

Mycorrhizal fungi differ in their capacity to produce rhizomorphs and there may be structural and functional distinctions between rhizomorphs produced by different fungal symbionts. Such features are now being investigated with a view to selection of mycorrhizal associates which have the capacity to improve the performance of forest crops particularly in semi-arid areas.

We thank Dr B. C. Jarvis for advice on isotope extraction and counting procedures, and acknowledge receipt of financial support from the SRC, NERC and the Forestry Commission.

The fossil vertebrate localities of the Maragheh region in Azerbaijan, northwestern Iran, are among the most renowned late Miocene localities in Eurasia. The fossiliferous beds are found to the north and east of the town of Maragheh on the southern and eastern slopes of the Sahand massif and at an altitude of 1,450–1,900 m (Fig. 1). The first collection was made by Khanykof in 1840. Subsequent invertigators of the fauna[1–15], established Maragheh as the site of one of the principal 'Pontian' mammal faunas of Eurasia. Recently, Tobien[16], Erdbrink *et al.*[17], Takai *et al.*[18] and ourselves (the Lake Rezaiyeh Expedition) have concentrated on developing the geochronological and palaeoenvironmental aspects of the Maragheh fauna. The similarity of the Maragheh fauna to those of Samos, Pikermi, Saloniki and Mt Luberon, in particular, was recognized by most workers. The most significant results of the investigations reported here are that the Maragheh fauna spans an extended geochronological range, ~9.5–7 Myr, that the so-called 'Pontian' mammal communities are provincially distributed, and diachronic in their appearance, and finally that the absence of hominoid primates from this site and other late Miocene sites with similar savannah-like faunas strongly suggests their adaptation at this time to more forested environments which existed in Eurasia and Africa before and during the Maragheh interval.

The late Miocene deposits in the Maragheh Basin consist of a thick series of volcaniclastic and pyroclastic continental strata which underlie a broad pediplain on the southern and eastern sides of the Sahand volcanic massif. On the southern side of Sahand the strata are virtually undeformed, and very gently inclined to the west-southwest. The entire late Miocene section has previously been termed the Maragheh Formation[19], but we restrict this name to the volcaniclastic series, and distinguish a basal pyroclastic formation, the Basal Tuff, on lithological and stratigraphical grounds. South of Sahand the Maragheh Formation is eroded to a thickness of about 300 m and consists of strata made up exclusively of detrital fragments of hornblende, andesite lava and pumice, interbedded at widely spaced intervals with layers of pumice–lapilli tuff. These nominally andesitic beds are generally unlaminated, poorly sorted silty grits with cobble lenses of andesite and hard iron-stained pumice cobbles, in depositional units 1–3 m thick. The siltstone beds are the most fossiliferous and consist of massive poorly sorted volcaniclastic overbank deposits 3–10 m thick. We interpret each of the fining-upwards sequences as having been produced by a single flood event, or perhaps waxing and waning events within a single flood. The amount of sediment laid down in any particular flood is thus variable, but no major hiatuses have been found in the stratigraphic succession.

The interbedded pumice–lapilli tuffs are composed of soft, angular blocks and chips of snow-white andesitic pumice mixed to a greater or lesser extent with andesitic lava detritus. Laminated, upper parts of the pumice–lapilli tuffs obviously were reworked to a certain extent, but the basal pumicite zones are 'draped' over palaeotopographical relief (buried gullies) with constant thickness, indicating primary pyroclastic deposition.

The Basal Tuff is (apparently) a single airfall unit of rhyolite tuff with a local thickness of over 80 m. The unit is a uniform, unbedded, structureless deposit of white, devitrified ash with many randomly orientated flakes of mica and fresh crystal fragments of feldspar and quartz. The Maragheh Formation seems to rest on the Basal Tuff with a low-angle regional unconformity. The stratigraphical data, supported by the radiometric and biostratigraphical evidence, indicate that the

All fission-track ages are derived from separated zircon crystals. Total-fusion K–Ar age determinations were obtained from materials indicated as follows: pl, high-temperature plagioclase; hb, hornblende; bi, biotite; an, high-temperature anorthoclase; WR, whole-rock samples. Decay constants $\lambda\beta = 4.962\times10^{-10}\ \mathrm{yr}^{-1}$; $\lambda e = 0.581\times10^{-10}\ \mathrm{yr}^{-1}$; isotopic abundance: $^{40}\mathrm{K} = 0.01167\%$ of total K. Decay constants and isotopic abundance used by Erdbrink *et al.*[18] according to pre-1978 standards are slightly different, but do not change the computed values significantly. Kamei *et al.*[19] do not give their precision limits but state (p. 157) that these are "usually under 10%". Analytical details of new dating presented here are available from M.H.A. and R.D.

0028–0836/80/440837—05$01.00

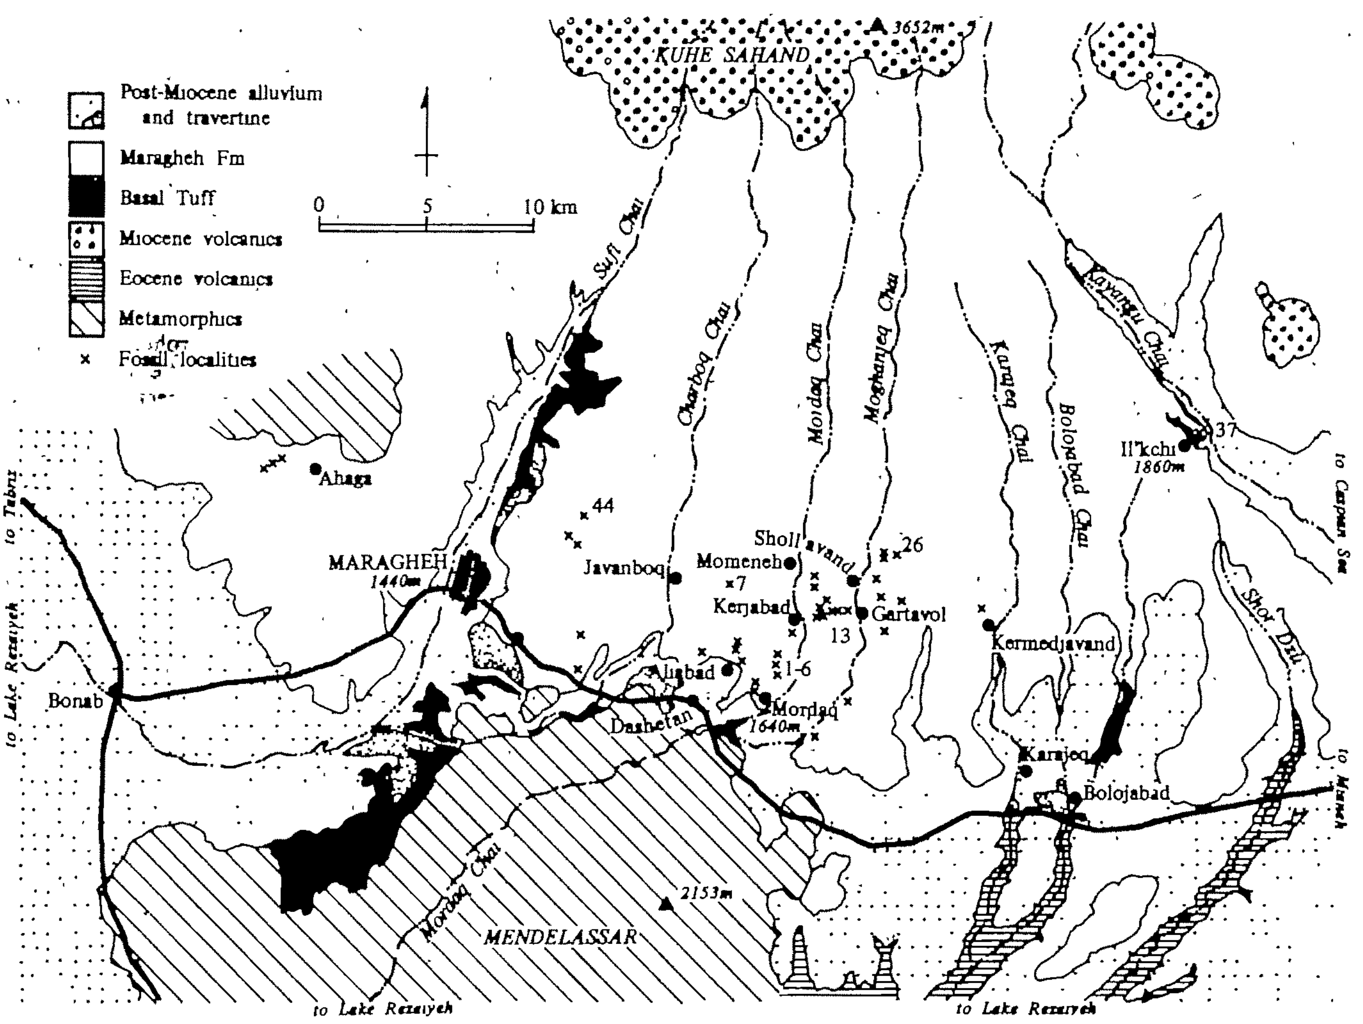

Fig. 1 Map of the southern part of the Maragheh Formation.

beds farthest to the west, and the fossils which they contain (at Kopran) were the earliest to have been deposited, and Il'kchi, the easternmost locality, seems to correlate with the youngest localities in the central area although it lies directly on the Basal Tuff. In the fossiliferous central area, the 'loose chippings' marker bed (LC), a distinctive and easily traced volcaniclastic breccia, was used as the key horizon for the allocation of Maragheh fossil localities to arbitrary 25-m stratigraphical intervals. The marker bed was also mapped over part of its exposures by Kamei[19] as the 'Scoria Bed', and it appears at the top of two of the sections measured by Erdbrink *et al.*[18] as 'trachytic breccia'.

We report here on 28 age determinations from the Basal Tuff and the Maragheh Formation in the fossiliferous district east of Maragheh. As summarized in Table 1 and Fig. 2, these determinations are based on 3 samples of the Basal Tuff and 10 samples from pyroclastic layers in the Maragheh Formation. Four of the five horizons dated by Erdbrink *et al.*[18], and three of the five horizons dated by Kamei *et al.*[19] from the same late Miocene sequence are represented in our samples. Our geochronology and that of Kamei *et al.*[19] are consistent with the stratigraphy described here, but the Kamei ages are systematically younger than ours at the same levels. The ages reported by Erdbrink *et al.*[18] on Maragheh pumicites are slightly to significantly older than ours from the same horizons, and are also inconsistent with the present stratigraphy, whereas their age analyses of the Basal Tuff are comparable with ours (see below).

As shown in Table 1, 11 of the 14 samples were dated both by fission-track (FT) analysis of pyroclastic zircons (M.H.A.) and by total-fusion K–Ar analysis of separated minerals (R.D.). Both biotite and anorthoclase were K/Ar dated in two Basal Tuff K–Ar samples. Of the 28 age determinations obtained, only one pair of FT and K–Ar ages (sample R3) were significantly different, and only one sample (R9) had an age that was clearly inconsistent with a simple superpositional interpretation. Furthermore, three horizons—Il'kchi middle pumice, layered marker pumice and Basal Tuff—were dated in at least two difference places, with good to moderate agreement.

The abundance of data, and the quality of the stratigraphy, nevertheless, clearly indicate problems in Maragheh geochronology that would not be apparent if there were only a few age determinations. There can be little question that the upper level of fossiliferous beds in the central area, and the isolated Il'kchi locality which we have correlated with this level, should be calibrated by the averages of 7.4 Myr respectively obtained on the directly superjacent pumicites in both areas. Unfortunately, the age determinations from the lower part of the section in the central area (for example, the ages obtained from the Murdaq 'ignimbrite' and the Gürt Dareseh pumicite) seem to be unreliable due to their large variation, and in addition two interpretations are possible from the dating of the Basal Tuff. We prefer to accept an age of 8.9 ± 0.5 Myr for the Murdaq ignimbrite as being both analytically satisfactory and stratigraphically consistent, the other, contradictory dates notwithstanding. We also conclude that the oldest Maragheh fossils are virtually certain to be younger than the cluster of FT and biotite K–Ar ages from the Basal Tuff, ~11 Myr, and may be younger than the age of the anorthoclase K–Ar age determinations of 9.3 Myr.

All the pyroclastic units in the Maragheh Formation contain accidental pebbles and grains of detrital andesite. For this reason, whole-rock age determinations on such units[18] must be regarded as dubious. Only the fact that the accidental contaminants are predominantly if not entirely derived from outcrops on the Miocene Sahand volcano, and not from even older rocks, gives such determinations an appearance of reliability. The Basal Tuff seems to contain no accidental fragments; on the other hand, whole-rock analysis would include the altered and devitrified matrix, from which some argon may have been lost. The discordantly young age reported by Erdbrink *et al.*[18] on a whole-rock sample may be erroneous for this reason. The lack of agreement between FT ages and anorthoclase K-Ar ages, as well as the discrepancy between biotite and anorthoclase K-Ar ages from the Basal Tuff is now under investigation.

The dating reported here gives a relatively unambiguous age for the upper limit of the Maragheh fossiliferous sequence of 7.4 Myr; preliminary and somewhat equivocal interpretations of the Basal Tuff samples suggest a maximum lower age limit of 11 Myr, but probably not more than 10 Myr. These limits are not limits of certainty, but represent the actual time-span of the Maragheh fossil fauna, interpreted here to be from about 9.5 to 7 Myr.

The biostratigraphy presented here (Table 2) combines the fossil mammal collections made by the Lake Rezaiyeh Expedition and Tobien's excavations, with information reported by Erdbrink *et al.*[18], Kamei *et al.*[19] and Bernor[20]. The Maragheh mammalian fauna is divided into three biostratigraphic intervals: lower Maragheh, extending from −150 m to −50 m below LC; middle Maragheh, extending from −50 m to −25 m below LC; and upper Maragheh, extending from −25 m to +25 m below/above LC.

In addition to the radiometric determinations cited above, detailed work on circum-Mediterranean East African late Miocene *Hipparion* evolution[21] has evaluated a recent analysis of *Hipparion* superspecific groups for use in provincial correlations between the Maragheh sites and several other Old World localities. These interpretations suggest that the Lower Maragheh *Hipparion* sp. 3 has a more primitive facial morphology than any of the *Hipparion* species from the Greek localities but compare closely with the early Vallesian *Hipparion* species *Hipparion catalaunicum*[22] and *Hipparion africanum*[23]. The Middle Maragheh *Hipparion H.* cf. *prostylum* occurs at Pikermi, Saloniki and Mt Luberon[24], and *Hipparion* cf. *mediterraneum* occurs at Pikermi, suggesting correlation of these localities with this Maragheh interval. In the Upper Maragheh, *H.* cf. *Hipparion dietrichi*, *Hipparion matthewi* and *H.* cf. *H. mediterraneum* are morphologically the most derived species of *Hipparion* in the sequence. These taxa, as well as *H.* cf. *Hipparion proboscideum* and *Hipparion 'minus'*, occur at Samos within a restricted chronological range (~0.5 Myr; N. Solounias, personal communication), suggesting correlation of Samos with Upper Maragheh, despite dating that indicates a relatively older age for the Samos material[25].

The biochronological interpretation of the Maragheh sequence given here broadly supports the radiometric determinations that refer it to an early Turolian to medial Turolian

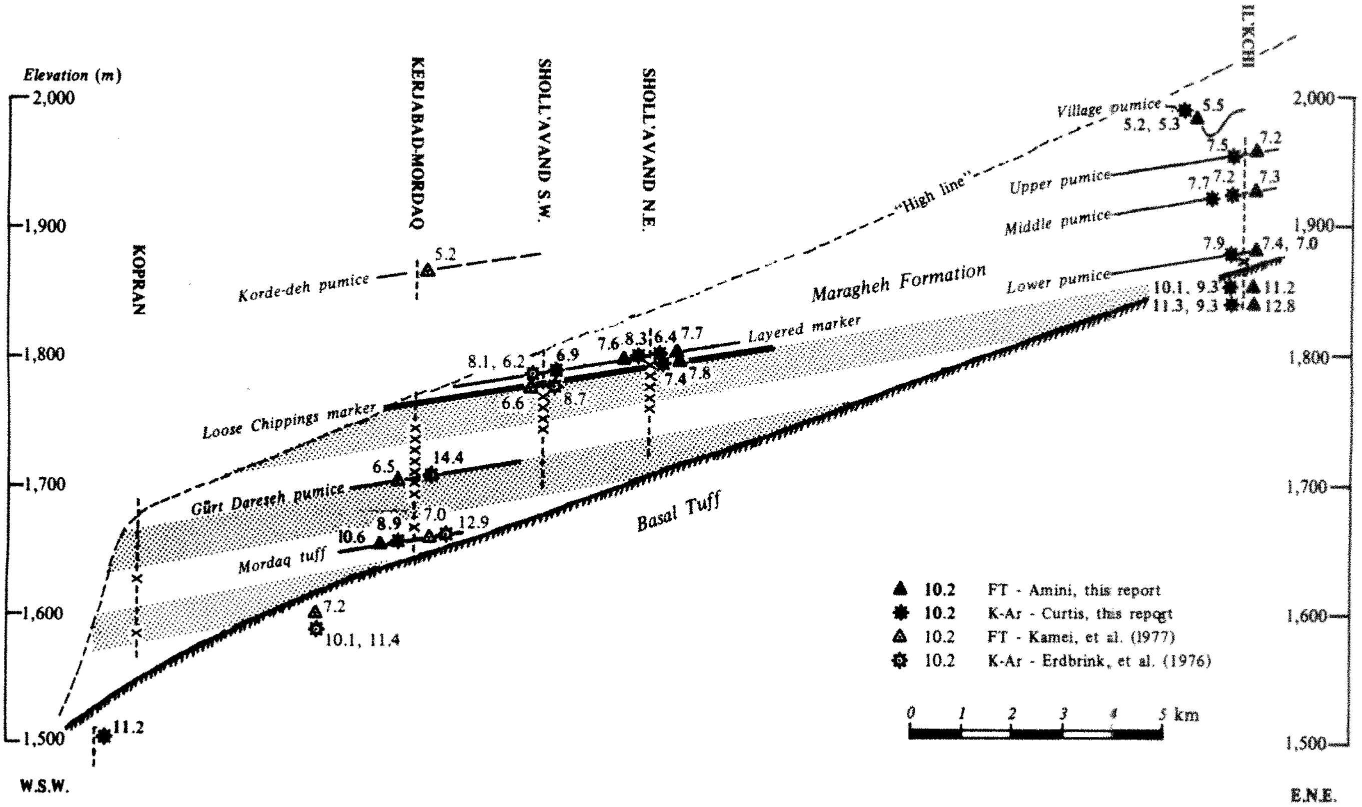

Fig. 2 Stratigraphical display of isotopic age determinations from the Maragheh Formation and Basal Tuff. See Table 1 for sample documentation. The FT and K–Ar ages obtained by Amini and Drake from the same samples are shown adjacent to one another. Repeat determinations, or determinations made on different materials from the same sample, are separated by commas. The sampling profiles on the line of section are generalized indications of the measured and studied thickness in the respective areas; portions shown by 'x' symbols represent intervals containing abundant mammalian fossils. Biostratigraphic subdivisions in 25-m increments from the plane of the LC marker are indicated by the stippled pattern. The 'high line' or interfluve maximum elevation is the residual thickness of the Maragheh Formation along the line of section inferred from the highest level of terrace deposits; thickness increases towards Sahand, where the Korde-deh tuff crops out.

BASAL TUFF

age (MN 11 and 12, ref. 26). Pro-rated ages for the various Maragheh biostratigraphical intervals can be advanced here as: ~9.5–8.5 Myr for Lower Maragheh; 8.5–8.0 Myr for Middle Maragheh; 8.0–7.5 Myr for Upper Maragheh.

No complete, articulated skeletons were found. Taphonomic studies in a single quarry, MMTT-13, revealed 48% of the bones to be part of smaller, articulated units, predominantly distal limb segments. Skulls with mandibles and vertebral strings were also present, fragmented single bones and isolated teeth rare, complete or almost complete disarticulated limb bones and mandibular rami common. The bones showed no preferred orientation; few were of animals estimated to have weighed less than 10 kg. Taphonomic data support the interpretation that the fossils were incorporated in overbank deposits and either buried almost immediately or exposed long enough to allow removal of only a few elements by scavengers.

The Maragheh fauna has long been thought to be one of the typical Turolian savannah faunas of Eurasia. Preliminary studies of habitat spectra[27] suggest that the ecological diversity spectra are not typical of modern savannah, which is dominated by wooded grassland habitat, but are what would be expected in a savannah dominated by woodland with adjacent wooded grassland.

As shown in the East African record, the hominids did not join the savannah biome until the Pliocene, and the Maragheh ecological setting is too open and seasonal for the dryopithecines, sivapithecines (and related forms such as *Ramapithecus*)[28]. The presence of a single *Mesopithecus* from Maragheh demonstrates that these animals were in the vicinity even though the predominant fauna was probably derived from the more open woodland and wooded grassland habitat.

We thank the Trustees of the L. S. B. Leakey Foundation who sponsored this project, Gordon Getty for his generous financial help and Dr W. A. Akersten, Dr G. H. Curtis, Mr G. T. Jefferson, Dr C. W. Naeser, Dr Nikos Solounias and Dr M. O. Woodburne for assistance. Transportation, field equipment, support personnel, housing and laboratory facilities in Iran were provided by the National Museum of Natural History under the direction of Dr Hind Sadek-Kooros, and coordinated by Mr Paul Houshmast. Laboratory facilities and curatorial support were provided at the University of California, Los Angeles, and the University of California, Riverside.

Embryogenesis in a *Drosophila* mutant expressing half the normal segment number

K. Sander, M. Lohs-Schardin & M. Baumann

Institut für Biologie I (Zoologie) der Universität,
D-7800 Freiburg i.Br., FRG

Insect segments are seriated developmental subunits whose borders largely control intra-segmental patterning[1]. The individual segment owes its specific character to position-dependent instructions given to its early embryonic progenitor cells[2]. In *Drosophila*, the segment borders first become visible as a series of transverse infoldings on the surface of the germ band[3]. We describe here development in a mutant (prd^{FR1}) which forms half the normal number of transverse infoldings spaced at twice the normal distance, thereby subdividing the germ band into a series of giant domains (Fig. 1 *a–c*). Each domain develops the tracheal pits of two normal segments (Fig. 1*e*), thus revealing its composite origin, but the larva expresses only one segment border per domain and the cuticle between these borders is similar to the normal segment in both size and zonation (Fig. 2). We conclude that this course of development reflects a conflict between the seriated instructions specifying local segment character (see Fig. 1*b*) and controlling influences exerted by the abnormally spaced infoldings and later by the definitive segment borders.

The mutant we describe maps at 2-43 ± 0.7. It was obtained by EMS treatment of wild-type males with ethyl methane sulphonate and subsequently found to be allelic to the *paired* mutants[4]; the allele, which we designate as prd^{FR1}, is balanced over the CyO chromosome. In approximately 25% of the eggs, probably the homozygous fraction, gastrulation seems to be slightly delayed and the cephalic furrow either fails to appear or forms some time after the onset of germ-band extension. The maximum length of the extended germ band exceeds 90% of the normal value. When transverse epidermal furrows first become visible in the scanning electron microscope (Fig. 1), they are spaced at about twice the normal distance, demarcating six giant domains, each of which contains about as many cells as two segment anlagen in the same region of the normal germ band. The posterior domains develop tracheal pits in a rather peculiar way (Fig. 1 *d–f*). In wild-type embryos, the corresponding segments each form a single pair of pits which subsequently disappear in the anterior border furrow[3]. In the mutant, one pair of pits forms next to each furrow and slightly later another pair develops more posteriorly. The anterior pits then disappear, as occurs in normal development, but the posterior pits persist on the body flanks, and the ensuing tracheal system is severely disrupted. Within or just behind the anteriormost epidermal infolding, a pair of invaginations form (Fig. 1*e*, *f*); we consider these to be the anlagen for the salivary duct because they later fuse mid-ventrally as in wild type embryos[3]. After head involution the ventral rim of the pre-oral cavity produces the larval cuticle markers[5] characterizing the anterior border of the prothorax. The methods of observation used do not allow us to determine whether the transverse folds give rise to the definitive segment borders, as they do in normal development.

The larva moves in the egg case but fails to hatch. In its cuticle, segment length exceeds that of the wild type by a factor of 1.2–1.5. The cuticle of the oversized segments is zonated as in normal segments[5] (Fig. 2) but each zone expresses traits characteristic of two consecutive segments (hence 'paired'[4]). The traits of the anterior partner of each segment pair are restricted to a narrow anterior strip of cuticle[4]. A comparable reduction of the traits of the anterior segments occurs in the head and the caudal

0028–0836/80/440841—03$01.00

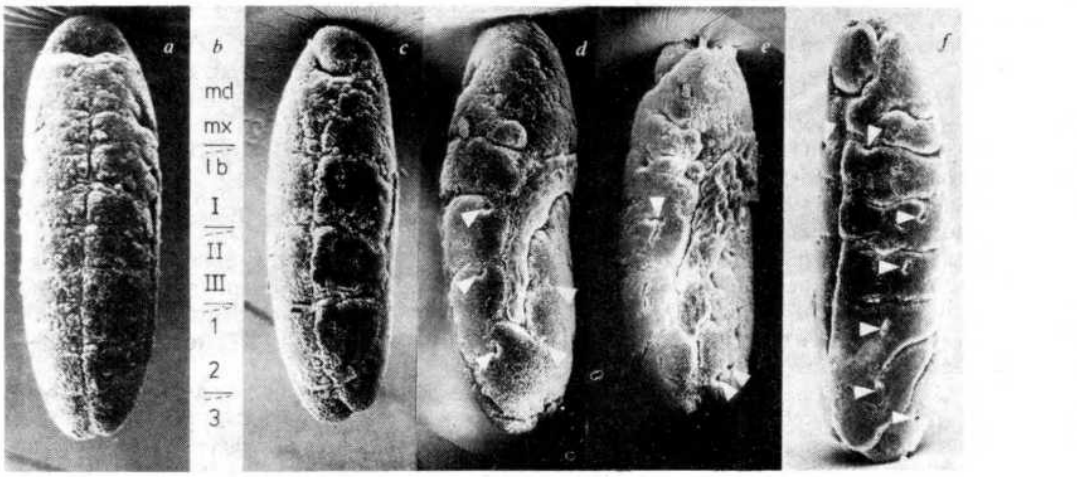

Fig. 1 Scanning electron micrographs of *Drosophila* embryos prepared by the technique of Turner and Mahowald[3]. *a*, *c*, Ventral views of normal-spaced and double-spaced patterns of epidermal infoldings at the stage of maximum germ band extension. Transverse lines link double-spaced infoldings in the mutant *paired* to the normal pattern. Embryo in *a* (possibly heterozygous for *paired*) is abnormal in showing a weaker expression of every second furrow (these are the furrows present in Fig. 1*c*). Lettering in *b* identifies segments in *a* but can also be taken to symbolize a prepattern specifying local segment character. Abbreviations: md, mandibular; mx, maxillar; lb, labial segments (head); I–III, thoracic segments; 1–3, anterior abdominal segments. A slight backward shift of the infoldings (dashed lines) is indicated by some observations and might account for the suppression of homologous cuticle elements in every second segment of the normal pattern[4]. *d–f*, Lateral views of germ band stages, ventral side at the left (negatives *d* and *e* were reversed to obtain this orientation). *d*, Onset of germ band shortening, to show anterior tracheal pits (arrows). *e*, Slightly later stage, posterior tracheal pits apparent and in most pairs linked to the anterior pit by a groove (one pair marked by arrows at bottom). The foremost anterior pit (top arrow) is about to enter the transverse furrow. *f*, The germ band is further contracted, posterior pits (horizontal arrows) persist on body flanks (albeit shifted anteriorly) and anterior pits have disappeared. Arrows at the top mark salivary duct pits also seen in *e*. *c–f* Represent typical specimens selected from more than 100 germ band stage embryos studied with the scanning electron microscope. Length of preparations varies between 0.33 and 0.4 mm.

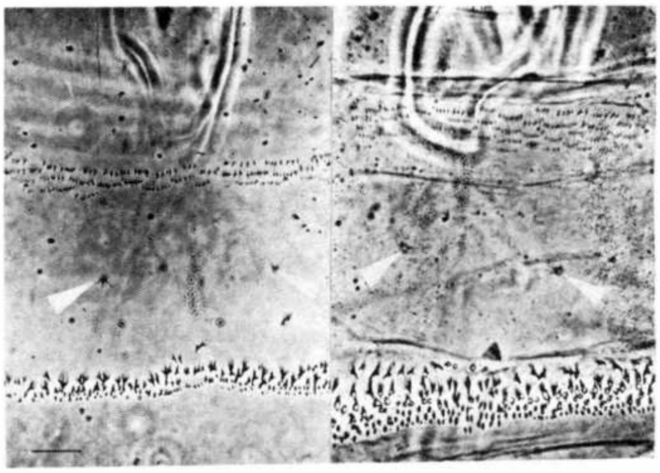
complex. Here the H-piece (anterior part of the cephalopharyngeal skeleton) and the supra-anal tuft are markedly reduced; the former is derived from the labial segment[6], the latter from the rudimentary 9th abdominal segment[3]. The protuberances carrying the posterior spiracles and their atria (8th abdominal segment) are abnormally large and somewhat deformed, providing further evidence for the spatial prevalence of the posterior partner in the paired segments. Up to 45% of mutant embryos show holes in the larval cuticle and/or lateral (rarely ventral) fusion of adjacent denticle belts. No large-scale cell elimination which could account for these anomalies or for the reduction in segment number or segment size was noted.

The abnormal segmentation pattern in *paired* is not linked to a specific local segment character. This was shown by combining the mutant with an extreme *Ultrabithorax* allele which confers mesothoracic character on all segments between the mesothorax and the posterior spiracles[7]. The ensuing larvae (if not disorganized) exhibit thoracic transformation of all abdomen-type segments but retain the abnormal distribution of the epidermal infoldings and the reduced number of definitive segment borders.

Abnormal subdivision of the germ anlage as described here is a novel type of developmental anomaly. We propose to name it 'embryonic malpartitioning'. We assume that the mutation primarily affects the positioning of the transverse ectodermal infoldings thought to mark the boundaries between adjacent segments[3]. The resultant abnormal pattern of furrows (Fig. 1*c*) seems to act as an aberrant 'partitioning grid' imposed on a germ anlage which carries the normal set of instructions for individual segment character (shown diagrammatically in Fig. 1*b*). This view is based on the findings that (1) the incipient spatial pattern of transverse furrows is more abnormal than the pattern of other visible epidermal anlagen (tracheal and salivary duct pits, Fig. 1), and (2) the mutant generally maintains the normal spatial proportions of abdomen and thorax in the germ band and larval cuticle. In any case, the abnormal subdivision of the germ band must progressively influence subsequent patterning, because the tracheal pits appear in full number and nearly normal spacing (Fig. 1*e*) whereas the cuticle which forms later shows only half the normal number of segments. Despite their composite character these segments approach normal segment length, although not as closely as do the fused segments observed in the bug *Oncopeltus*[1].

Why the mutant should so exactly double-space the grid of epidermal infoldings (Fig. 1*c*) is a most intriguing question. To assume suppression of every second furrow of the normal pattern merely alters the problem because some wild-type patterned germ bands from our mutant stock partly suppress the alternative set of furrows (Fig. 1*a*). The double-spacing therefore probably reflects some basic property of the mechanisms responsible for the periodic positioning of epidermal infoldings in normal development. Mechanisms based on dissipative structures which can be envisaged as a spatial series of 'stationary waves'[8,9] could be inherently prone to this type of partitioning error; for instance, the mutant cells might recognize only the positive or the negative maxima (or zero transitions) whereas the wild-type cells could respond to both (possibly in succession). However, abnormal distribution of the periodic signals themselves cannot be excluded. Early anomalies like the defective cephalic furrow and subnormal germ band length might indicate changes in the geometrical boundary conditions which are critical for dissipative patterning and probably also for other spacing mechanisms. Whether the epidermal infoldings in the mutant initiate the full sequence of functions characterizing

Fig. 2 Phase contrast micrographs of ventral cuticle from the posterior thoracic region of *paired* (right) and wild-type (left) first instar larva. Note the typical transverse zonation of the mutant segment, and the increase in the number of denticle rows roughly proportional to the increase in segment length; a similar 'multiplication of elements'[13] has been described previously in oversized segments[14]. Arrows mark Keilin's sense organs. The band of denticle rows at the bottom is the anterior rim of the abdomen. Scale bar, 0.02 mm.



a typical segment border (including its function as compartment boundary[10]) is not known. It even remains to be shown (for example, by defect mapping[5]) whether the infoldings in the mutant harbour the progenitors of those hypoderm cells which subsequently express the cuticular segment borders. In the absence of proof for this, we can consider alternative possibilities. The most attractive of these is that the folds form across the prospective territory of the anterior segment of each pair (Fig. 1*b*) and that in this abnormal position they prevent some region of the prospective hypoderm from expressing its strip of the cuticular pattern. If the starting conditions for periodic patterning were liable to several kinds of disturbance, the transverse folds might be shifted to different positions (the 'floating grid' hypothesis). The resulting seriated cuticular defects should then affect different strips of the intra-segmental pattern. Several classes of mutant exhibiting such defects have been found[4] and observations on their early development may serve to test this assumption.

If, on the other hand, the infoldings represent functional segment borders, their aberrant distribution raises the question of how in normal development the pattern of segment borders is kept in register with the pattern of instructions specifying local segment character (Fig. 1*b*). One possibility is that both patterns develop independently on the basis of the same axial system of positional information, for instance, an axial gradient[2,11]. The mutant described here would then misinterpret this information when spacing its segment borders, but not when defining local segment character. Homoeotic mutants like *Ultrabithorax*, on the other hand, would misinterpret the same positional information with respect to local segment character[11,12]. The former error would result in aberrantly demarcated segments, the latter in assigning a wrong character to some correctly demarcated segments.

Parathyroid hormone stimulates bone resorption via a Na–Ca exchange mechanism

Nancy S. Krieger & Armen H. Tashjian Jr*

Laboratory of Toxicology, Harvard School of Public Health, Boston, Massachusetts 02115 and *Department of Pharmacology, Harvard Medical School, Boston, Massachusetts 02115

Parathyroid hormone (PTH) stimulates the release of calcium from bone and is thought to initiate its action by a direct effect on the plasma membrane of bone cells[1]. Although specific membrane receptors for PTH have not yet been identified in bone, they have been characterized in kidney[2], and PTH does stimulate production of cyclic AMP in bone[3]. However, the mechanism by which PTH causes the release of Ca from bone is not understood. We have determined that several agents that alter ion transport across biological membranes inhibit PTH-stimulated bone resorption *in vitro*. These agents include ouabain, veratridine and certain monovalent cation ionophores, which transport monovalent cations selectively[4,5]. The inhibition of bone resorption is dose dependent and reversible within the first 24 h of treatment. All these compounds would be expected to increase intracellular sodium concentration in bone cells. Also, we find that decreasing the extracellular Na^+ concentration prevents PTH-stimulated resorption. Therefore, we propose that PTH acts on bone to stimulate Ca release by means of a Na–Ca exchange mechanism. Decreasing the Na gradient across the bone cell plasma membrane would prevent the Na–Ca exchange and thus inhibit the physiological response to PTH.

PTH stimulates the release of Ca from bone in organ culture, an action analogous to its physiological effect on the skeleton *in vivo*[1]. Studies in bone have demonstrated an early stimulated increase in Ca influx both *in vivo*[6] and *in vitro*[7]. A possible role for Na ions in hormonal stimulation of Ca release from bone has been postulated[8] but not demonstrated experimentally.

Our results using intact neonatal mouse calvaria in organ culture show that monovalent cations do play an important role in the release of Ca from bone that is enhanced by PTH. Bone resorption stimulated by 0.1 U ml^{-1} PTE (United States Pharmacopeia Parathyroid Extract, Eli Lilly Company) was inhibited by veratridine, ouabain and the monovalent cation ionophores, nigericin, monensin and X-206 (Table 1). Inhibition by ouabain was reversed almost completely by KCl (Table 1, Expt 2) whereas KCl had no effect on the inhibition produced by the monovalent ionophores (for example, Table 1, Expt 4).

Inhibition of stimulated bone resorption by nigericin was reversible within the first 24 h that the ionophore was present (Fig. 1*a*). However, after 48 h in the presence of both PTH and ionophore, the inhibition of bone resorption was no longer reversible (Fig. 1*b*). Similarly, if calvaria were pretreated with nigericin alone and then stimulated with PTE after washing out the ionophore, there was no subsequent response to PTE after prolonged (>24 h) pretreatment with ionophore. When similar experiments were performed with ouabain, the results were comparable; inhibition of stimulated resorption was reversible within the first 24 h of treatment, but not after 48 h of treatment with ouabain (N.S. K., unpublished observations).

To test directly for the role of monovalent cations in the PTH-stimulated Ca release from bone, experiments were performed in medium containing various concentrations of Na^+ and K^+ (Table 2). Decreasing the Na^+ concentration below the control level of 150 mM resulted in a dose-dependent inhibition of PTE-stimulated Ca release from the calvaria. Below 100 mM Na^+ there was no response to PTE. Removing K^+ from the medium had no significant effect on PTE-stimulated bone resorption nor on the inhibition of stimulated resorption produced by ouabain or nigericin. However, increasing the K^+ concentration above the control level of 5 mM blunted or reversed the inhibition by ouabain of PTE-stimulated resorption without altering the inhibition produced by nigericin.

All of the inhibitory agents used in this study alter monovalent ion fluxes across the plasma membrane and would be expected

Table 1 Inhibition of PTH-stimulated bone resorption *in vitro*: effects of veratridine, ouabain and monovalent cation ionophores

Expt no.	Treatment	Medium calcium ($mg\ dl^{-1}$)
1	Control	6.2 ± 0.67
	PTE ($0.1\ U\ ml^{-1}$)	13.8*
	Veratridine (0.3 mM)	6.2
	PTE ($0.1\ U\ ml^{-1}$) + veratridine (0.3 mM)	6.3
2	Control	7.1 ± 0.88
	PTE ($0.1\ U\ ml^{-1}$)	12.8*
	KCl (15 mM)	8.0
	PTE ($0.1\ U\ ml^{-1}$) + ouabain (0.3 mM)	6.1
	PTE ($0.1\ U\ ml^{-1}$) + ouabain (0.3 mM) + KCl (15 mM)	10.4*
3	Control	8.0 ± 0.79
	PTE ($0.1\ U\ ml^{-1}$)	15.5*
	PTE ($0.1\ U\ ml^{-1}$) + nigericin (10^{-7} M)	7.5
	PTE ($0.1\ U\ ml^{-1}$) + monensin (3×10^{-7} M)	6.4†
	PTE ($0.1\ U\ ml^{-1}$) + X-206 (10^{-7} M)	8.1
4	Control	6.3 ± 0.46
	PTE ($0.1\ U\ ml^{-1}$)	9.4*
	KCl (15 mM)	7.2
	PTE ($0.1\ U\ ml^{-1}$) + nigericin (10^{-7} M)	6.0
	PTE ($0.1\ U\ ml^{-1}$) + nigericin (10^{-7} M) + KCl (15 mM)	5.7

Calvaria from 4–5-day-old neonatal mice were incubated at 37 °C in Dulbecco's modified Eagle's medium containing heat-inactivated (56 °C, 60 min) horse serum (15%) and fetal calf serum (2.5%)[15,16]. Treatment was begun at zero time with concentrations of each agent which were determined to be maximally effective by complete dose-response experiments. Cultures were gassed daily and the medium changed once at 24 h. Medium Ca concentrations were measured at 24-h intervals using an automatic fluorometric titration method. Values given are the mean of at least four bones per group at the end of a 72-h treatment period. By analysis of variance the s.e. was calculated from the residual error term for each experiment. Because the number of bones in each group in a given experiment was the same, the s.e. for each group was the same, and therefore for simplicity the s.e. is given only for the control group in each experiment.

* $P < 0.001$, † $P < 0.05$, compared to control cultures.

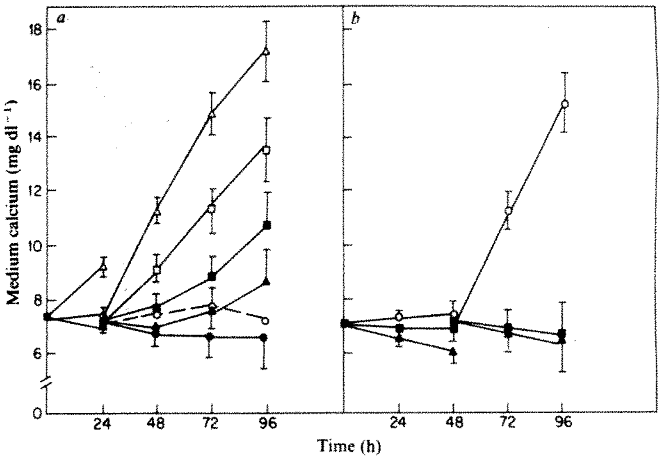

Fig. 1 Effects of pretreatment and reversibility of bone resorption inhibited by nigericin. *a*, Calvaria were cultured as described in Table 1 legend. Bones were treated with $0.1\ U\ ml^{-1}$ PTE without or with 10^{-7} M nigericin. Medium was changed at 24 h and fresh hormone and ionophore readded after washing each calvarium twice with 2 ml control medium. ○, Control; △, PTH alone; □, control medium for 24 h, then PTH; ■, PTH + nigericin for 24 h, then PTH alone; ▲, nigericin for 24 h, then PTH alone; ●, PTH + nigericin. *b*, Cultures were prepared and incubated in parallel with those in *a*, except that medium was changed and calvaria washed at 48 h. ○, Control for 48 h, then PTH; ■, PTH + nigericin for 48 h, then PTH alone; ▲, nigericin for 48 h, then PTH alone. Values are the mean ±s.e. for at least four bones per group.

to increase the intracellular concentration of Na^+. The cardiac glycoside, ouabain, is known to inhibit specifically the Na, K-dependent adenosine triphosphatase [($Na^+ + K^+$)ATPase], thereby preventing Na^+ efflux in exchange for K^+ influx[9]. Our observation that high K^+ reversed the inhibition by ouabain of PTE-stimulated bone resorption supports the argument that the ouabain effect described here is due to inhibition of ($Na^+ + K^+$)ATPase activity in bone. K^+ has been shown to compete in a complex manner with ouabain for binding to the ($Na^+ + K^+$)ATPase and to antagonize specifically the effects of cardiac glycosides in other target tissues[10]. Also, 0.3 mM ouabain maximally inhibited ($Na^+ + K^+$)ATPase-dependent ^{86}Rb uptake by calvaria (N. S. K., unpublished observations).

Monovalent cation ionophores allow fluxes of Na^+ and other monovalent cations along electrochemical gradients across the plasma membrane of the cell[4,5]. Ionophore-mediated Na^+ influx is unrelated to the influx that occurs via the voltage-dependent Na channel. However, veratridine binds directly to the Na channel, stabilizing it in the open conformation and thereby increasing Na^+ influx[11].

Once the intracellular Na^+ concentration is increased sufficiently to decrease the magnitude of the transmembrane Na^+ concentration difference, the Na^+ gradient across the plasma membrane would no longer be favourable for the Ca^{2+} efflux to occur that is coupled to Na influx[8,12]. If PTH-stimulated bone resorption requires Na–Ca exchange, inhibition of that exchange by increasing intracellular Na^+ would explain the common effects of the agents we used to inhibit bone resorption. Alternatively, ouabain, veratridine and the ionophores or high intracellular Na^+ concentrations might disrupt some other critical step in the mechanism of action of PTH by an indirect effect on cell metabolism. However, the findings given in Table 2 make this less likely. The transmembrane Na^+ concentration difference was decreased by lowering extracellular Na concentration. This manoeuvre had the same effect as increasing intracellular Na^+, providing strong evidence to support the necessity for a Na–Ca exchange mechanism in the PTH-stimulated release of Ca from bone. A recent model of how cardiac glycoside inhibition of the ($Na^+ + K^+$)ATPase affects Ca^{2+} levels in cardiac muscle cells proposes a similar coupling between a Na–Ca exchange mechanism and the action of the Na pump to regulate transmembrane cation movements[9].

Table 2 Effects of medium Na^+ and K^+ concentrations on PTE-stimulated bone resorption

Medium		Medium calcium ($mg\ dl^{-1}$)			
[Na^+] (mM)	[K^+] (mM)	Control	PTE	PTE + ouabain	PTE + nigericin
150	5	7.2 ± 0.38	10.4*	6.3*	6.7†
120	5	4.9 ± 0.25	6.4*	5.6†	ND

50	5	5.6 ± 0.36	6.0	6.0	6.2
150	0	6.4 ± 0.50	9.5*	4.7	5.4
150	10	5.6 ± 0.48	9.1*	7.5‡	5.5
150	30	7.0 ± 0.28	11.0*	8.4*	5.2*

Calvaria were cultured as described previously[9] except that the medium was made using an MEM-Select-amine kit (Grand Island Biological Co.) and salt concentrations were adjusted to the desired compositions shown. Isotonicity was maintained using choline chloride whenever the NaCl concentration was decreased below 150 mM. Bones were treated with $0.1\ U\ ml^{-1}$ PTE without or with 0.3 mM ouabain or 10^{-7} M nigericin and medium was changed once at 24 h. Values given are the mean ±s.e. of four bones per group after 72 h of treatment. As in Table 1, the s.e. for each different medium tested is presented with the control value. The concentrations of Na^+ and K^+ in unmodified medium are 150 and 5 mM, respectively. ND, Not determined.

* $P < 0.001$, † $P < 0.05$, ‡ $P < 0.01$, compared to control for each different medium.

The time dependence of the reversibility of nigericin (and ouabain) inhibition, and of the pretreatment effects on PTE-stimulated resorption are also consistent with a mechanism involving an increase in intracellular Na^+. Coupled transport of Na^+ and amino acids or sugars has been described[13]. Altering the Na^+ gradient would affect this transport system and, with prolonged treatment, such transport would decrease and cellular energy metabolism would be inhibited. This might explain the irreversibility of prolonged inhibition by the agents used. Such a general effect on cellular metabolism is unlikely to explain the inhibition of PTE-stimulated resorption, however, because the inhibition of resorption occurs more rapidly (within 6 h)[14] than the more long-term changes in metabolism.

The effects of pretreatment with nigericin and ouabain imply that their inhibitory actions are not the result of a direct competitive interaction at the level of the PTH receptor. This conclusion is supported by the ability of these compounds to inhibit bone resorption stimulated by prostaglandin E_2 and 1,25-dihydroxyvitamin D_3 as well as PTH[14]. Therefore, it seems that Na–Ca exchange may be the final common step in the mechanisms of action of several hormones that stimulate bone resorption.

We thank Dr Stanley Goldin and Ms Kut-Nie Tan for helpful discussions, and Mrs Elizabeth Moore for statistical analyses. This research was supported by the USPHS (AM 10206); N.S.K. received a NRS award (AM 05595).

Disruption of optic fibre growth following eye rotation in *Xenopus laevis* embryos

Philip Grant & Eric Rubin*

Department of Biology, University of Oregon, Eugene, Oregon 97403

Eye rotation is an experimental paradigm used to study axial specification of the amphibian retina and its connections to the tectum[1–4]. Jacobson reported[4] that the naso-temporal and dorso-ventral axes are determined sequentially and independently between Nieuwkoop–Faber (NF)[5] stages 28 and 32 in *Xenopus*. Others claim, however, that both retinal axes are determined much earlier and not independently in *Xenopus* and *Rana*[6–8]. We now find that in *Xenopus* this operation can disturb the exit of optic fibres from the retina with the severity of disruption depending on the time of surgery. Eyes rotated 180° at NF stage 26–27, before any fibres develop, form aberrant retinal fascicle patterns in which the first optic fibres to differentiate (pioneer fibres), failing to exit from the eye, are deflected into circling instead of radial trajectories. Optic fibres appearing later follow these early misguided axons, creating circular bundles. Eyes rotated later (NF 32–34), after optic fibres differentiate, develop normal but inverted patterns because radial fascicles in the retina at the time of operation accurately guide all newly arising fibres to the optic nerve head. This stage-dependent sensitivity of retinal fascicle development must be considered when interpreting the results of rotation experiments.

While testing Sperry's hypothesis of neuronal specificity in *Xenopus*, Jacobson[4] claimed that after 180° rotation of the embryonic eye at NF stage 28, the retina regulated, and a normally ordered retinotectal projection developed, whereas rotation at stage 30 led to inversion of only the naso-temporal axis. Rotation at stage 32 produced a completely inverted retinotectal projection with both axes rotated. Others[7] find in *Xenopus*, however, that rotation of eye vesicles at stage 21–22 gave either rotated retinotectal maps or compound eyes, one normal and the other rotated. Likewise in *Rana*, at Shumway[9] stage 16–17 and at stage 26 in *Xenopus*, eye rotation resulted in inverted retino-tectal maps[6,8] with the map's orientation matching the position of the choroid fissure.

In such studies in *Xenopus*, ganglion cell fibres are assumed not to develop until stage 33 (refs 5, 10, 11). Hence, all eye operations before that stage are assumed to be completed before any optic fibres appear in the retina. We found, however, that optic fibres develop early in *Xenopus*[12–14]. Fibres appear as early as NF 28, before the retina completes invagination. They form bundles which enter the optic stalk and reach the brain by NF 32. These bundles organize into a stereotyped radial pattern within the early embryonic retina[12]. Evidently, optic fibres differentiate in the retina and form bundles precisely during those stages when the retina is assumed to undergo axial specification[4]. Thus eye rotation before or after the appearance of retinal fibres may have different effects on development of fascicle patterns and may, in turn, affect fibre outgrowth and connections in the brain. For example, the presence of degenerating axons in the optic stalk may guide regenerating axons to their targets in the brain[15].

To determine how the presence of optic fibres at the time of the operation affects development of fascicle patterns, embryonic eyes were rotated 180° at early stages (NF 26–28), before fibres had developed, and at later stages (NF 32–34), after optic fibres had entered the optic stalk and diencephalon. Control operations involved removal of the eye and replacement in normal orientation. When embryos reached tadpole stages 54–55, the operated eyes were removed and the retinas prepared as silver-stained whole mounts to reveal the fibre patterns[12,16]. A similar whole-mount technique has been used for the developing chick retina[17–19]. Silver-stained serial sections[20] of embryos fixed at hourly intervals after surgery were also prepared to determine how optic fibres emerge from rotated eyes.

A normal retinal fascicle pattern is shown in Fig. 1. A lesion at the dorsal pole of the eye identifies the dorsal quadrant. The long, thin fascicles in this quadrant are arranged in a distinctive arcuate pattern that differs from the pattern of shorter, thicker bundles in the ventral quadrant. Nasal and temporal quadrant fascicle patterns are very similar.

Twelve of 14 retinas in control eyes operated at early NF stages 26–28 gave rise to normal patterns (Table 1). On the other hand, 13 of 25 early rotated eyes were quite abnormal with bundles of circling axons (Fig. 2). Two retinas were normal in orientation and symmetry whereas eight eyes (one-third) exhibited 90°-rotated or 180°-rotated patterns (Fig. 3). Although some retinas possessed an optic nerve, those retinas exhibiting circling fibre patterns usually had no optic nerves or abnormally thin nerves.

The absence of optic nerves on some retinas indicates that optic fibres did not emerge. In silver-stained serial sections of early rotated eyes we found that a choroid fissure developed dorsally in most instances but no choroid or an abnormal choroid fissure developed in some embryos. Though some fibres exited through dorsally located fissures, others remained within the optic fibre layer or penetrated and grew in the receptor layer (Fig. 4) or over the cornea, sending branches into the dorsal head mesenchyme.

Table 1 Retinal fibre patterns in 180° rotated eyes

			Normal patterns rotated through			Abnormal patterns		
Stage of operation	Series	No. eyes* stained	0°	90°	180°	Circling fibres	Crossing† fibres	Diffuse‡
Early (NF stages 26–28)	Control	14	12	0	0	2	—	—
	Experimental	25	2	1	7	13	1	1
Late (NF stages 30–33)	Control	12	11	0	0	—	—	1
	Experimental	18	0	4	13	—	—	1

Xenopus embryos reared at room temperature were anaesthetized in 100% Steinberg's solution containing MS 222 (1/3,000). The left eye was cut out of the orbit with tungsten needle and hair loop, then replaced in the orbit without rotation (controls) or rotated 180° (experimentals). Healing for 1 h was assisted by placing a small glass bridge over the eye. Animals were placed in 10% Steinberg's and allowed to develop to late-stage tadpoles (55–58) when they were re-anaesthetized. A lesion was made in the dorsal pole of the retina with a tungsten needle or a Biolaser beam. The animal was killed and the left eye removed from its orbit. After fixing in formol (10%)-sucrose (0.1M) for at least seven days, the lens, cornea, sclera and pigmented epithelium were carefully dissected away. The clean retina was then slit radially in four places and prepared as a whole flat mount. It was stained with silver according to a modified Bielchowsky precedure[16] and mounted in glycerol on a slide. Orientation of each retina was related to the position of the dorsal lesion. Each specimen was photographed in reflected light in a Zeiss Universal photomicroscope with a 4X Zeiss Epiplan HD objective and 6X eye piece. Kodak 4 × 5 Ektaplan negatives were prepared as contact prints giving a final magnification of almost ×40. To analyse bundle patterns the whole mounts were examined in photographs, under the stereomicroscope and under the light microscope using transmitted light.

* Data based on whole mounts of NF stage 55–58 tadpole retinas.

† A few fibres crossed others.

‡ Patterns stained too diffusely to interpret.

In eyes rotated at NF stages 32–34, 11 of 12 control eyes were normal, but most rotated eyes developed rotated patterns; 95% of fascicle patterns were approximately normal but rotated. Most of these (13/18) were inverted 180° whereas others were rotated only 90°. No normally oriented patterns were obtained although fascicle patterns in each retinal quadrant were normal for that quadrant. All retinas had optic nerves of normal thickness.

The emergence of fibres from eyes rotated at late stages was more normal. In serial sections of embryos examined 4–24 h after rotation, optic fibres emerged through a dorsal fissure. No fibres emerged through ectopic sites or grew into the receptor layer. In only one case did fibres remain in the head mesenchyme and collect into a thick neuroma. Otherwise, fibres leaving such a dorsally oriented fissure penetrated the region occupied by oculomotor nerves and eye muscles.

Thus, rotation of the embryonic eye anlage at early stages before fibres appear, and not the surgical procedure itself, affects development of retinal fascicle patterns. Most patterns are abnormal; the one-third normal but rotated patterns, resembling those obtained after late rotation, may have been older eyes (stage 28–29) with a few fibres already present at the optic nerve head[14]. Staging of early embryos is somewhat unreliable and such staging errors could occur[13]. Also, the two normal patterns may be partly due to errors in the operation or to derotation[19]—rotated eyes may return to a normal orientation during healing. Rotation at later stages, after fibres have emerged from the retina and entered the stalk, resulted in normally organized but inverted patterns. Of the combined 43 experimental eyes, only two yielded a normally oriented fascicle pattern.

We suggest that circling fibre patterns develop in eyes rotated early, before fibres are present, because axons that arise after the operation are unable to emerge and conseqently grow abnormally within the retina. This hypothesis is consistent with the observation that retinas with the most abnormal circling fibre patterns usually lack an optic nerve and it suggests that fibre outgrowth shortly after rotation is abnormal because the surgical procedure and tissue healing disrupt proper orientation of the first ganglion cell fibres. As the first ganglion cells

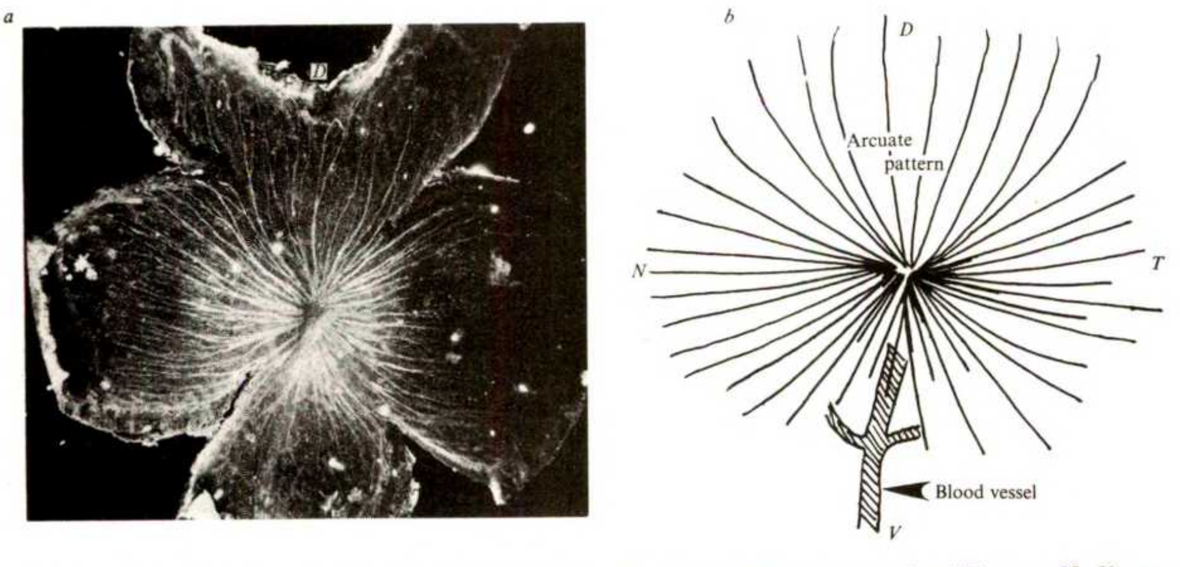

Fig. 1 *a*, Normal fascicle pattern in the optic fibre layer of a silver-stained whole mount of a NF stage 58 *Xenopus* retina. *b*, Diagram to assist identification of specific fascicle patterns. The characteristic thin, long, arcuate fascicles in the dorsal quadrant can be distinguished from the shorter and thicker bundles in the ventral quadrant. The nasal and temporal bundle patterns are mirror images of one another. The ventral blood vessel (hyaloid artery) in the retina is stained lightly and is useful as another orienting marker. Orientation is based on the notch (*D*) located at the dorsal pole of the retina. Magnification ×30. *D*, *V*, *N* and *T* refer to dorsal, ventral, nasal and temporal poles, respectively, corresponding to the position of the eye in the orbit.

differentiate, their axons are guided to the dorsally orientated fissure, if present, or randomly to some other retinal site, if the fissure is abnormal or absent. A few fibres may penetrate the stump of the optic stalk attached to the eye and enter the head mesenchymal space. If closure of the dorsal fissure is abnormal or delayed, or if the stump has healed over before fibres reach the fissure, then many of the earliest fibres do not emerge and grow within the retina instead. As newly differentiating axons at the margin of the growing retina follow pre-existing fibre bundles[12], only a few abnormally directed pioneering fibres appearing at early stages are sufficient to generate masses of circling fibres. Comparable circling fibre patterns have been noted in the regeneration of sensory fibres within the insect epidermis when regrowth of cuticle prevented fibres from returning to the central nervous system[21]. It remains to determine why the first fibres trapped in eyes form circular patterns, rather than random tangles.

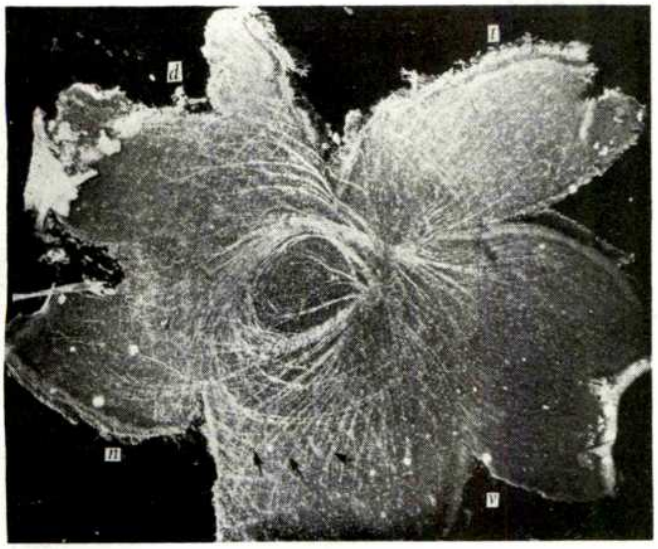

Fig. 2 Early rotation. Eye rotated 180° at stage NF 27/28 and prepared as a silver-stained whole mount at stage 56. Pattern of fascicles is highly abnormal with many fibres circling on themselves within the optic fibre layer of the retina. Some fibres do organize into radial fascicles (arrows) but their number and thickness is very much reduced. *d, v, n* and *t* refer to dorsal, ventral, nasal and temporal poles, respectively, corresponding to the position of the eye in the orbit. ×30.

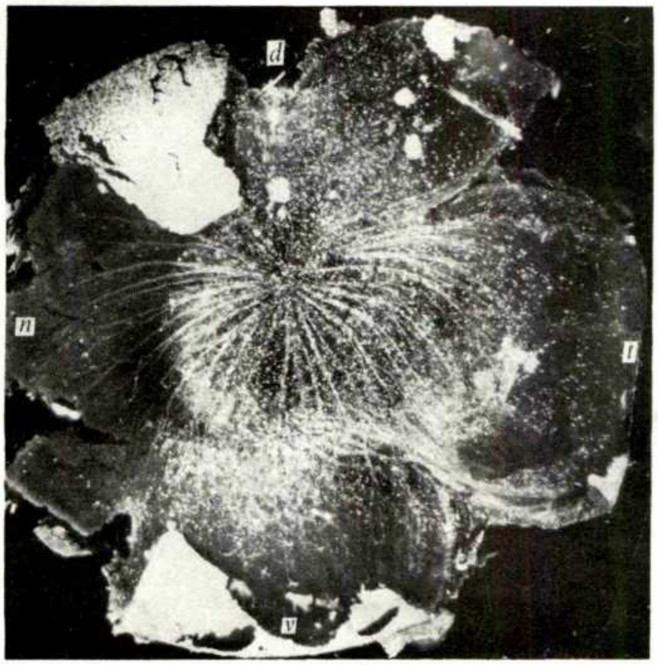

Fig. 3 Late rotation. Eye rotated 180° at NF stage 33 and prepared as a whole mount at stage 56. A normal but 180° inverted fascicle pattern is obtained. Arcuate fascicles characteristic of dorsal quadrant now oriented in opposite direction towards ventral pole. *d, v, n* and *t* refer to dorsal, ventral, nasal and temporal poles, respectively. ×40.

At later stages (NF 32), eyes have formed a normal fissure and fibres have already entered the optic stalk. Fibre pathways to guide ganglion cell axons to the optic nerve head and out of the fissure are thus established before the operation. After eye rotation, fibres in the proximal stump of the optic stalk grow out before wound closure and enter the head mesenchyme. All subsequent ganglion cell axons developing in the inverted eye are guided along the pre-existing fascicles to the optic nerve head, into the proximal stalk and out into the head mesenchyme. They reach the brain following aberrant pathways in most cases, usually along the oculomotor nerves or branches of the trigeminal nerve to the hind brain[22]. As quadrant-specific patterns of retinal growth are unaffected by eye rotation, a normal but inverted fascicle pattern develops within the retina.

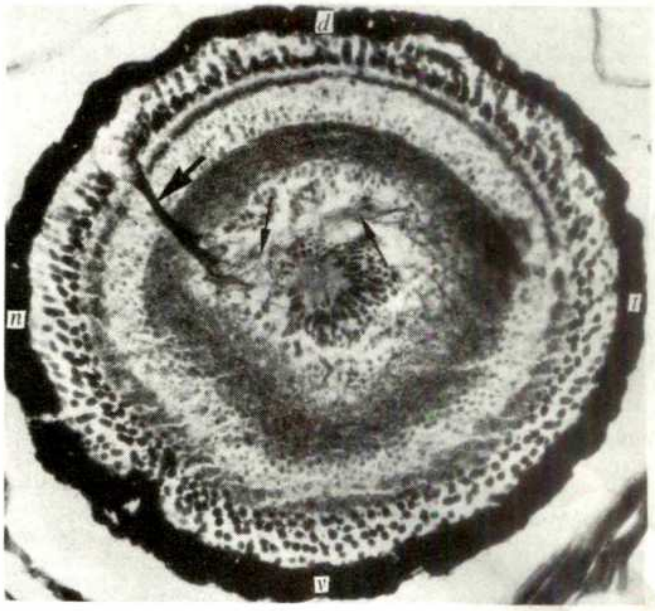

Fig. 4 Early rotation. Left eye rotated at NF stage 26/27 and fixed in aqueous Bouins at NF stage 48. Animal embedded in paraffin, sectioned in the sagittal plane, and stained with silver according to a modified Holmes stain[20]. Axons inside optic fibre layer of retina (small arrows) circle and collect into a large bundle (large arrow) which penetrates the receptor layer ectopically in dorso-nasal quadrant, at some distance from optic nerve head. Fibre bundle follows receptor layer at periphery when traced into more lateral sections. Some fibres eventually emerge abnormally and enter the dorsal mesenchymal space around the eye. *d, v, n* and *t* refer to dorsal, ventral, nasal and temporal poles, respectively. ×180.

These results are consistent with the idea that two processes govern the development of optic fibre fascicles in the retina: fibre following and the kinetics of annular ring growth at the retinal margin[12]. These rules are invoked in space–time models ordering growth and connection of retinal ganglion cell axons to visual centres in the brain[12,23]. It seems that most mapping experiments concerned with retinotectal connections and axial specification need to be re-examined in terms of the effects of surgery on development of retinal fascicle patterns and the emergence of optic fibres from the eye. Experiments correlating fascicle patterns and optic fibre pathways with retinotectal mapping from experimentally modified retinas are under way.

We thank Harry Howard and Carol Cogswell for assistance with photography, and Charles Kimmel and Charles Cima for criticisms. This research was supported in part by NSF grant BSN-75-23241 and grant EY 02646 from the National Eye Institute.

Aspartate and glutamate as possible neurotransmitters of cells in layer 6 of the visual cortex

Robert W. Baughman & Charles D. Gilbert

Department of Neurobiology, Harvard Medical School, 25 Shattuck St, Boston, Massachusetts 02115

Earlier work[1–8] has suggested that aspartate, glutamate and γ-aminobutyric acid (GABA) act as transmitters in the cerebral cortex. There is reasonable evidence for the identity of the cell population responsible for GABA release[9–12] but until now there has been little evidence concerning the sources for release of aspartate and glutamate. Here we have used two approaches to identify possible neurotransmitters used by cells in the visual cortex: measurement of the efflux of endogenous compounds in conditions of synaptic release and localization of these compounds to particular cell classes using neurotransmitter-specific histochemical techniques. Our results suggest that the acidic amino acids aspartate and glutamate may be cortical neurotransmitters, as shown by calcium-dependent release from endogenous stores and by uptake specific to pyramidal cells in layer 6 of the cortex. These substances may therefore have a role in the function of layer 6 cells, which are responsible for the recurrent projection from the cortex to the lateral geniculate nucleus and for the projection within the cortex from layer 6 to layer 4.

The release experiments were carried out with a tissue-slice preparation from rat visual cortex. An elevated potassium medium was used to induce synaptic release, and a similar medium with low calcium and high magnesium, which should block synaptic release, was used as a control. The release of endogenous compounds from slices incubated in each of these two media was measured using a HPLC system. The system used was capable of detecting compounds containing a primary amino group, with a detection limit of about 10 pmol. Its principal advantage in the present study was to enable us to analyse substances released from endogenous stores in the tissue. Rates of release for a series of amino acids measured in stimulated and control conditions are given in Table 1. To illustrate more clearly the changes in release between the stimulated and control media, the ratio of the rates of release for the two conditions are shown in Fig. 1. Marked increases were observed for aspartate (12-fold), glutamate (14-fold) and GABA (sixfold). The ratios for the other amino acids ranged from one- to twofold. These findings are consistent with previous work[1–8].

Autoradiographic localization based on uptake of ^{3}H-L-aspartate and ^{3}H-L-glutamate has been relatively unsuccessful for labelling of cell bodies, possibly because these substances are rapidly metabolized following uptake. The D-form of aspartate, which is not metabolized, is accumulated in brain tissue through the same high-affinity uptake system that transports the L-forms of both aspartate and glutamate and thus offers the possibility of labelling aspartate- or glutamate-accumulating neurones[13]. For this reason we used ^{3}H-D-aspartate to label the cortical cells that may be responsible for the previously demonstrated aspartate and glutamate release. Although it should be possible to label these cells at the site of injection, they may also be labelled by neurotransmitter-specific retrograde transport following injection at their distant efferent targets[14,15]. As cells in different cortical layers have distinct projections, we made injections in

Table 1 Release of various amino acids in stimulated and control conditions

	Release rate (pmol per mg wet wt per 5 min) Stimulated	Control
Taurine	49 ± 16	37 ± 15
Aspartate	206 ± 35	17 ± 4
Threonine	74 ± 14	34 ± 5
Serine	171 ± 54	88 ± 21
Glutamine	76 ± 29	63 ± 9
Glutamate	552 ± 171	38 ± 7
Glycine	98 ± 12	50 ± 10
Alanine	115 ± 22	54 ± 9
Valine	10 ± 2	12 ± 9
isoLeucine	21 ± 6	12 ± 3
Leucine	39 ± 14	21 ± 5
Tyrosine	6 ± 2	4 ± 1
Phenylalanine	10 ± 3	6 ± 1
beta-Alanine	5 ± 2	3 ± 2
GABA	111 ± 25	20 ± 6
Histidine	20 ± 4	14 ± 5
Lysine	19 ± 4	13 ± 6
Arginine	11 ± 6	7 ± 2

Blocks of visual cortex were sliced at 200-μm thickness with a tissue chopper. The tissue slices were suspended in an Earle's bicarbonate-buffered salt solution (143 mM Na^+, 5 mM K^+, 1.8 mM Ca^{2+}, 0.8 mM Mg^{2+}, 125 mM Cl^-, 26 mM HCO_3^-, 1.0 mM $H_2PO_4^-$, 0.8 mM SO_4^{2-}, 5.5 mM glucose) gassed with 5% CO_2/95% air at 37 °C. The slices were incubated in a series of buffers (5 ml of each) with changes every 5 min. For the stimulated release experiments, the slices were incubated with three consecutive 5-min changes of normal medium followed by a 5-min incubation (stimulated release) in high-potassium (50 mM K^+, 98 mM Na^+) medium. For the control release experiments, the slices were incubated with two 5-min changes of normal medium, followed by a 5-min incubation in low-calcium (0.1 mM Ca^{2+}, 10 mM Mg^{2+}, 132 mM Na^+) medium and a 5-min incubation (control release) in high-potassium, low-calcium (50 mM K^+, 0.1 mM Ca^{2+}, 10 mM Mg^{2+}, 87 mM Na^+) medium. All buffer solutions contained 1 μM *n*-leucine as an internal standard. At the end of the incubation series the sections were weighed, and the fractions from each buffer change were frozen in liquid nitrogen, lyophilized and desalted in 6 M HCl in acetone. The compounds present in the final extract were analysed on a HPLC, with a sulphonated divinylbenzene polystyrene cation exchange column (Dionex DC-5A resin in a 4 mm × 15 cm stainless steel column), and *o*-phthalaldehyde fluorescence detection[19]. This procedure detects compounds containing primary amino groups, such as amino acids and many peptides. Quantification was based on peak heights compared with the *n*-leucine internal standard.

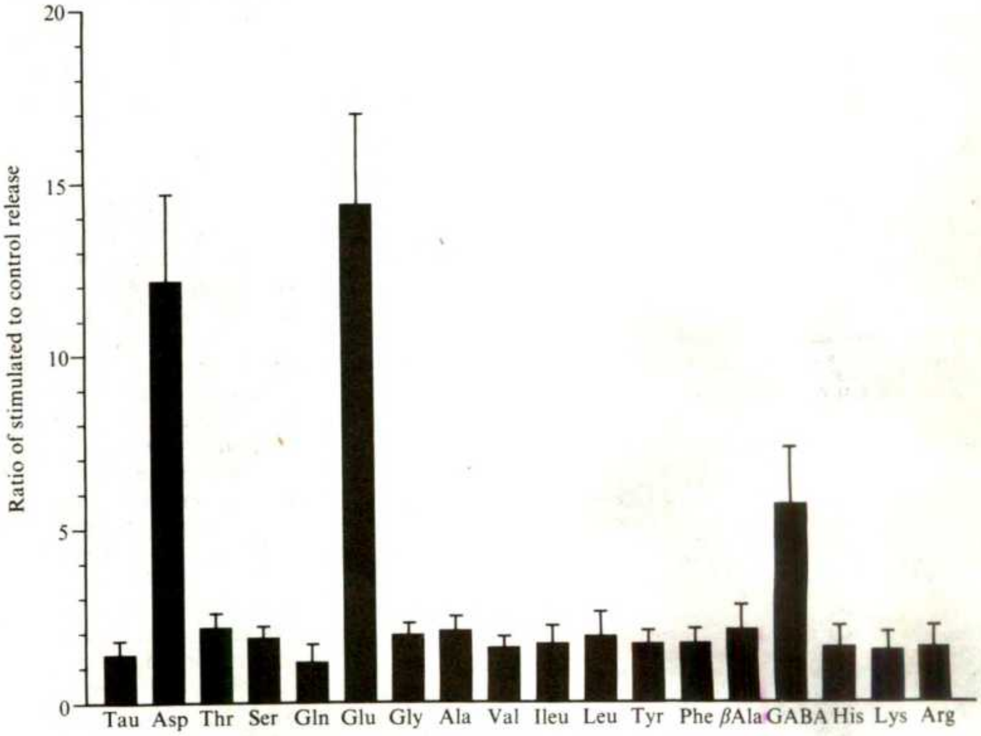

Fig. 1 Ratios of the rates of release of endogenous amino acids in stimulated and control conditions (from Table 1).

several areas to determine the population(s) capable of transporting the label retrograde from their terminals. These areas included the lateral geniculate nucleus (LGN), which receives input from cortical layer 6, the superior colliculus, which receives input from layer 5, and area 19, which receives input from layers 2 and 3 of area 17 (ref. 16). The most striking result was observed after the injections in the LGN (Fig. 2). Many cell bodies in layer 6 were labelled and a diffuse band of label was present in layer 4. No labelled cortical cells were seen after injections in the superior colliculus, and only a few were seen in area 17 after the injection in area 19. Following injections in area 17 the local pattern of cortical labelling was similar to that seen following retrograde transport from the LGN, that is, there was a diffuse band of label in layer 4 and many labelled cells in the deeper layers, especially layer 6. Thus within the visual cortex the ability to accumulate ^{3}H-D-aspartate seems to be particularly localized in layer 6 cells.

Following injections in the LGN, the cells in layer 6 are probably labelled by retrograde transport. The band in layer 4, however, could represent labelling either of geniculate terminals of the extensive plexus of collaterals of layer 6 cells which arborize in that layer[17]. Two lines of evidence support the latter: (1) at the injection site in the LGN the principal neurones are unlabelled, so it is unlikely that they take up the label and transport it to the cortex. (2) After cortical injections there was only a diffuse patch of label in the LGN at the topographically appropriate site, with no labelling of cell bodies. This is consistent with the idea that the geniculate neurones do not take up the ^{3}H-D-aspartate, and furthermore demonstrates that the layer 6 cells are capable of transporting the label anterograde to their terminals in the LGN. Thus the band of label in layer 4 seen after the injection in the LGN is probably the result of filling of collaterals of layer 6 cells.

Therefore, several results support the specificity of uptake of ^{3}H-D-aspartate by the layer 6 cortical cells. From the retrograde transport experiments we found that the layer 5 cells and the cells in the LGN, for example, do not take up and transport the label whereas the layer 6 cells do. Furthermore, after injections of label in the cortex the layer 6 cells are the predominant cell class responsible for uptake in the vicinity of an injection encompassing all layers. Previous studies, which have examined changes in high-affinity uptake of ^{3}H-D-aspartate and in endogenous content of aspartate and glutamate following cortical

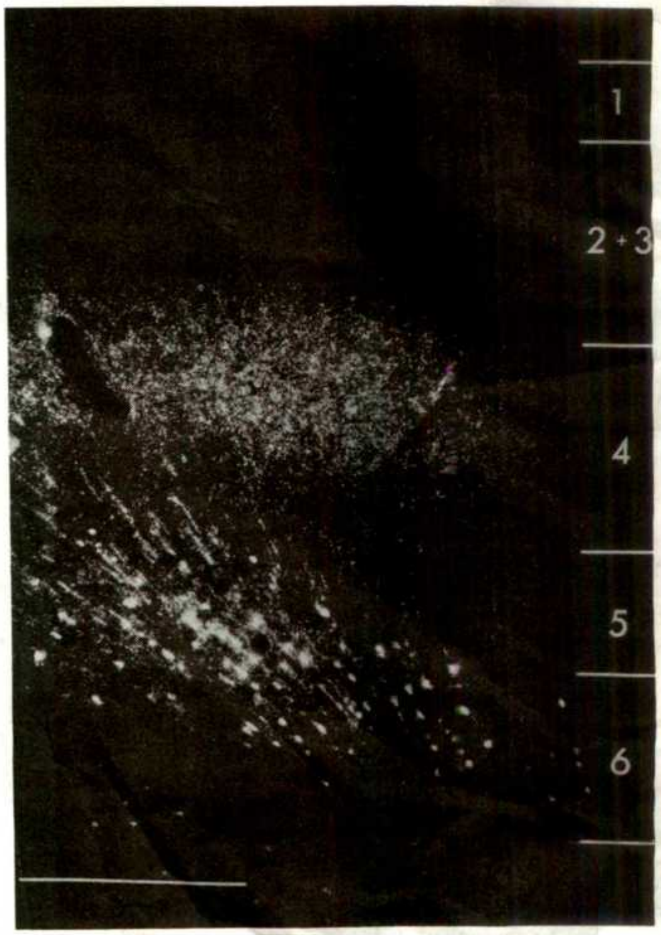

Fig. 2 ^{3}H-D-aspartate (50 μCi in 0.5 μl buffered saline) was pressure-injected from a recording pipette[20] into the LGN of the cat. The animal was resuscitated and, after 2 days, re-anaesthetized and perfused with a glutaraldehyde fixative. The brain was sectioned and the sections processed for autoradiography. The figure shows the pattern of labelling in the cortex, with labelled cells in layer 6 and a band of diffuse label in layer 4 (3-week exposure time). Bar, 500 μm.

ablation, have suggested that both the corticogeniculate and corticocollicular pathways are associated with aspartate and glutamate[18]. The present results suggest, however, that these compounds are only associated with the corticogeniculate pathway.

We have thus provided additional evidence based on release of endogenous compounds that aspartate and glutamate, as well as GABA, may act as neurotransmitters in visual cortex. The above results do not exclude the possibility, however, that aspartate and glutamate may be metabolites of the true transmitter. We have also shown that uptake of ^{3}H-D-aspartate is particularly associated with the cells in layer 6 that participate in the corticogeniculate pathway and that project to layer 4. These findings may be useful in determining the role of this cell class in cortical and geniculate function.

Cell movements in *Xenopus* eye development

Christine Holt

Medical Research Council Cell Biophysics Unit, King's College,
26–29 Drury Lane, London WC2B 5RL, UK

The vertebrate eye develops morphological markers, such as the ventral choroid fissure, which define its anatomical polarity in relation to the body. Also, retinal nerve fibres behave as though regionally differentiated by forming ordered, topographical maps of the visual field in the brain[1–4]. It has long been held that these two features of eye polarity—its structure[5–10] and the neural specificity of the ganglion cells[11,12]—are labile in the early eye vesicle and become determined relative to body axes at a subsequent stage of development. Contrary to these earlier findings, recent experiments[13–15] show that the structure and connectivity of the eye are already determined by the time it first appears as a distinct eye vesicle; surgical construction of eye pigmentation chimaeras[14] suggested that normal tectal maps, previously reported after early eye rotations, may have arisen from neural retina cells recruited from the optic stalk after the operation. In agreement, using a radioactive tag which marks neural retina as well as pigment epithelium, I report here that during normal development in *Xenopus laevis*, cells in the ventral retina, where the choroid fissure forms, move into position from the optic stalk region during eye-cup formation. Depending on developmental stage, surgical eye rotations may intercept their movement and this provides a simple explanation of results previously taken to indicate a change from a labile to a determined state of eye polarity.

During development in *Xenopus*, the eye rudiment arises as a lateral protrusion of the neural tube and becomes a distinct eye vesicle at stage 22 (ref. 16). The vesicle, whose epithelium remains connected with the neural tube by the optic stalk until the eye-cup stage, then elongates dorsally leaving the stalk attached to its ventral pole. Before the outgrowth of optic nerve fibres, the vesicle invaginates on itself to form the double-walled eye cup. This inward movement, beginning dorsally at stage 27, brings the presumptive neural retina adjacent to the proximal wall of the vesicle, the presumptive pigment epithelium[17], which attenuates into a thin layer of flattened cells. The choroid fissure develops as a vertical cleft in the ventral part of the eye, beginning at stage 29 in the vesicle margin and elongating to completion along with retinal invagination at stage 32 (ref. 18). Its formation establishes continuity between the inner retinal surface and the optic stalk, thereby providing a direct pathway to the brain for pioneer ganglion cell fibres which begin to leave the eye through the apex of the fissure at stages 30–31 (refs 18, 19). An assumption implicit in the studies using eye rotation surgery to investigate the state of determination of eye polarity in embryos[5–12] has been that the boundaries of the eye vesicle define those of the newly invaginated eye cup. On this basis, the ventral fissure region should arise from cells already within the eye vesicle. The results presented here show this interpretation of eye morphogenesis, at least in *Xenopus*, to be erroneous.

To trace the cell movements involved in the morphogenesis of the eye cup between stages 22 and 32, a series of experiments was performed in which the whole or part of the *Xenopus* eye rudiment was excised, incubated in a droplet of operating medium containing ^{3}H-thymidine (^{3}H-TdR; 10^{-6} M, 46 Ci mmol^{-1}) for 10–15 min, then washed thoroughly in fresh medium (six changes) and replaced orthotopically in the original embryo. The operating medium was two-thirds strength Niu Twitty[20] solution containing 1:10,000 tricaine methane sulphonate (MS 222; Sandoz) at *p*H 7.6, and the animals were reared at 18–20 °C after the operations. They were fixed 12–48 h later (stages 36–42), serially sectioned at 1–4 μm thickness and prepared for light microscope autoradiography. As the eye, optic stalk and neural tube epithelia are continuous until later eye-cup stages, with no distinct boundaries between them, individual operations unavoidably included a variable number of cells from the optic stalk; however, cuts were made distally as close to the outlines of the vesicle as possible.

Ventral halves of eye vesicles from seven embryos (stages 24–27) were exposed to ^{3}H-TdR in this way. All the autoradiographs showed a labelling pattern similar to that shown in Fig. 1*a*, which is a stage 36 eye where ventral-half incubation was performed at stage 26. The fissure (arrow), which is prominent in this parasagittal section, divides the ventral retina into two lobes. The ^{3}H-TdR-labelled neural retina cells lie in a band dorsal to the ventral fissure. They do not occupy the ventral retinal lobes, the position expected if the cells within the early eye vesicle give rise to this region. There are sharp boundaries between the heavily labelled incubated cells and the retinal regions above and below. This shows that the sparse grains visible ventrally do not represent the outcome of serial dilution of label by normal cell division in the peripheral retina after the operation, but are due to background and possibly a small amount of diffusion at the time of surgery.

Further evidence for this proximo-distal movement of ventral neuroepithelial cells is presented in Fig. 1*b* and *c*. Whole eye vesicles were removed from six embryos during stages 22–28, incubated with ^{3}H-TdR and replaced. All the autoradiographs show label over the entire eye apart from an area of ventral neural retina (Fig. 1*b*) containing the fissure, except for one at stage 28, where surgery was judged to be deep, leading to label over the whole eye. When, in a 'negative' experiment, the eye vesicle is removed and the whole embryo incubated in ^{3}H-TdR, the autoradiographs show label confined to the ventral retina (Fig. 1*c*); brain cells are also heavily labelled (not shown). Further preparations of whole eyes labelled after the onset of cup formation at stage 27 gave rise to a progressively smaller

0028-0836/80/440850-03$01.00

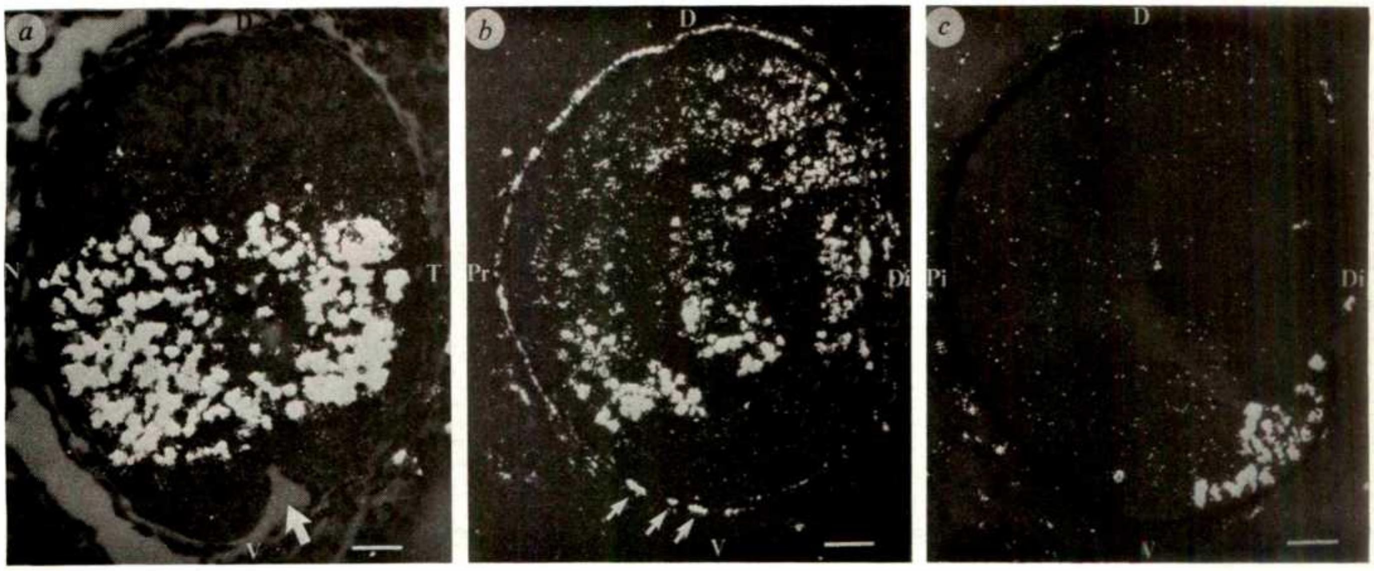

Fig. 1 Autoradiographs of *Xenopus* eyes, using combined light- and dark-field microscopy. Cells containing ^{3}H-TdR, following *in vitro* incubation in ^{3}H-TdR (see text), are strongly labelled with dense autoradiographic grains (white) above their nuclei. *a*, Parasagittal section of a stage 37 eye; the ventral fissure is indicated by an arrow. *b*, *c*, Transverse sections of stage 41 eyes from complementary experiments detailed in the text; the arrows in *b* indicate the ^{3}H-TdR-labelled pigment epithelial cells which are out of register with labelled neural retina (see text). D, Dorsal; V, ventral; ^{3}H-TdR incubation was performed at stage 26 in *a*, stages 22–23 in *b* and stage 24 in *c*. N, Nasal; T, temporal; Pr, proximal; Di, distal. Scale bars, 30 μm.

area of unlabelled cells occupying the ventral retina, with no such cells appearing after the fissure is fully formed. Therefore, cells positioned in the ventral margin of the eye vesicle do not define the ventral boundary of the newly invaginated eye cup, but are displaced dorsally by the late-arriving cells involved in ventral fissure formation.

Autoradiographs from whole eye incubations frequently show ^{3}H-TdR-labelled pigment epithelial cells in the otherwise unlabelled ventral region of the eye (Fig. 1*b*). This shows that neural retina and pigment epithelial cells move relative to each other and suggests that the boundaries of the pigment epithelial cell markers used in chimaeric eyes[14] may not reliably define the origin of the underlying neural retina.

As cells which come to comprise the ventral retina are in varying stages of transit from proximal to distal neuroepithelium, 180° eye rotation surgery, thought to reveal the time of polarization of the eye[5–10], could give rise to different fissure positions in the eye cup depending on when and where the cuts are made. Deep surgery at vesicle stages, or shallow surgery at early eye-cup stages (Fig. 2*c*) could translocate the entire population of presumptive ventral retina cells dorsally to give a dorsally positioned fissure, whereas shallow surgery at vesicle stages (Fig. 2*a*) might leave them still attached to the stalk, capable, providing healing is successful, of differentiating a normally positioned fissure. Double fissures, dorsally and ventrally located, would result if surgery divided this population of cells in two (Fig. 2*b*). These different patterns of anatomical polarity in the eye have been obtained after rotations at various stages in anuran[6], urodele[5,7,8] and chick[9,10] embryos, and the earliest stage at which dorsal fissures appeared was taken to represent the critical period at which the polarity of the eye becomes determined. As the origin of the fissure-forming cells was not considered in these experiments and was assumed to be in the eye at all stages of rotation, the 'labile' period can simply be explained by incomplete rotation of the whole eye rudiment at vesicle stages.

Jacobson[12] described a critical period during which he thought the polarity of the functional nerve connections from the eye become specified in *Xenopus* (stages 28–31). Although no anatomical evidence was presented, this functional polarization was determined separately from the anatomical polarization of the eye[21] (but see also ref. 11). However, Gaze *et al.*[14] and Sharma and Hollyfield[15] systematically failed to isolate a critical stage of polarization and found that even at early stages (stage 22), 180° rotation gave rise to either whole or partly rotated eye anatomy with functional connections of corresponding polarity. Using albino/wild-type chimaeras, Gaze *et al.* showed that eye vesicle rotations frequently result in eyes of compound origin with a rotated dorsal part (graft-derived) and a normally

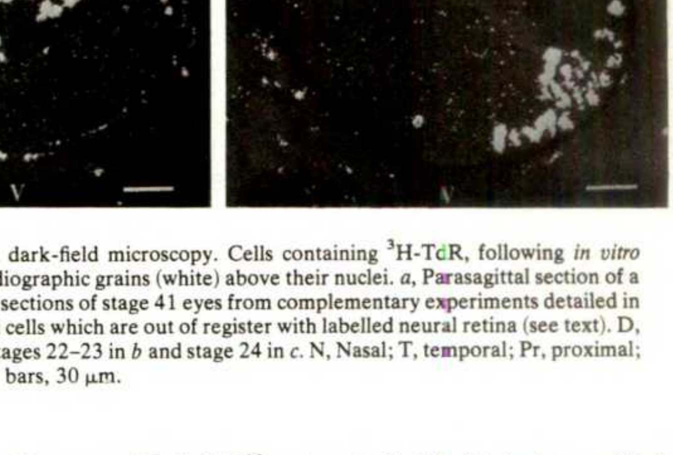

Fig. 2 Schematic representation of eye morphogenesis showing eye rotation surgery (dashed lines) in suggested relation to cell movements in the ventral neuroepithelium (striped region) drawn in transverse section. *a*, Optic vesicle stage (before stage 28 in *Xenopus*). The rotation surgery shown does not include future fissure-forming ventral retina cells. *b*, Invaginating eye at stage of ventral fissure formation (during stages 29–31 in *Xenopus*). The surgery shown divides the ventral cells. *c*, Newly invaginated eye cup (after stage 32 in *Xenopus*) in which the surgery shown includes the ventral retina and fissure. The resulting fissure positions and map ordering are explained in the text. nt, Neural tube; os, optic stalk; ov, optic vesicle; nr, neural retina; oc, optic cup; pe, pigment epithelium.

oriented ventral part (host-derived). They suggested that the unrotated eye tissue, derived from the optic stalk of the host, may have given rise to tectal maps interpreted as evidence for ocular respecification[9]. The present results favour this interpretation, but suggest that the origin of ventral retinal tissue outside the visible outline of the eye vesicle is a normal feature of development, rather than the outcome of cell proliferation stimulated by tissue mismatch caused in eye rotation surgery. The cell movements described here may be related to Hirose and Jacobson's observation[22], based on cell marking in early cleavage stages of *Xenopus*, that the ventral part of the eye apparently originates from the contralateral neural epithelium.

I thank Dr J. H. Scholes for his advice and assistance throughout, Drs W. R. Lieb and H. Saibil for helpful discussions, and Dr R. M. Gaze and his colleagues for advice and *Xenopus* eggs. This work was supported by an SRC studentship.

Methyltetrahydrofolate is a potent and selective agonist for kainic acid receptors

A. Ruck, S. Kramer, J. Metz & M. J. W. Brennan*

Brian Research Group, Departments of Medical Biochemistry
and Haematology, School of Pathology of the University of the
Witwatersrand and South African Institute for Medical Research,
Johannesburg 2001, South Africa

Kainic acid, a dicarboxylic acid containing pyrrolidine, is a potent neuronal depolarizing agent in the mammalian central nervous system, being some 50 times more effective than the putative neurotransmitter L-glutamate[1–5]. As kainic acid is a structural analogue of glutamic acid, it has been proposed that the potent excitatory effects of kainate reflect its restricted conformation, which is optimal for interaction with excitatory glutamate receptors[2,4]. More recent studies, however, do not support this hypothesis. In invertebrates kainic acid has been found to be a rather weak agonist at excitatory glutamate receptor sites[6,7], whereas at the crustacean neuromuscular junction[8], on certain neurones of *Helix aspersa*[9] and in the mammalian cerebral cortex[3], kainic acid seems to act at receptors distinct from those which mediate the neuroexcitatory action of glutamate. In addition, the ionic requirements for kainate-induced neuronal depolarization differ from those for glutamate-induced depolarization in the mammalian brain[10], and glutamate-induced excitation of rat cortical neurones can be antagonized preferentially by drugs which are very weak in blocking kainate-induced depolarization[11]. Finally, the characteristics of binding sites for ^{3}H-kainic acid in rat brain are consistent with the existence of specific kainate receptors on neuronal membranes[12]. Thus, the kainate sites may represent receptors for an unidentified endogenous substance probably containing the glutamate structure. Here we report that the pteroylmonoglutamate compound methyltetrahydrofolate (MTHF) is a potent competitor for ^{3}H-kainic acid binding sites in rat cerebellar membranes. This action is specific in that MTHF is very weak or inactive at sites for ^{3}H-glutamate or ^{3}H-γ-aminobutyric acid (GABA) respectively. Electrophysiological studies in frog spinal cord suggest that MTHF is an agonist at the kainate receptors. The implications of these results are discussed.

In membranes prepared from rat cerebellum[13], ^{3}H-kainic acid labelled a single class of receptor sites having a dissociation constant (K_d) of 25 nM. Kainic acid and MTHF displaced 50 nM ^{3}H-kainic acid from these sites with apparent inhibition constants (K_is) of 0.08 μM and 0.88 μM, respectively (Table 1), and respective Hill coefficients calculated from the displacement data were 0.92 ($r = 0.97$) and 0.94 ($r = 0.99$). L-Glutamate was a relatively weak competitor for the ^{3}H-kainate site ($K_i = 28.3$ μM) and GABA (100 μM) was ineffective in displacing ^{3}H-kainic acid binding.

In the same membrane preparation, ^{3}H-glutamate labelled two populations of receptor. Mean K_d values of 314 nM and 1,850 nM were obtained for the high and low affinity sites, respectively. Binding of 100 nM ^{3}H-glutamate was displaced by glutamate ($K_i = 0.61$ μM) but not by kainic acid (100 μM) or GABA (100 μM). MTHF was a relatively weak competitor for the high affinity glutamate site ($K_i = 83.5$ μM) (Table 1). Binding of 10 nM ^{3}H-GABA to the membranes was displaced by GABA ($K_i = 0.069$ μM) but not by kainic acid, glutamate or MTHF at concentrations of 100 μM.

MTHF is the predominant form of folate in the blood and in cerebrospinal fluid (CSF)[14,15]. It is taken up into the brain by an active process[16], and subcellular fractionation studies have shown a high concentration in synaptosomal fractions[17]. Our data demonstrate that MTHF interacts specifically with kainate receptors on neuronal membranes. In this respect it is almost as potent as kainic acid itself (Table 1). In the frog spinal cord, MTHF induces neuronal depolarization followed by a long period during which the membrane is unresponsive to applied glutamate or electrical stimulation[18]. The depolarization induced by MTHF is not antagonized by glutamate diethyl ester, a drug which preferentially blocks glutamate responses[19], and is not effective in blocking kainate-induced excitation[11]. Thus, MTHF mimics the electrophysiological action of kainic acid in a vertebrate preparation. In addition, MTHF has convulsive properties in experimental animals[20,21], and administration of folates to epileptic patients is known to increase the frequency of fits. These observations are consistent with a neuroexcitatory action of MTHF. Thus, MTHF interacts specifically and with high affinity at one class of excitatory receptor sites and has agonist activity at these sites. These are characteristics expected of an endogenous, excitatory, neuromodulatory substance.

Recent studies have shown that *in situ* injection of kainic acid into brain produces a characteristic pattern of neuronal degeneration[22–25]. The microanatomical selectivity of these lesions together with structure–activity studies on kainate analogues suggest that the neurotoxicity of the compound may be related to its electrophysiological activity[26–28]. There is some evidence that MTHF is neurotoxic. In vitamin B_{12} deficiency, there is a marked accumulation of MTHF in the blood and CSF[29,30]. The occurrence of foci of neuronal destruction in the

Cerebella from adult Wistar rats were homogenized in 15 vol ice-cold 0.32 M sucrose in a glass homogenizer and centrifuged at 1,000*g* for 10 min at 4 °C; the pellet was discarded and the supernatant centrifuged at 20,000*g* for 20 min. This pellet was resuspended in ice-cold distilled water, dispersed with a Brinkmann Polytron PT-10 (setting 6) for 20 s and centrifuged at 8,000*g* for 20 min. The supernatant fluid was collected and the pellet carefully rinsed to collect the upper layer. This suspension was then centrifuged at 48,000*g* for 20 min and the pellet washed once in distilled water. Synaptic membranes were stored at −20 °C until use (24–72 h). Frozen pellets were suspended by sonication in 0.05 M Tris-citrate buffer (*p*H 7.1), centrifuged at 48,000*g* for 10 min and resuspended in buffer (0.1–0.4 mg protein per ml) for binding assays. Solutions containing MTHF were prepared immediately before use, although the compound is stable for some 12 h at 4 °C. Binding of ^{3}H-kainic acid (2.4 Ci mmol^{-1}, Amersham)[12], ^{3}H-glutamate (21 Ci mmol^{-1}, Amersham)[33] and ^{3}H-GABA (65 Ci mmol^{-1}, Amersham)[13] was assayed in triplicate centrifuge tubes. Incubation of membranes (0.1–0.4 mg protein) in the presence of ^{3}H-kainic acid, ^{3}H-glutamate or ^{3}H-GABA was continued for 60 min at 4 °C, 15 min at 30 °C, or 5 min at 4 °C, respectively. After incubation, the reaction was terminated by centrifugation at 48,000*g* for 10 min. The pellets were superficially washed with two 5-ml aliquots of ice-cold buffer and then dissolved by incubating for 30 min at 55 °C in 1.5 ml Protosol (NEN). Dissolved pellets were counted in 10 ml Aquagel I liquid scintillant (Chemlab) in a Packard Tri-Carb 2660 spectrometer with automatic quench correction. Total specific binding of radioligand was defined as the difference between total binding and that in the presence of 0.1 mM unlabelled ligand. IC_{50} values were determined by log-probit analysis using at least five inhibitor concentrations, and apparent K_i values calculated from the equation $K_i = IC_{50}/(1 + [^3\text{H-ligand}]/K_d)$. K_d values of 25 nM, 314 nM and 22 nM (calculated from Scatchard analysis of saturation isotherms) were used for ^{3}H-kainic acid, ^{3}H-glutamic acid and ^{3}H-GABA binding sites, respectively. Each value is the mean ± s.e.m. of four experiments each done in triplicate.

brains and spinal cords of B_{12}-deficient patients might be explained on the basis of a neurotoxic effect of excess MTHF. It is interesting that the highest serum MTHF levels are indeed found in patients who have subacute combined degeneration of the spinal cord[31]. In addition, Brennan *et al.*[32] have recently demonstrated a selective reduction in high affinity GABA uptake in the brains of B_{12}-deficient fruit bats. This finding suggests a destruction of GABAergic neurones in the B_{12}-deficient state, which is consistent with a neurotoxic action of MTHF.

These studies were supported in part by grants from the South African MRC and the Atomic Energy Board of South Africa, M.J.W.B. is in receipt of a grant from the Loewenstein Research Foundation.

Lymphocyte activating factor promotes T-cell growth factor production by cloned murine lymphoma cells

Kendall A. Smith, Kevin J. Gilbride & Margaret F. Favata

The Immunology Program, Norris Cotton Cancer Center, Dartmouth–Hitchcock Medical Center, Hanover, New Hampshire 03755

Evidence has indicated that two soluble factors are essential for a T-cell proliferative response to antigen or lectin[1–3]. One such factor, thought to be of T-cell origin, is distinguished by its ability to initiate and maintain continuous T-cell growth (T-cell growth factor, TCGF)[4–6]. A second activity of macrophage origin augments lectin-initiated proliferative responses of thymocytes or adherent cell-depleted splenocytes (lymphocyte activating factor, LAF)[7]. Although it has been suggested that LAF promotes T-cell proliferation by facilitating the production of TCGF by T-cells[1–3], direct evidence supporting this hypothesis has been lacking. We describe here experiments with a murine thymic lymphoma which releases TCGF in response to lectin. In serum-free, defined medium, highly purified LAF promotes a concentration-dependent increase in TCGF release. Because the proliferation of T cells depends on the concentration of TCGF available[8,9], these results indicate that LAF and TCGF constitute an essential bimodal amplification system which ultimately determines the extent of T-cell clonal expansion.

To approach the functional relationship of LAF and TCGF, we sought LAF-responsive cells which could be cultured in a lymphokine-free medium. WEHI-7, an irradiation-induced Thy 1^+ lymphoma cell line of BALB/c origin[10] (Salk Institute Cell Distribution Center), was placed into culture with Iscove's modification of Dulbecco's modified Eagle's medium (IMDM) supplemented with bovine serum albumin, transferrin, cholesterol and soybean lipid[11,12]. The WEHI-7 cells were screened for TCGF production at multiple cell concentrations in the presence of concanavalin A (Con A) or phytohaemagglutinin (PHA) and LAF. No detectable TCGF activity was found in the culture medium in the absence of lectin stimulation, although both PHA- and Con A-elicited TCGF activity were found. LAF obtained from lipopolysaccharide (LPS)-stimulated human peripheral blood mononuclear cells did not cause detectable TCGF production, although LAF increased lectin-dependent TCGF production three- to fivefold. A typical experiment is shown in Fig. 1, where TCGF activity elicited by Con A in the absence and presence of LAF was assayed by the dose-dependent tritiated thymidine (^{3}H-TdR) incorporation of a TCGF-dependent cytolytic T-lymphocyte line (CTLL)[9].

0028-0836/80/440853—03$01.00

To investigate whether WEHI-7 was heterogeneous with respect to TCGF production, the cell line was cloned by limiting dilution in microtitre plates (0.3 cells per well, Poisson-calculated probability of co-fertile wells <0.05). Forty-one clones were obtained, and when tested for TCGF, 50% of the clones did not produce detectable TCGF activity regardless of whether lectin or LAF was present. In contrast, all of those clones which released TCGF on lectin stimulation also responded to LAF by at least a twofold increment in TCGF production. Thus, the WEHI-7 cells behaved similarly to normal T-cells: both lectin and LAF were required for optimal TCGF production[3].

In previous experiments it was observed that the extent of T-cell proliferation was TCGF-concentration dependent[8,9]. Therefore, if LAF augmented TCGF production, it seemed likely that LAF availability might be rate limiting in the ultimate T-cell proliferative response, especially if the effect of LAF on TCGF production was also concentration dependent. To examine this possibility, LAF partially purified by molecular gel chromatography and isoelectric focusing was added to TCGF-producing and nonproducing WEHI-7 clones in the presence of an optimal stimulatory concentration of Con A. As shown in Fig. 2, LAF clearly promoted a dose-dependent increase in TCGF release from one clone but not from the other clone.

The identification of a murine T-cell lymphoma that produces TCGF in response to lectin stimulation supports the impression that TCGF is T-cell derived. It was necessary to utilize cloned cells to provide such evidence as it was known that T-cell-enriched, normal cell populations required the presence of adherent cells for optimal TCGF production[2,3,13]: therefore the small amount of TCGF released by T-cell-enriched splenocytes could have been derived from residual adherent cells. As cloned thymic lymphoma cells were capable of producing TCGF in the absence of aherent cells and as LAF augments TCGF production, the data indicate that adherent cells contribute an early amplifying signal to T cells capable of TCGF production. Thus, the availability of a clonal population of cells, which can be studied in the absence of serum, provides the cellular system for detailed studies of the mechanism of LAF action and the molecular mechanism of TCGF production. Because both LAF and TCGF are essential for the T-cell proliferative response, such experiments will be important not only to investigate the nature of these lymphokines but also because information gained at the molecular level may increase insight into possible defects of lymphokine function which could underlie disease states.

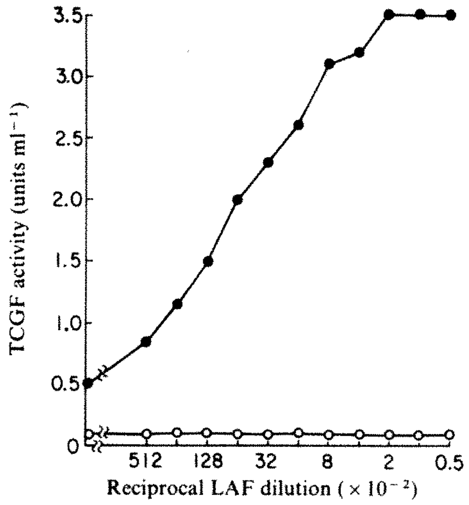

Fig. 2 LAF-concentration-dependent production of TCGF activity from WEHI-7 clone 49 (●) and clone 8(○). Clones were tested for TCGF production as described in Fig. 1 legend. The LAF preparation was partially purified by Sephadex G-75 chromatography (active fractions migrated with an apparent molecular weight of 20,000) followed by isoelectric focusing over a *p*H gradient of 3-10. LAF used for the experiment displayed was derived from the isoelectric focusing gradient, *p*H 6.85. Both the Sephadex G-75 fractions and the isoelectric focusing fractions which contained LAF activity displayed no detectable TCGF activity before addition to the WEHI-7 clones.

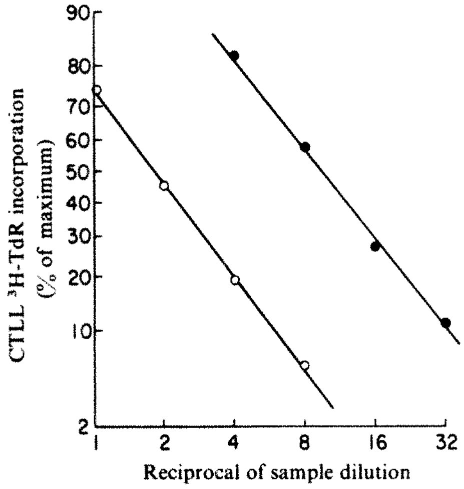

Fig. 1 TCGF activity elicited from WEHI-7 cells by Con A in the absence (○) and presence (●) of LAF. WEHI-7 cells (2×10^{6} cells ml^{-1}) were cultured for 24 h in IMDM[11,12] with Con A (2.5 μg ml^{-1}, Miles-Yeda). LAF was obtained from LPS (20 μg ml^{-1}, *Escherichia coli*, Gibco-stimulated human peripheral blood mononuclear cells cultured in serum-free RPMI 1640 medium (Gibco) for 48 h. Before use, the LAF-containing conditioned medium was concentrated 60-fold by passage through a YM-10 Amicon filter (Amicon), dialysed against 7,500 vol of saline, 500 vol of RPMI 1640, and assayed for LAF and TCGF activity as previously described[3,15]. No TCGF activity was detectable in the LAF preparation. The LAF preparation was added to the WEHI-7 cell cultures at a final dilution of 1:1,000. WEHI-7 conditioned medium was assayed for TCGF activity[3,15] using a TCGF-dependent cytolytic T-lymphocyte line (CTLL-2)[16]. The CTLL response to TCGF was quantified and displayed as the reciprocal of the sample dilution which resulted in 50% of the maximum CTLL ^{3}H-TdR incorporation elicited by a standard rat TCGF preparation[15]. ^{3}H-TdR incorporation was determined by the addition of 2 μCi ml^{-1} ^{3}H-TdR (specific activity 1.0 Ci mmol^{-1} Schwarz-Mann) during the last 4 h of a 24-h culture period as described previously[15]. In the experiment shown, maximum ^{3}H-TdR incorporation yielded 19,500 c.p.m. In the absence of TCGF the CTLL incorporated 75 c.p.m.

Because TCGF ultimately mediates T-cell proliferation and because the magnitude of TCGF elaboration is LAF-concentration dependent (Fig. 2), the data indicate that LAF and TCGF function in a bimodal amplification system which finally determines the extent of antigen- or lectin-initiated T-cell clonal expansion. Thus, it may be anticipated that physiological and pharmacological agents known to influence the immune response may do so by altering lymphokine function. Immunosuppressive agents which inhibit LAF-mediated TCGF production would have profound effects on the humoral and cellular immune response, as both cytolytic and helper T-cell proliferation is TCGF-concentration dependent[9,14]. For example, we have recently found that glucocorticoid hormones inhibit both the production and action of LAF which in turn results in a complete abrogation of TCGF production[3,5]. Similarly, immunoenhancing agents may function through the LAF–TCGF amplification network. As pointed out by Oppenheim *et al.*[7], many of the agents used as immunological adjuvants are also potent LAF inducers. As one can study separately the production and action of both LAF and TCGF, the mode of action of immunosuppressive and immunoenhancing agents may be amenable to experimental analysis.

Alloreactivity of an antigen-specific T-cell clone

Benjamin Sredni & Ronald H. Schwartz

Laboratory of Immunology, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, Maryland 20205

The apparent high frequency of alloreactive T cells has suggested that the two subpopulations—T cells specific for soluble protein antigens and alloreactive T cells—must overlap[1–3]. However, the existence of a set of germ-line genes encoding a family of anti-MHC (major histocompatibility complex) antigen-specific T-cell receptors has also been postulated to explain the high frequency of alloreactive clones[4–7]. In these latter models the two T-cell subpopulations are viewed as separate. Studies on whole T-cell populations have examined these two points of view by looking for cross-stimulation of alloreactive cells with antigen and vice versa[8–11]. Although significant cross-reactions have been reported, the problem of nonspecific recruitment made interpretation of results difficult. Recent developments in the cloning of antigen-specific T lymphocytes[12–16] have finally allowed investigation at the single-cell level where the results should be unambiguous. von Boehmer *et al.*[14] have isolated a cytotoxic clone specific for the H–Y antigen in conjunction with the syngeneic MHC antigens coded for by D^b. This clone was also cytotoxic for spleen cells bearing the alloantigens coded for by D^d in the absence of the H–Y antigen. However, because cytotoxic clones only grow in the presence of T-cell growth factor (TCGF) and because von Boehmer *et al.* were unable to stimulate or enrich for D^d-specific cytotoxic activity from bulk cultures initially stimulated with H–Y and D^b-bearing spleen cells[14], they hesitate to conclude that the same cell can respond to both foreign and alloantigens. We show here that a (dinitrophenyl-ovalbumin)(DNP-OVA)-specific T-cell clone from a B10.A mouse can be stimulated to divide (and propagate) *in vitro* with B10.S allogeneic spleen cells in the absence of DNP-OVA and B10.A antigen-presenting cells. Extensive recloning strongly suggests that a single T-cell clone is responding to two separate stimuli, a specific alloantigen and a soluble antigen in conjunction with self-MHC products.

B10.A mice were immunized with DNP-OVA and T-lymphocyte colonies prepared from the draining lymph nodes as previously described[12]. Most of the colonies tested were shown to be antigen specific, that is, their cells could be stimulated to divide with DNP-OVA but not other antigens such as GAT or purified protein derivative (PPD). One of these colonies was chosen to study alloreactivity as shown in Table 1. Cells from this colony could be stimulated to divide in the absence of DNP-OVA with either B10.S or B10.D2 irradiated spleen cells but not spleen cells from mice of six other independent halotypes. No change in the results was seen if syngeneic B10.A spleen cells were also added. This latter condition is essential for antigen stimulation although not sufficient by itself (Table 1). These results suggested that an antigen-specific cell could also manifest alloreactivity.

However, this conclusion depends on the colony being a true clone. Although all the colonies grew up completely isolated in the agar and were easy to pick independently of one another, whether each colony derived from a single cell is not clear as a large number of cells (2×10^6) were seeded in the agar allowing for the possibility of recruitment of nearby cells into the colony.

Table 1 Maintenance of alloreactivity on recloning

Source of spleen cells	Proliferative response (c.p.m. ± s.e.m.)		
	Colony	Clone 5	Subclone 5.6
B10.A	25 (±5)	150 (±95)	180 (±52)
B10.A + DNP-OVA	9,600 (±680)	14,700 (±2,300)	39,200 (±1,950)
B10	30 (±5)	130 (±55)	233 (±116)
B10.D2	9,100 (±600)	236 (±82)	410 (±35)
B10.M	10 (±2)	160 (±105)	46 (±8)
B10.P	10 (±1)	153 (±42)	230 (±41)
B10.Q	45 (±5)	190 (±150)	60 (±20)
B10.RIII	25 (±15)	107 (±18)	53 (±12)
B10.S	18,200 (±2,400)	15,900 (±2,000)	36,300 (±1,900)
B10.PL	15 (±5)	50 (±25)	80 (±39)

A colony of DNP-OVA-reactive proliferating T lymphocytes was derived from primed B10.A lymph node cells as previously described[12]. Small numbers of cells from this colony were cloned in soft agar with 80% plating efficiency. Of the 14 subcolonies which were picked and expanded, cells from one, clone 5, were again cloned in soft agar, this time with a 91% plating efficiency. Six of these colonies were picked and expanded. The table shows the antigen specificity and alloreactivity of the original colony, clone 5, and subclone 5.6. 10^4 T cells from the original colony and clone 5 or 2×10^4 T cells from subclone 5.6 were mixed with 10^4 irradiated (2,000 rad) spleen cells of various MHC haplotypes in the presence of 5% Con A supernatant. In the test for antigen stimulation, 10% Con A supernatant was used and 100 μg ml^{-1} of DNP-OVA was added. The cells were cultured for 6 days in RPMI 1640 plus 10% FCS with supplemental feeding at day 3 (ref. 12). At 16–18 h before collecting, the cultures were pulsed with 1 μCi of tritiated thymidine. The data shown are mean (c.p.m.) ± s.e.m. for triplicate determinations.

To investigate this problem, 200 cells from one colony were supplemented with 10^4 irradiated B10.A spleen cells and recloned in soft agar[12]. The use of a few T cells assured us that all colonies which developed would not have other T cells near them in the agar. Thus we could be sure that each of the colonies was derived from a single cell. After five days of incubation 160 colonies were observed in the agar for a plating efficiency of 80%. Of 15 of these colonies picked and expanded in liquid culture, 14 survived to test for antigen specificity; the remaining colony was lost because of microbial contamination. Cells from all 14 subcolonies showed an identical antigen specificity, responding to stimulation with DNP-OVA but not GAT or PPD (data not shown). Furthermore, as shown for a typical example in Table 1, cells from all 14 subcolonies responded to allo-stimulation with irradiated B10.S spleen cells. The dose-response curves shown in Fig. 1 indicate that the irradiated B10.S spleen cells could stimulate the B10.A T cells in the

0028-0836/80/440855—03$01 00

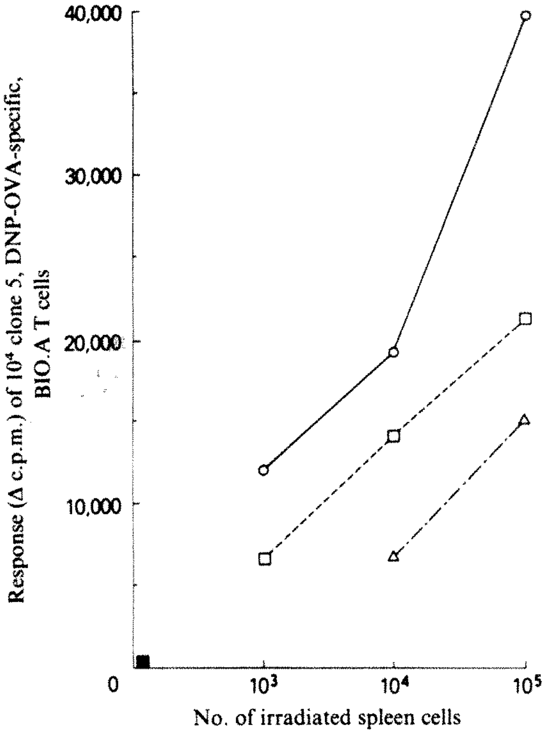

Fig. 1 10^4 T cells from B10.A clone 5 specific for DNP-OVA in association with B10.A spleen cells were stimulated with various numbers of irradiated allogeneic B10.S spleen cells in the absence of Con A supernatant (0% IL-2, △) or the presence of 5% (v/v) IL-2 (□) or 10% IL-2 (○). ■ indicates that no stimulation was seen with 10% IL-2 in the presence of 10^5 irradiated syngeneic B10.A spleen cells.

absence of any added growth factor in the culture (0% IL-2), provided that the T cells were cultured at a high enough density (10^4 per well) and a sufficient number of stimulator cells was added ($\geq 10^4$). However, addition of 5% or 10% concanavalin A (Con A) supernatant to the cultures improved the magnitude of the allogeneic proliferative response at all spleen cell doses, even though these concentrations of Con A supernatant were totally nonstimulatory in the presence of similar numbers of syngeneic B10.A spleen cells. The allostimulation of B10.S spleen cells was not due to a 'back-reaction', that is, recruitment into proliferation of the cloned T cells by alloreactive T cells in the irradiated spleen cell population, because cells from a B10.S macrophage colony were also capable of eliciting a response (data not shown).

Interestingly, none of the subcolonies responded to irradiated B10.D2 spleen cells. This suggests that the original colony was not a true clone but was contaminated with an alloreactive cell specific for H-2^d MHC antigens. The loss of reactivity against H-2^d antigens on recloning made us decide to reclone again to assure ourselves that the remaining alloreactivity for B10.S antigens was indeed associated with the same cells showing specificity for DNP-OVA. In this experiment the cells were recloned in the presence of 25% Con A supernatant in the bottom agar layer to improve the plating efficiency. The number of colonies observed ranged over 170–194 per 200 cells plated with a mean plating efficiency of 91 ± 2%. Six of these colonies were picked and expanded in liquid culture. All six could be stimulated with either DNP-OVA in the presence of syngeneic spleen cells or irradiated B10.S allogeneic spleen cells (Table 1, subclone 5.6). The failure to separate these two activities on recloning suggests strongly that the subcolonies were already true clones and that a single T cell possesses receptors for both specificities.

Previous studies with this B10.A T-cell clone had demonstrated that recognition of DNP-OVA was MHC restricted, requiring syngeneic B10.A irradiated spleen cells to present the antigen[12]. The gene(s) controlling this histocompatibility restriction was mapped to the I-A^k subregion of the MHC. Table 2 shows a similar type of genetic mapping experiment for alloreactivity. Data are shown for one clone but all 14 gave the same result—mapping of the gene(s) to the I-A^s or I-B^s subregion. Because the major lymphocyte-activating determinant (LAD) locus has been mapped to the I-A subregion[19], it is reasonable to conclude that the stimulating alloantigens in this case map to I-A^s. Thus, the same T cell which can respond to DNP-OVA in conjunction with I-A^k is also stimulated by I-A^s. The studies so far do not allow us to determine whether the same receptor or separate receptors account for the two specificities possessed by the clone.

These results have important implications for theories of T-cell recognition, as some of these theories[4,20] have postulated that alloreactive and antigen-specific T cells are separate subpopulations. Such models could account for the results presented here by postulating that we have identified a rare clone in which the receptor for the antigen, DNP-OVA, happens to cross-react with a determinant on the alloantigen, I-A^s. This is a testable hypothesis as it postulates that in this rare instance, the alloantigen is actually presented to the T cell like a foreign antigen, that is, in conjunction with I-A^k on the syngeneic antigen-presenting cell. As already mentioned, B10.S spleen cells will stimulate the clone in the absence of the additional B10.A spleen cells which are required for DNP-OVA presentation. However, it could be argued that sufficient B10.A spleen cells are present in the T-cell population, as a result of the feeding requirements for propagating the clone, to allow for the presentation of I-A^s antigens.

To test the possibility that I-A^s was recognized in conjunction with I-A^k, we grew one of the clones by stimulating it only with irradiated B10.S spleen cells in the presence of 5% Con A supernatant. At no time during the 39-day propagation were the cells exposed to DNP-OVA or B10.A spleen cells, even when the cultures were split. At the end of this time the cells were retested for specificity. As shown in Table 3, the cells retained their antigen specificity, responding to DNP-OVA and the carrier OVA but not to GAT or the hapten on another carrier, DNP-GLA. They also retained their allospecificity for B10.S and did not acquire any other alloreactivity. To reduce further the possibility that residual B10.A spleen cells remained in the T-cell cultures, the clone was propagated for another 29 days, this time in the complete absence of all spleen cells and antigen. This was done by increasing the concentration of the Con A supernatants (TCGF) to 50% (v/v). Again the clone maintained both its alloreactivity and antigen specificity (Table 3). Thus, after 68 days without adding B10.A spleen cells, presumably a time vastly longer than the lifetime of any irradiated spleen cells,

Table 2 Genetic mapping of allostimulation

Spleen cells		Clone 5
Strain	MHC haplotype	(c.p.m. ± s.e.m.)
B10.A + DNP-OVA	kkkkkdddd	14,700 (±2,300)
B10.A	kkkkkdddd	150 (±95)
B10.S	sssssssss	15,900 (±2,000)
B10.S (9R)	ss?kkdddd	15,700 (±800)
A.TL	skkkkkkkd	90 (±15)
A.TH	ssssssssd	15,700 (±2,300)

10^4 B10.A anti-DNP-OVA clone 5 T cells were stimulated with 10^4 irradiated (2,000 rad) spleen cells from various strains in the presence of 5% Con A supernatants. A 6-day tritiated thymidine incorporation assay was performed as described in Table 1 legend. The data are expressed as c.p.m. ± s.e.m. for triplicate determinations. The letters in the MHC haplotype column refer to the haplotype source of origin of the K, I-A, I-B, I-J, I-E, I-C, S, G and D regions of the murine MHC. The value for A.TH spleen cells was obtained in a separate experiment carried out in exactly the same conditions.

Table 3 Specificity of an alloreactive clone grown in the absence of antigen and syngeneic spleen cells

		Proliferative response (c.p.m. ± s.e.m.) of clone 5 expanded with:		
Antigen	Spleen cells	DNP-OVA and B10.A spleen	Allogeneic B10.S spleen	50% Con A supernatant
None	B10.A	90 (±29)	63 (±3)	120 (±6)
DNP-OVA	B10.A	15,700 (±1,000)	14,100 (±2,000)	14,000 (±1,200)
OVA	B10.A	13,700 (±1,200)	14,900 (±1,300)	14,300 (±1,170)
DNP-GLA	B10.A	143 (±70)	70 (±17)	50 (±12)
GAT	B10.A	150 (±55)	73 (±26)	50 (±21)
None	B10.S	15,900 (±2,015)	13,800 (±800)	13,100 (±400)
None	B10.D2	236 (±80)	60 (±15)	90 (±12)

DNP-OVA-specific B10.A T-cell clone 5, which is normally propagated by feeding every three days with 10^4 irradiated B10.A spleen cells and 100 μg ml^{-1} of DNP-OVA in medium containing 20% (v/v) Con A supernatant, was propagated with 10^4 irradiated B10.S spleen cells and 5% Con A supernatant for 39 days followed by propagation with 50% Con A supernatant alone for an additional 29 days. The table shows the antigen specificity and alloreactivity of the original clone (column 1), the clone after being grown with allogeneic spleen cells (column 2) and the clone after being grown with high concentrations of Con A supernatant (column 3). Antigen specificity was assessed in a 6-day thymidine incorporation assay using 10^4 T cells, 10^4 syngeneic, irradiated (2,000 rad) B10.A spleen cells, 10% Con A supernatant and 100 μg ml^{-1} of DNP-OVA, GAT and DNP-GLA or 300 μg ml^{-1} of OVA (see Table 1 legend). Alloreactivity was assessed by adding 10^5 irradiated B10.S or B10.D2 spleen cells in the presence of 5% Con A supernatant. The data are expressed as mean c.p.m. ± s.e.m. for triplicate determinations.

the alloreactivity of the clone was not diminished. These results strongly indicate that the T-cell clone is responding directly to I-A^s antigens and not to these antigens in conjunction with syngeneic I-A^k gene products.

Overall our data demonstrate that individual T cells do exist which can recognize and respond to both alloantigens and soluble protein antigens. This dual specificity can be explained in a number of ways. One could postulate two completely independent sets of receptors randomly expressed in all lymphocytes[2], alloantigen recognition through high affinity cross-reactions with the anti-self MHC receptor[3] or the antigen-specific receptor[6,7], or recognition through a combination of both the anti-self MHC and antigen-specific receptors[8,10]. Further studies are required with more T-cell clones to distinguish between these various models for T-cell recognition.

A G_1 rate model accounts for cell-cycle kinetics attributed to 'transition probability'

LaRoy N. Castor

Institute for Cancer Research, Fox Chase Cancer Center,
7701 Burholme Avenue, Philadelphia, Pennsylvania 19111

Smith and his colleagues[1–4] have proposed that the duration of the cell cycle is determined by a random transition, analogous to the random decay of a radioactive nucleus, by which a cell passes from an 'A state' within the G_1 phase to a 'B phase' that includes the rest of the cycle. The experimental support for this transition probability hypothesis is the tendency of a cumulative plot of differences of cycle times of sibling cells (the β curve) to be exponential and parallel to the exponential tail of a cumulative plot of the cycle times themselves (the α curve). However, a close examination of four of the most extensive sets of experimental data now suggests that the two β curves with the steepest slopes may not, in fact, be exponential. These and all the other characteristics of the experimental curves are best matched by computer simulations using a cell-cycle model that will be termed here a G_1 rate model. This model is consistent with differences in cell metabolism, rather than a transition at an inherently unpredictable time, being the physiological basis for differences in cycle times within a cell population.

As cycle control occurs mainly in the G_1 phase, the formulation of any realistic model requires that the G_1 phase be treated separately from the remainder of the cycle. Monte Carlo simulations of α and β curves were performed using different combinations of exponential, reciprocal–normal, log–normal and normal distributions in two successive phases. Matches to the published curves were most readily obtained with normally distributed reciprocals of G_1 times (called G_1 rates by Sisken and Morasca[7]) and normally distributed times of passage through a second ($S+G_2+M$) phase. If t is the complete cycle time for a cell passing through the G_1 phase at a rate r_1 and through the remainder of the cycle in time t_2,

$$t = 1/r_1 + t_2$$

Let ω' and ω'' be random numbers from a normal distribution having zero mean and unit standard deviation, with ω' maintained the same in two sibling cells and ω'' generated separately for each of the siblings. The complete G_1 rate for a single cycle can be written as

$$r_1 = \bar{r}_1 + k_1[c_1\omega' + (1-c_1)\omega'']$$

in which $\bar{r}_1$ is the mean G_1 rate over the entire cell population and c_1 is a fraction determining the degree of sibling correlation. The value of k_1 is related to the standard deviation, σ_1, of the G_1 rate

$$k_1 = \sigma_1[c_1^2 + (1-c_1)^2]^{-1/2}$$

Similarly, using comparable notation and new random numbers, the complete time of the second phase is

$$t_2 = \bar{t}_2 + k_2[c_2\omega' + (1-c_2)\omega'']$$
$$k_2 = \sigma_2[c_2^2 + (1-c_2)^2]^{-1/2}$$

In Fig. 1, experimental α and β curves (individual points) are matched with computer simulations for 100,000 sibling pairs of cycles using the G_1 rate model (solid and dashed lines). The experimental data are from publications of the Smith group, except for set b (ref. 8), which has not been previously plotted as α and β curves. In the four sets of points a downward bend at the top of the β curve[9] is most pronounced for the steepest curve (a) and progressively less pronounced in the three other sets, left to right. The computer simulations for the G_1 rate model show the

Table 1 Ability of G_1 rate and transition probability models to generate β curvatures found experimentally

Data	Pairs	β at midpoint	Experimental		G_1 rate model			Transition probability model		
			Slope	Curvature	Mean slope	Mean curvature	P^*	Mean slope	Mean curvature	P^*
a	37	0.70	−1.328	−0.691	−1.258	−0.476	0.22	−1.276	+0.002	0.02
b	256	0.25	−0.701	−0.288	−0.708	−0.368	0.67	−0.699	+0.005	0.06
c	107	0.35	−0.367	+0.147	−0.371	+0.108	0.58	−0.410	−0.099	0.85
d	24	0.40	−0.156	+0.242	−0.174	−0.069	0.74	−0.187	−0.145	0.78

For each model and each data set, 10,000 β curves were simulated using the same number of sibling pairs as was used experimentally (column 2). Parameters for the G_1 rate model were those of Fig. 1. For the transition probability model, β curves were generated for i cycles from the relationship $t_{ik} = (\ln N_i)/K$, with t_{ik} being the time spent in the A-state, K the measured slope of the experimental β curve, and N_i one of a set of random numbers, distributed uniformly between zero and unity. Each experimental and simulated curve was divided into upper and lower portions at a midpoint (column 3) chosen to delineate effectively the experimental curvature. Slopes (natural log units h^{-1}) were calculated by linear regression, using approximately 1,000 values at equal time intervals along line segments between the data points. Curvature was defined as the difference of the slopes of the upper and lower portions of a curve divided by its overall slope.

* Proportion of the 10,000 simulated β curves having a curvature more negative than the experimental curve.

same progression. For the simulations the major influence on the slopes of the α and β curves is the mean G_1 rate. Varying this parameter over a factor of 4.6 (with some adjustment of other parameters to give optimal matches to experiment) changes the slope of the β curve by a factor of 8. Other combinations of mean and standard deviation can also match the α and β curves. The correct combination could be determined if the mean G_1 time were known, but this was not measured for the experimental cell populations.

The two sibling correlation factors, c_1 and c_2, establish the slope of the β curve in relation to the slope of the α curve. The closeness with which a β curve approximates a straight line is enhanced when $c_1 \ll c_2$. This principle corresponds, to a rough approximation, with the assumption of no sibling correlation in the first phase of the transition probability model and perfect sibling correlation in the second phase[2-4]. However, the β curvature in set *b* was better matched with c_1 slightly greater than c_2, suggesting that there is no general rule that the G_1 phases of siblings are weakly correlated.

To examine the role of sampling error in determining β curvature, 10,000 simulations of each β curve were generated for each of the two models, using the same number of sibling pairs as was used experimentally. The proportion of the 10,000 simulated curves having a curvature more negative than the curvature found experimentally was then a measure of the frequency with which this curvature will be generated by the model. The repeated simulations (Table 1) show that the curvatures of all four sets of experimental data are within the range of values frequently attained with the G_1 rate model, as are the curvatures of sets *c* and *d* for the transition probability model. However, the transition probability model infrequently attains the curvatures of either set *a* ($P = 0.02$) or set *b* ($P = 0.06$). These data do not completely exclude the transition probability model as an explanation of cell-cycle control, but they suggest that a model that gives a slight downward curvature to steep β curves provides a more likely explanation.

These results with a model having a reciprocal–normal distribution in the G_1 phase are in contrast to those of Shields[4], who constructed α and β curves from 100 simulated cell cycles based on reciprocal–normal and log–normal models and concluded that neither model generated an exponential β curve. Aside from the problem of sampling error in such a small number of simulations, it is not reasonable to compare the two-phase transition probability model with a single-phase model, particularly as the major site of cycle control is known to be in the G_1 phase. By restricting the reciprocal–normal distribution to the G_1 phase, the G_1 rate model achieves higher coefficients of variation and brings the β curvature into a range that can accurately match the experimental β curves. Shields also concluded that only the transition probability model leads to

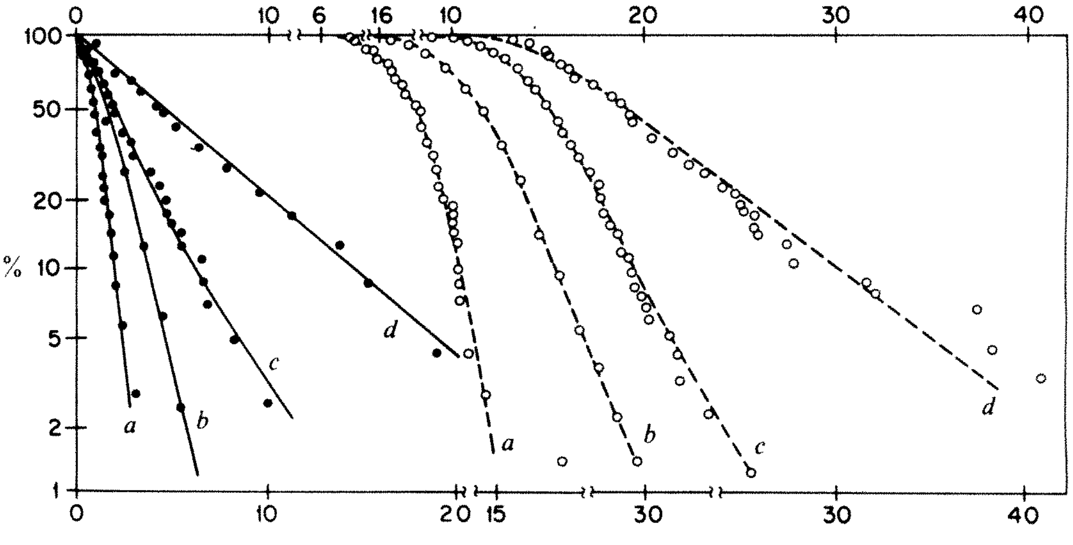

Fig. 1 Comparisons of published experimental data (●, ○) and Monte Carlo simulations using the G_1 rate model (—, ---) of the % of sibling pairs with a difference of cycle times $< t$ (β curves: ●, —) and the % of cell-cycle times $< t$ (α curves: ○, ---) against time, t. The simulations used 100,000 sibling pairs. They took into account the finite time a culture could be filmed (24, 125, 36, 60 h for *a*–*d*, respectively). Times between film frames were considered to be negligibly small except for *b*, which was 1 h. (These refinements had little effect on the simulated curves except for depression of both curves of *d*.) Numbers in parentheses are the six parameters ($\bar{r}_1, \sigma_1, c_1, \bar{t}_2, \sigma_2, c_2$) determining the simulated curves. *a*, Ref. 2, Fig. 2 (0.3, 0.03, 0.30, 7.3, 2.0, 0.70); *b*, ref. 8, Fig. 5 (0.131, 0.03, 0.68, 13.3, 2.0, 0.55); *c*, ref. 3, Fig. 1 (0.250, 0.11, 0.0, 10.5, 2.3, 0.70); *d*, ref. 3, Fig. 4 (0.065, 0.03, 0.40, 4.2, 1.0, 0.70). Measured correlation coefficients of simulated cycle times of siblings were: *a*, 0.83; *b*, 0.70; *c*, 0.36; *d*, 0.22.

parallel and exponential β curves when the data are divided into groups according to the shorter cycle time of each sibling pair. However, simulated β curves using the G_1 rate model have the same characteristic, within the sampling error of the experimental data (unpublished results).

Recent experiments using flow cytometry[10] have shown a 10% coefficient of variation in the RNA content of cells in early G_1 phase, comparable with the 10% coefficient of variation in the G_1 rate of set *a*, Fig. 1. The RNA content of individual cells was found to be correlated with the rate of progression through both the G_1 and S phases. Thus, much of the variation of cycle times within a population can be attributed to constitutive variations in the capacity of cells to synthesize protein. Theoretically, there could be a random transition in addition to the variation due to constitutive differences[5]. However, the present results show that the α and β curves can be accounted for completely without postulating such a transition, and there is no independent experimental evidence for one. The most reasonable hypothesis for interpreting the distribution of cycle times in a cell population is that it results from cell-to-cell variations in rates of metabolic reactions and in times required to complete essential steps in the cycle.

I thank Dr David Rigney for devising the original computer program and for many fruitful discussions. The simulations were performed on a PDP-11/70 computer (Digital Equipment Corp.), and the work was supported by DHEW grants CA-06927, CA-22780 and CA-24961 awarded by the National Cancer Institute and by an appropriation from the Commonwealth of Pennsylvania.

Cytosolic calcium ion activity in epithelial cells of *Necturus* kidney

Chin O. Lee, Ann Taylor & Erich E. Windhager

Department of Physiology, Cornell University Medical College,
New York, New York 10021

Calcium ions are believed to play an important role in the control of cellular function[1], and have recently been implicated in the regulation of sodium and water transport in epithelia[2–8]. In epithelial cells, as in excitable cells[1], low cytosolic free calcium levels may be maintained, in part, by a process of Na–Ca exchange across the plasma membrane[5,8–12]. In a recent model of transepithelial sodium transport in which a regulatory role for calcium ions was incorporated, it was assumed that cytosolic calcium ion activity of epithelial cells is similar to that of excitable cells[13]. However, no direct measurements of cytosolic calcium ion activity in epithelial cells in normal transporting conditions have yet been made. We report here the direct measurement with Ca^{2+}-selective microelectrodes of cytosolic calcium ion activity in proximal tubular cells of *Necturus* kidney. The results indicate that cytosolic calcium ion activity in these cells is ~10^{-7} M, and are consistent with the view that a Na–Ca exchange system, located at the basolateral cell membrane, plays a role in maintenance of low cytosolic calcium ion activity.

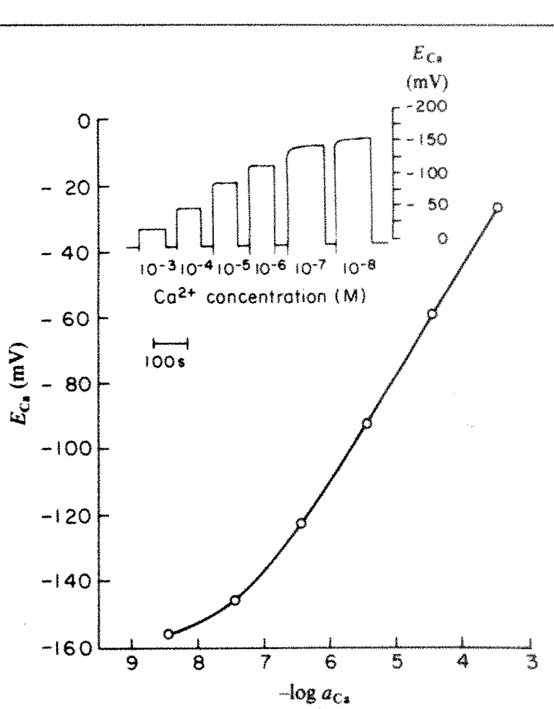

Fig. 1 Inset, microelectrode potentials measured at different calcium concentrations. Response times of the microelectrodes (time to reach a stable potential) were in the range of several seconds to one min. Main figure, microelectrode potentials plotted against $-\log a_{Ca}$. Solutions of 10^{-8}, 10^{-7}, 10^{-6}, 10^{-5}, 10^{-4} and 10^{-3} M Ca^{2+} concentration were used to calibrate the microelectrode. Those containing 10^{-8}, 10^{-7}, 10^{-6} and 10^{-5} M Ca^{2+} were made from a Ca^{2+} buffer containing EGTA. The Ca^{2+} concentrations of the solutions were calculated with the apparent stability constant of 4.90×10^6 M^{-1} for Ca-EGTA at *p*H 7.0. The solutions containing 10^{-4} and 10^{-3} M Ca^{2+} were made by dilution of 0.1 M $CaCl_2$ solution. All the solutions contained 100 mM K^+ and 1 mM Mg^{2+}, and had a *p*H of 7.0 The solutions have the same ionic strength, and hence probably the same activity coefficent of Ca^{2+}. In this study, the Ca^{2+} activity coefficient of 0.35, calculated by the extended Debye-Huckel equation[28] was used to obtain the calibration curve shown in the main part of the figure. This procedure is justified because calculated and measured Ca^{2+} activity coefficients at various ionic strengths are in reasonably good agreement[29,30]. The microelectrode potentials were not affected by *p*H changes in the range 7–8. In this study, the results are presented as activities, rather than Ca^{2+} concentrations, because: (1) many cell processes respond to ionic activities; (2) the microelectrodes measure potentials related to ionic activities; (3) expressing the results as ion concentration assumes that the activity coefficient of Ca^{2+} in the cytosol is equal to that of Ca^{2+} in the calibration solutions.

Experiments were performed on proximal tubules of doubly perfused kidneys of *Necturus maculosus*[14,15] using Ca^{2+}-selective microelectrodes. This preparation was chosen because of the relatively large size of the epithelial cells (~20 μm in diameter) and because the transport properties of this nephron segment have been reasonably well characterized[16,17]. Recently, Ca^{2+}-selective microelectrodes have been developed[18–20], which make measurements of cytosolic Ca^{2+} activities feasible. Ca^{2+}-selective microelectrodes were made employing a Ca^{2+}-selective liquid composed of 10% neutral ligand (*N*, *N'*-di(11-ethoxycarbonyl)undecyl-*N*, *N'* 4, 5-tetramethyl-3, 6-dioxaoctane diacid diamide), 1% sodium tetraphenylborate and 89% *o*-NPOE[21]. Glass micropipettes with tip diameters of ~1 μm or less were pulled from borosilicate glass capillaries (Corning Glass Works, code 7740). The inner surface of the micropipettes was silanized by exposure to dichloro-dimethylsilane gas. The micropipettes were first filled with 100 mM $CaCl_2$ solution; the Ca^{2+}-selective liquid was drawn up to 400–800 μm from the tip. Each microelectrode was calibrated before and after use by the procedure illustrated in Fig. 1. The inset shows the potential recordings measured in calibration solutions containing calcium ion concentrations of 10^{-8}–10^{-3} M (see

0028-0836/80/440859—03$01.00

Fig. 1 legend). At calcium levels $>10^{-6}$ M the potential changes corresponded to those predicted by the Nernst equation—a 29.6 mV change for a 10-fold change in calcium ion concentration. However, at calcium ion concentrations between 10^{-6} and 10^{-7} M, the potential changes varied from 10 to 25 mV; and between 10^{-7} and 10^{-8} M, from 5 to 15 mV. (The microelectrode characteristics have been considerably improved since our initial work[22].) In the main part of Fig. 1, the potentials recorded by the microelectrode are shown plotted against calcium ion activities, using an activity coefficient of 0.35 (see legend). Such a calibration curve was constructed for each electrode for the determination of intra- or extracellular calcium ion activites. Selectivity coefficients (k_{CaK}) of the microelectrodes against K^+ were in the range 1×10^{-6}–7×10^{-6}. Selectivity coefficients (k_{CaNa}) of the microelectrodes against Na^+ were in a range similar to or slightly greater than k_{CaK}. Considering the low cytosolic Na ion activities of *Necturus* proximal tubular cells[23], cytosolic Ca^{2+} activity measurements will not be significantly affected by changes in cytosolic Na^+ activity. (Detailed properties of the microelectrodes will be published elsewhere; C.O.L., in preparation.)

Figure 2 illustrates the measurement of basolateral cell membrane potential, V_M, and cytosolic calcium ion activity, a^i_{Ca}, in a proximal tubular cell of *Necturus* kidney. An epithelial cell was first impaled with a Ca^{2+}-selective microelectrode (see lower trace). When the intracellular potential recorded with this microelectrode had reached a stable value, a second cell of the same tubule was impaled with a conventional microelectrode (see upper trace). On this impalement, the potential recorded by the Ca^{2+}-selective microelectrode, E_{Ca}, fell by an amount equal to the peritubular cell membrane potential, and then reached another stable value. The rapid change in E_{Ca} represents the electronic subtraction of V_M from E_{Ca}. The E_{Ca} following the subtraction represents the cytosolic calcium ion activity. In 11 successful measurements on seven kidneys (out of a total of 52 experiments), the cytosolic calcium ion activity of *Necturus* proximal tubular cells averaged 116 ± 32 nM (mean ± s.d.), and the peritubular membrane potential was −56.6 ± 4.0 mV. Assuming that the activity coefficient of cytosolic Ca^{2+} is the same as that calculated for extracellular fluid (0.34), the cytosolic calcium ion activity of 116 mM is equivalent to a cytosolic free calcium ion concentration of 341 nM. (This assumption is justified if the cytosolic ionic strength is not too different from that of the extracellular fluid.) The value of 341 nM for cytosolic calcium ion concentration is in a range similar to that previously reported for other cell types[24].

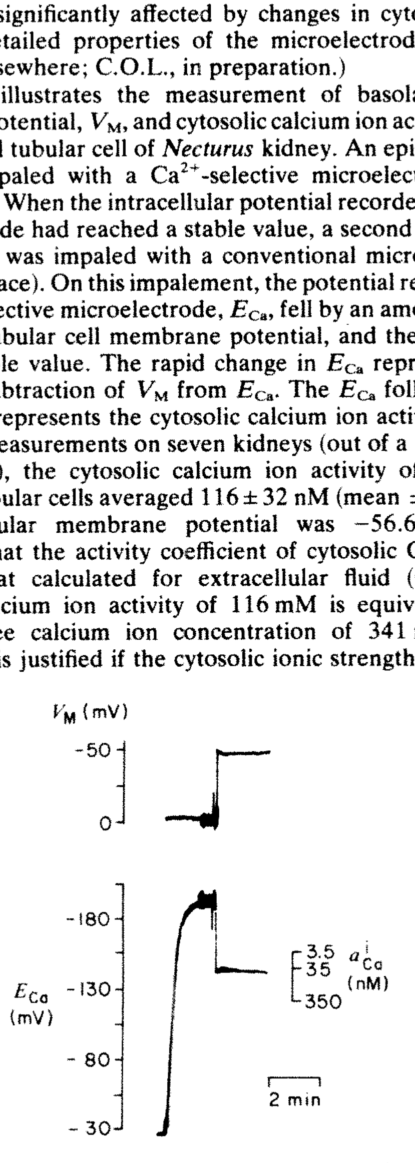

Fig. 2 Potential recordings obtained with a conventional microelectrode (upper trace) and a Ca^{2+}-selective microelectrode (lower trace) for determination of cytosolic Ca^{2+} activity. Experiments were performed on cells of proximal tubules of doubly perfused kidneys of *N. maculosus*. Both the aorta and the renal portal vein were perfused with a modified Ringer's solution[25] containing 100 mM Na^+. The kidney was also superfused with the same solution. The perfusion fluid was saturated with a gas mixture of 99% O_2 and 1% CO_2 to achieve a *p*H of 7.5–7.6. All experiments were carried out at room temperature (22–23 °C). Cells of the same tubule were impaled with the conventional microelectrode and the Ca^{2+}-selective microelectrode.

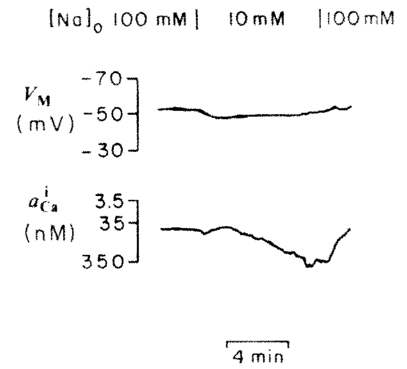

Fig. 3 Recordings of simultaneous measurements of peritubular cell membrane potential (V_M) and cytosolic calcium ion activity (a^i_{Ca}) during alteration of Na^+ concentrations in peritubular fluid. The low $[Na]_o$ solution was made by equimolar substitution of choline chloride for sodium chloride. The extracellular Ca^{2+} concentration was kept constant at 1.8 mM.

To measure the electrochemical gradient for calcium reabsorption by proximal tubular epithelium, calcium ion activities were measured in tubular and peritubular fluid of perfused kidneys. In 17 measurements on five kidneys, Ca^{2+} activity averaged 0.48 ± 0.07 mM in tubular fluid, and 0.61 ± 0.04 mM in peritubular fluid ($P<0.001$). In these tubules, the mean transepithelial potential difference was −5.6 ± 1.2 mV, lumen negative. Net fluid reabsorption was measured in separate experiments by the split-droplet technique[25]; the half time of reabsorption averaged 30.9 ± 10 min ($n = 7$), a value comparable to that obtained by previous investigators[25]. These results indicate that, in the process of calcium reabsorption, calcium ions may enter the cell passively across the luminal membrane, but must be extruded actively against a steep electrochemical gradient across the peritubular cell membrane.

Figure 3 shows simultaneous measurements of the basolateral membrane potential, and cytosolic calcium ion activity, in the control condition, and during reduction and subsequent restoration of the Na^+ concentration, $[Na]_o$, in the peritubular fluid. When $[Na]_o$ was reduced from 100 to 10 mM, the membrane potential depolarized by several millivolts. After the reduction of $[Na]_o$, cytosolic calcium ion activity increased slowly and reached a relatively stable level after 5 to 6 min. In eight successful measurements (out of 30 experiments), cytosolic calcium ion activity averaged 371 ± 59 nM ($P<0.001$) 6 min after the change in $[Na]_o$. In four experiments it was possible to extend the recording into the recovery period following restoration of normal $[Na]_o$. In these experiments, the membrane potential and cytosolic calcium ion activity returned to levels similar to the initial value; cytosolic calcium in activity averaged 376 ± 78 nM (±s.d.) 6 min after lowering $[Na]_o$ and had recovered to a mean value of 106 ± 22 nM (±s.d.; $P<0.001$) 2 to 3 min after restoring $[Na]_o$ to 100 mM. In individual impalements after restoration of normal $[Na]_o$, cytosolic calcium ion activities did not differ significantly from those in the initial control period; in the control period, cytosolic calcium ion activity averaged 115 ± 17 (±s.d.; $n = 6$), and after restoration of normal $[Na]_o$, 118 ± 47 ($n = 5$; *P*, not significant).

These results are consistent with the hypothesis that a Na–Ca exchange system operates across the peritubular cell membrane and plays a significant role in the maintenance of low cytosolic calcium ion activity in proximal tubular cells of *Necturus* kidney. These findings indirectly support the view[22] that the reported reduction in Na efflux from the lumen of isolated perfused rabbit proximal tubules in response to a decrease in contraluminal sodium concentration is associated with an increase in cytosolic calcium ion activity as previously postulated[8,13,26]. Likewise an elevation of cytosolic calcium ion levels may be causally related to the inhibition of net transport of sodium and of the hydro-osmotic response to vasopressin, observed in amphibian tight epithelia, on exposure to low serosal sodium concentrations[5,12,27]. We conclude that cytosolic Ca ion activity, regulated in part through a process of Na–Ca exchange across the basolateral cell membrane, may be important in the physiological regulation of sodium and water absorption by these epithelial tissues.

We thank Dr W. Simon for providing the neutral calcium ligand. This study was supported by NIH grants, USPHS HL 21136, AM 11489 and AM 19022.

Evidence for an adaptive DNA repair pathway in CHO and human skin fibroblast cell lines

Leona Samson & Jeffrey L. Schwartz

Laboratory of Radiobiology, University of California, San Francisco, San Francisco, California 94143

When *Escherichia coli* is chronically exposed to very low, nontoxic doses of a monofunctional alkylating agent (notably *N*-methyl-*N'*-nitro-nitrosoguanidine, MNNG), the adaptive DNA repair pathway is induced which enables the bacteria to resist the killing and mutagenic effects of further alkylation damage[1–3]. Mutation resistance in adapted bacteria is achieved, at least partly, by a greatly increased capacity of the cells to eliminate the minor DNA alkylation product O^6-methylguanine[4–6], which has been strongly implicated as premutagenic[7,8] and precarcinogenic[9]. We now show that the chronic treatment of a Chinese hamster ovary (CHO) and a SV40-transformed human skin fibroblast (GM637) cell line with non-toxic levels of MNNG renders the cells resistant to the induction of sister chromatid exchange (SCE) by further alkylation damage. CHO cells also become resistant to killing (GM637 cells have not yet been tested). Having ruled out explanations such as changes in cell cycle distribution, mutagen permeability and mutagen detoxification, we conclude that resistance is probably achieved by the cells becoming more efficient at repairing alkylation damage, analogous to the adaptive response of *E. coli*[1].

The existence of an inducible error-free mammalian DNA repair pathway, like adaptation, could significantly affect our approach to assessing the mutagenic and carcinogenic risk of chemicals in our environment. Chronic treatment of rats with the alkylating agent dimethylnitrosamine (DMN) has been reported to enable the livers of these animals specifically to avoid the accumulation of O^6-methylguanine[10,11]. Paradoxically, chronic DMN treatment is much more carcinogenic to the rat liver than a single high dose[12]. However, chronic DMN exposure also induces intense liver cell proliferation, which might obscure the role of the O^6-methylguanine lesion in hepatocarcinogenesis[10]. Thus, although there seems to be a biochemical analogue of adaptation in the rat liver, its biological effects such as carcinogenesis, cell killing and mutation, are either obscured or cannot be quantified. The aim of our study was, therefore, to determine whether adaptation can be observed in established mammalian cell lines which would be potentially much more versatile than the rat liver system.

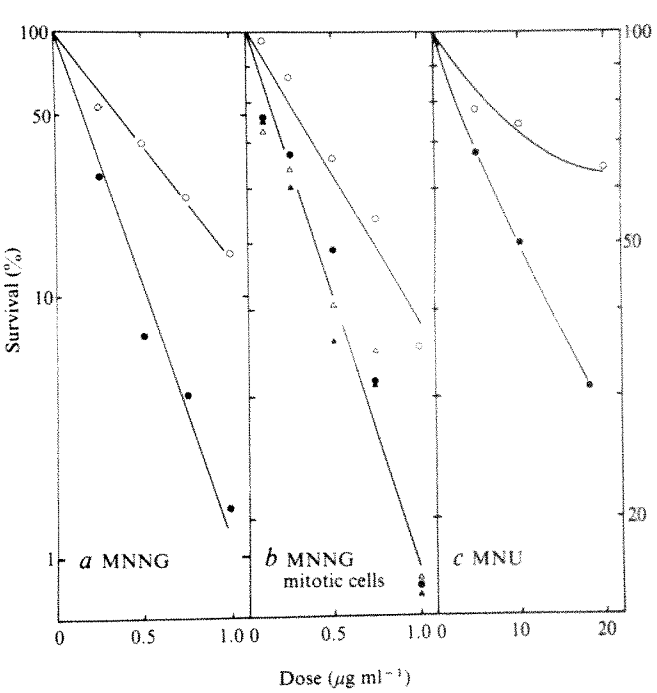

Fig. 1 The effect of MNNG pretreatment on the survival of CHO cells challenged with MNNG or MNU. Cells were grown for 48 h in Ham's F12 medium supplemented with 5% fetal calf serum, penicillin (100 U ml^{-1}), streptomycin (100 μg ml^{-1}) and L-glutamine (0.03%). Every 6 h, one set of cultures was treated with 0.01 μg ml^{-1} MNNG. Three hours after the final pretreatment dose, pretreated (○) and control (●) cells were either trypsinized (*a* and *c*) or synchronized by mitotic shake-off (*b*) and then plated into 100-mm Petri dishes. Each dish was challenged with either MNNG (0–1.0 μg ml^{-1}) or MNU (0–20 μg ml^{-1}). To measure the decay of resistance, cells that had been pretreated for 48 h (△) were grown for a further 24 h before mitotic shake-off and challenge (▲, 72 h control). After 10 days at 37 °C, the cultures were fixed and stained. Colonies were counted in duplicate dishes.

As an initial approach we have used cell survival and SCE as our endpoints. The bacterial studies had shown that the adaptive response could only be observed when both the low dose used to adapt the cells and the high challenge dose used to estimate the degree of resistance fell within critical boundaries[2,13]. Thus, to ensure the greatest chance of detecting adaptation in mammallian cells, a wide range of doses would have to be tested. As SCE induction has been correlated with mutation induction by simple alkylating agents[14] and with the persistence of O^6-methylguanine lesions in certain cell lines[15], we chose this far less time-consuming assay.

MNNG has a reported half life of between 14 min (ref. 16) and 80 min (ref. 17) in cell culture medium. Consequently, the

0028–0836/80/440861—03$01.00

nearest one can get to continuously exposing cells to MNNG is to deliver multiple doses over a prolonged period. (Only the most successful of several dose regimes tested will be dealt with here.) CHO cells received 0.01 μg ml^{-1} MNNG once every 6 h for 48 h. Pretreated and control cells were then challenged with various MNNG doses up to 100 times this concentration, and the resulting cell killing measured. At each challenge dose pretreated cells survived better than control cells, with about a twofold difference in the slopes of the survival curves (Fig. 1*a*, *b*). Similarly, CHO and GM637 cells that had been pretreated for 48 h and 72 h, respectively, were very resistant to the SCE-inducing effects of MNNG. Resistance to both killing (Fig. 1*b*) and SCE induction (Figs 2*a*, 3*a*) decayed when pretreatment was stopped.

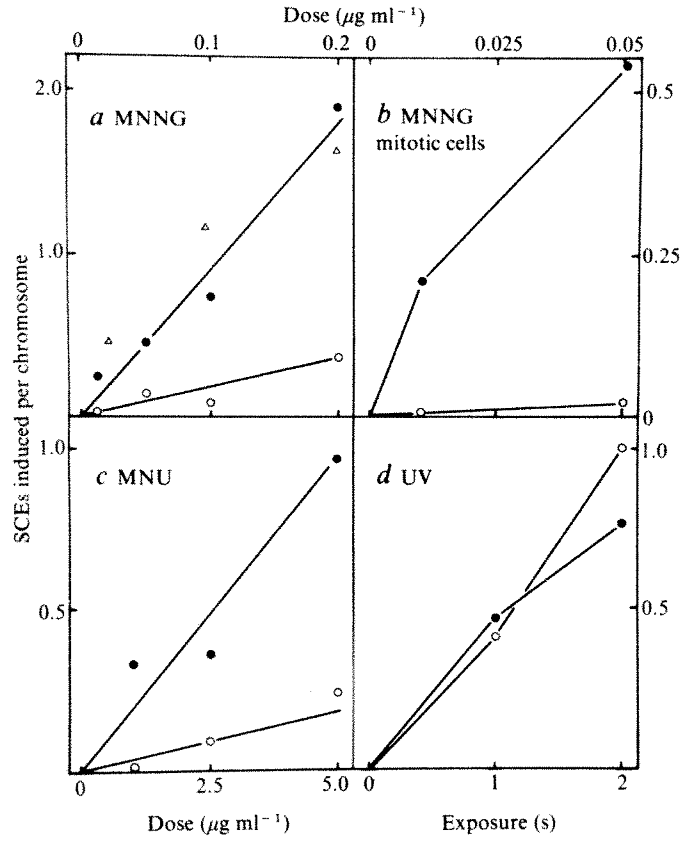

Fig. 2 The effect of MNNG pretreatment of CHO cells on the induction of SCEs. Cells were cultured as described in Fig. 1 legend. At 3 h (○) or 24 h (△) after the final adapting dose, pretreated (○, △) and control (●) cells were challenged with MNNG (0–0.2 μg ml^{-1}), MNU (0–5 μg ml^{-1}) or UV light (0–2 s, fluence rate 12 erg mm^{-2} s^{-1}), and then cultured for two rounds of DNA replication (26 h) in complete medium containing 10 μM bromodeoxyuridine. Colcemid (2×10^{-7} M) was present for the final 2 h. Mitotic cells were collected by shaking, treated with 0.075 M hypotonic KCl, then fixed in 3:1 methanol/glacial acetic acid. SCEs were differentiated by a modified fluorescence-plus-Giemsa technique[23], and at least 20 cells were counted per point. Induced SCEs were calculated by subtracting background levels (0.35–0.5 for control, 0.85–1.0 for pretreated cells) from the total SCE values.

Because the sensitivity of CHO cells to MNNG fluctuates throughout the cell cycle[18], a change in cell cycle distribution could generate an apparent change in the sensitivity of the overall population. However, pretreated and control CHO cells have approximately the same mitotic indices (1.25% and 1.4%, respectively) and proceed through the cell cycle at similar rates (Fig. 4*a*). Moreover, a cell cycle redistribution cannot account for increased MNNG resistance in CHO cells because homogeneous populations of mitotic cells also display differential sensitivity to MNNG killing (Fig. 1*b*) and SCE induction (Fig. 2*b*). An extended period in G1 might account for the observed increase in MNNG resistance[19], but G1 was shown to be the same in pretreated and control populations that had been challenged with 0.5 μg ml^{-1} MNNG (Fig. 4*b*).

We considered that resistance to MNNG could be achieved either by preventing alkylation from taking place or by dealing with alkylation damage more efficiently. As alkylation by MNNG is thiol stimulated, a reduction in cellular thiol levels could inhibit alkylation by this agent[17]. However, thiol depletion cannot explain our results because MNNG-pretreated cells were also found to be resistant to two alkylating agents which are unaffected by cellular thiol levels[20]; CHO cells were resistant to killing (Fig. 1*c*) and SCE induction (Fig. 2*c*) by methylnitrosourea (MNU) and GM637 cells were resistant to SCE induction by MNU (fig. 3*b*) and ethylnitrosourea (ENU) (Fig. 3*c*). Moreover, pretreatment does not alter the permeability of the cells to mutagen, because, for both CHO and GM637, the DNA purified from control and pretreated cultures that had been exposed to 2.5 μg ml^{-1} ^{3}H-MNU (120 Ci mol^{-1}) had similar specific activities. We therefore deduce that chronic MNNG exposure enables both CHO and GM637 cells to handle alkylation damage somewhat more efficiently and so become resistant to alkylating agents. This resistance seems to be specific for alkylation damage because MNNG-pretreated cells are not resistant to the induction of SCE by UV light (Figs 2*d*, 3*d*).

Thus, the response of two mammalian cell lines during continuous low-dose exposure to the carcinogen MNNG has, so far, exactly paralleled *E. coli* adaptation: a treatment which neither kills cells nor disturbs cell growth induces a resistance to alkylation damage, but not UV damage which decays once treatment is stopped. Furthermore the induced resistance in

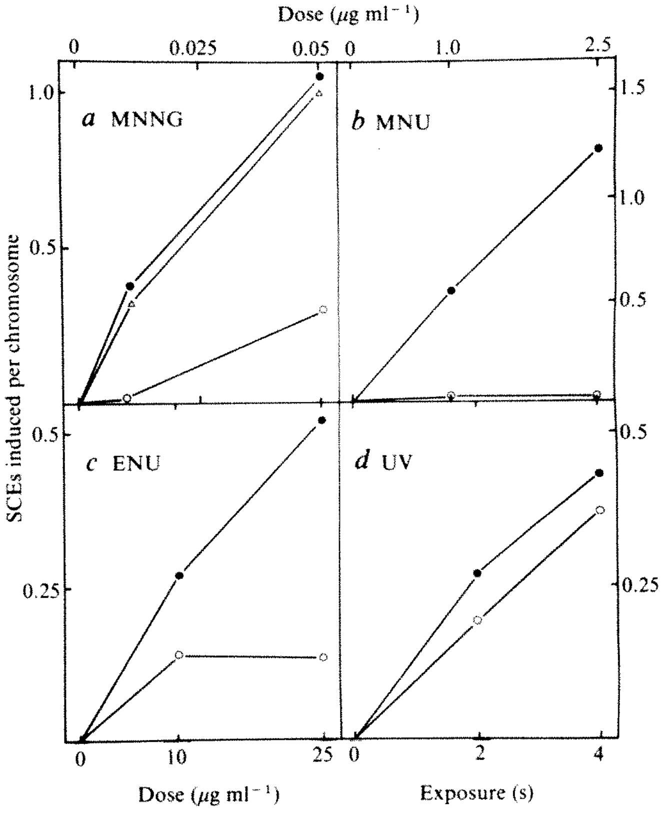

Fig. 3 The effect of MNNG pretreatment of GM637 cells on the induction of SCEs. GM637 cells were grown in minimum essential medium supplemented with 15% fetal calf serum, penicillin (100 U ml^{-1}), streptomycin (100 μg ml^{-1}), and L-glutamine (0.03%). Cells were treated and analysed as described in Figs 1 and 2 legends, except that the pretreatment regime lasted 72 h. The background SCE values were 0.26 SCEs per chromosome for controls (●) and 0.34 SCEs per chromosome for pretreated cells (○, △). Recovery (△) was measured 1 week after the final pretreatment.

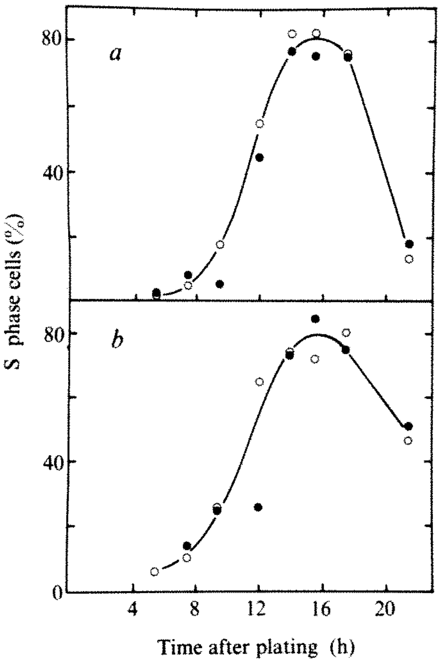

Fig. 4 The effect of MNNG pretreatment on the onset of DNA replication in synchronized CHO cells. Cells were pretreated as described in Fig. 1 legend. Three hours after the final adapting dose, pretreated (○) and control (●) cells were collected by mitotic shake-off (the mitotic index was about 0.95). Half of each group of cells were challenged with 0.5 $\mu g\, ml^{-1}$ MNNG (*b*), the other half remained unchallenged (*a*). The cells were plated into tissue culture slide chambers at a density of 10^3 cells per cm^2. At various times after plating, one set of slides was pulse labelled for 20 min with 10 $\mu Ci\, ml^{-1}$ ^3H-thymidine, then washed and fixed for autoradiography. For each data point 150–350 cells were counted.

mammalian cells becomes saturated at high challenge doses (GM637, Fig. 3*a*; CHO data not shown) with the same biphasic kinetics seen in bacteria[13]. It is improbable that our results could be attributed to the inducible error-prone DNA repair pathway reported to exist in mammalian cells because this pathway can act on UV damage[21,22]. However, it is not yet known whether the induced resistance to the killing and SCE-inducing effects of alkylating agents is accompanied by resistance to their mutagenic effects.

We thank John Cairns, James Cleaver, Regine Goth-Goldstein, Robert Painter and Sheldon Wolff for their interest and helpful advice, and Peter Tattersall for supplying the CHO cell line. L.S. was supported by a SRC postdoctoral fellowship, and the work was supported by the US Department of Energy.

Ca^{2+}-calmodulin-dependent phosphorylation and platelet secretion

Masakatsu Nishikawa, Toshio Tanaka & Hiroyoshi Hidaka

Department of Pharmacology, Mie University School of Medicine, Edobashi, Tsu 514, Japan

Protein phosphorylation may play a critical role in stimulus-coupled secretion of platelets. Some platelet proteins become phosphorylated on exposure to agents such as thrombin and collagen[1–5], and the smallest of these phosphoproteins (molecular weight 20,000), has been identified as a light chain of myosin[6–8]. Phosphorylation of myosin light chain increases the activity of actin-activated myosin ATPase[8] and the resultant contraction of the actomyosin presumably mediates the release reaction[6,9]. Platelet myosin light chain kinase has been identified as a calcium-dependent enzyme requiring calmodulin for its activity[10,11]. Calmodulin is a Ca^{2+}-binding protein with a molecular weight of ~18,000 which seems to be involved in a wide variety of cellular processes[12]. Although a growing body of evidence suggests that non-muscle actomyosin, such as that isolated from platelets, is regulated by Ca^{2+}-calmodulin-dependent light chain phosphorylation, the precise relationship between the phosphorylation and the function of platelets is not clearly established. We now present pharmacological evidence that a calmodulin-mediated system, such as Ca^{2+}-dependent myosin light chain phosphorylation, also plays an important role in the phenomenon of the release reaction. *N*-(6-aminohexyl)-5-chloro-1-napthalene-sulphonamide (W-7) (refs 13–15) is shown to bind selectively to calmodulin *in vitro* and inhibit its biological activity.

The effects of the calmodulin-interacting agent W-7 on human platelet aggregation and the ATP release induced by collagen (2 $\mu g\, ml^{-1}$), ADP (2 μM) and thrombin (0.1 $U\, ml^{-1}$)

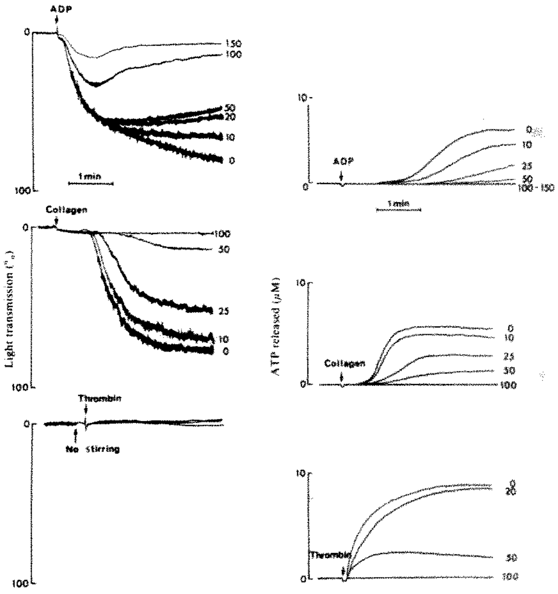

Fig. 1 Effect of W-7 on platelet aggregation and secretion induced by ADP (2 μM), collagen (2 $\mu g\, ml^{-1}$) or thrombin (0.1 $U\, ml^{-1}$). Secretion of ATP (right-hand traces) was measured by the firefly luminescence assay method and aggregation (left-hand traces) was determined simultaneously in the same cuvette turbidimetrically. The stirring motor was turned off to prevent aggregation in the experiment involving platelet stimulation by thrombin. The standard platelet reaction mixtures consisted of 0.4 ml of citrated platelet-rich plasma (PRP), 50 μl of Chrono-Lumi luciferase luciferin reagent, 50 μl of a dilution of W-7 (in saline), and aggregating agent. In experiments involving platelet activation by thrombin, 0.4 ml of washed platelet suspension ($4.0 \times 10^8\, ml^{-1}$) was used in place of PRP. The platelets were preincubated without (0) or with W-7 (the final concentration shown in μM by each curve) for 3 min before stimulation.

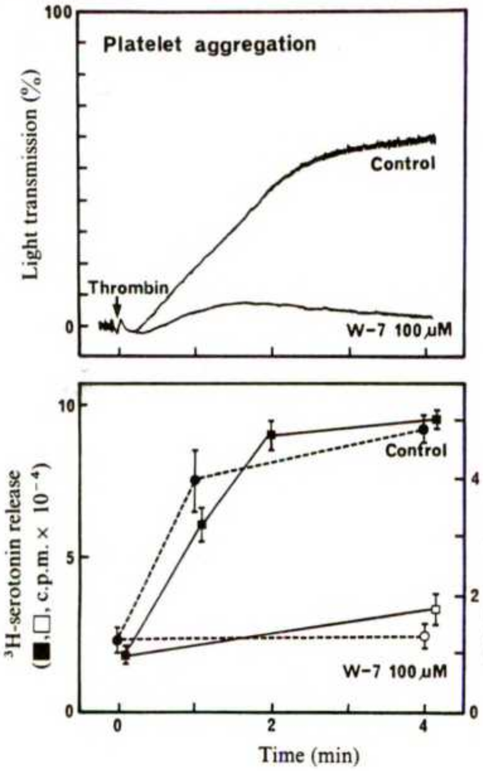

Fig. 2 Time course of platelet aggregation (top), and ^{3}H-serotonin release and 20,000-MW MLC phosphorylation (bottom) in response to thrombin (0.25 U ml^{-1}) amd the effect of W-7 (final concentration 100 μM) preincubation. Serotonin secretion and phosphorylation are shown as means ± s.e.m. ($n = 3$) ■, □, ^{3}H-serotonin release; ●, ○, MLC phosphorylation. Open symbols, W-7 100 μM; closed symbols, controls. *Method*: Human platelets suspension in 20 mM Tris-HCl pH 7.4, 150 mM NaCl, 0.1% glucose, 0.35% bovine serum albumin was incubated with ^{32}P-orthophosphate at 1 mCi ml^{-1} for 30 min at 25 °C. ^{3}H-serotonin creatinine sulphate at 1 μCi ml^{-1} was added, and the platelets suspension was incubated for another 30 min, then spun at 600g for 5 min and the supernatant discarded. The pellets were resuspended in the same buffer to give a platelet count of 5–10 × 10^8 per ml. The platelet reaction mixtures consisted of 1.8 ml of labelled platelets suspension, 0.2 ml of saline (control) or W-7 (concentration 100 μM) and thrombin (0.25 U ml^{-1}). The platelets were preincubated with saline or W-7 in the aggregometer (Rikadenki) for 3 min before stimulation with thrombin. The reaction was terminated with 1 ml of ice-cold 150 mM NaCl, 10 mM EDTA, 0.8 mM phenylmethylsulphonyl fluoride (PMSF), soybean trypsin inhibitor (0.2 mg ml^{-1}), then spun at 1,200g for 10 min at 4 °C. Samples of supernatant fluid (1 ml) were removed immediately and transferred into liquid scintillation vials. 10 ml of ACS II (Amersham) was added and the sample counted in a Beckman scintillation counter. Platelet pellets were frozen and extracted with a high ionic strength buffer containing 0.5 M KCl, 20 mM K_2PO_4 pH 7.4, 1 mM EGTA, 0.4 mM PMSF. The insoluble material was removed by centrifugation at 150,000g for 20 min at 4 °C. Each extract was electrophoresed on 1% SDS 10% polyacrylamide gel. The gels were stained with Coomassie brilliant blue, and photographed. ^{32}P content of 20,000-MW protein was determined by liquid scintillation counting of 2-mm gel slices.

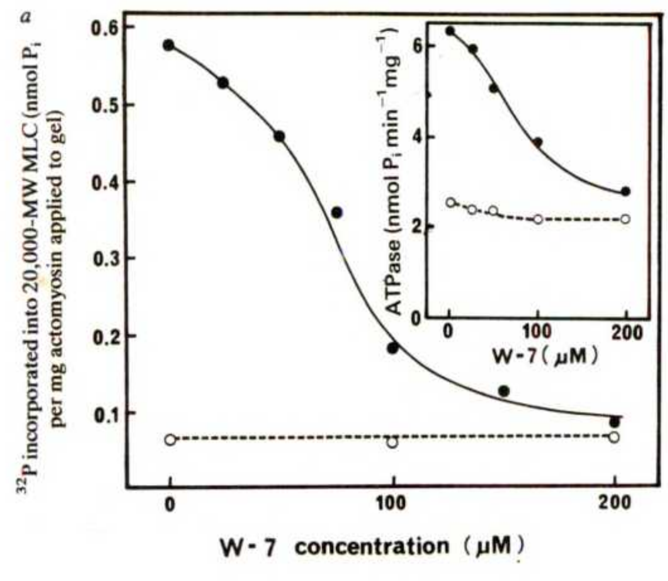

Fig. 3 *a*, Inhibition by W-7 of endogenous phosphorylation of the 20,000-MW MLC and actomyosin ATPase activity (inset) from human platelets in the presence of 100 μM Ca^{2+}(●) and in the presence of 2 mM EGTA (○). *b*, 8 M urea-gel electrophoresis (left) and its autoradiography (right) for detecting phosphorylation of the 20,000-MW MLC of platelet actomyosin. 1, Ca^{2+} 100 μM; 2, Ca^{2+} 100 μM + W-7 50 μM; 3, Ca^{2+} 100 μM + W-7 100 μM; 4, Ca^{2+} 100 μM + W-7 200 μM; 5, EGTA 2 μM. a, The unphosphorylated 20,000-MW MLC; a′, the phosphorylated 20,000-MW MLC. *Phosphorylation analyses*: The reactions were carried out at 25 °C for 10 min in 200 μl of reaction mixture containing 20 mM Tris-HCl pH 7.5, 125 mM KCl, 10 mM $MgCl_2$, 0.5 mM [γ-^{32}P]ATP (2 μCi per tube), platelet actomyosin (1.5 mg ml^{-1}), various concentrations of W-7, and 100 μM $CaCl_2$ or 2 mM EGTA. The reactions were initiated by the addition of ATP and terminated by the addition of 20 μl of 5% SDS containing 0.1 M 2-mercaptoethanol and 20% sucrose, *a*, The solution containing 60 μg protein was applied to SDS-polyacrylamide gel and electrophoresis was carried out using 10% acrylamide and 100 mM sodium phosphate buffer (pH 7.2). The gels were then stained with Coomassie brilliant blue, photographed and sliced into 2-mm portions from which the radioactivity was eluted. ^{32}P radioactivity was analysed by liquid scintillation spectrometer. *b*, Urea polyacrylamide slab gel electrophoresis was carried out by the method of Perrie *et al.*[18], using 10% polyacrylamide, 8 M urea, and 25 mM Tris-150 mM glycine buffer, pH 8.6. Samples of 60 μg of protein were applied to the gel. The gel was run, stained, destained and prepared for autoradiography. *ATPase assay*: ATPase activity was determined in 600 μl of medium containing 50 mM Tris-malate buffer pH 7.0, 50 mM KCl, 10 mM $MgCl_2$, 1 mM ATP, platelet actomyosin (0.4 mg ml^{-1}), various concentrations of W-7, and either 2 mM EGTA or 100 μM $CaCl_2$. Incubations were carried out for 30 min at 35 °C. The reaction was stopped by the addition of trichloroacetic acid to a final concentration of 10%. Inorganic phosphate was measured by the method of Allen[21].

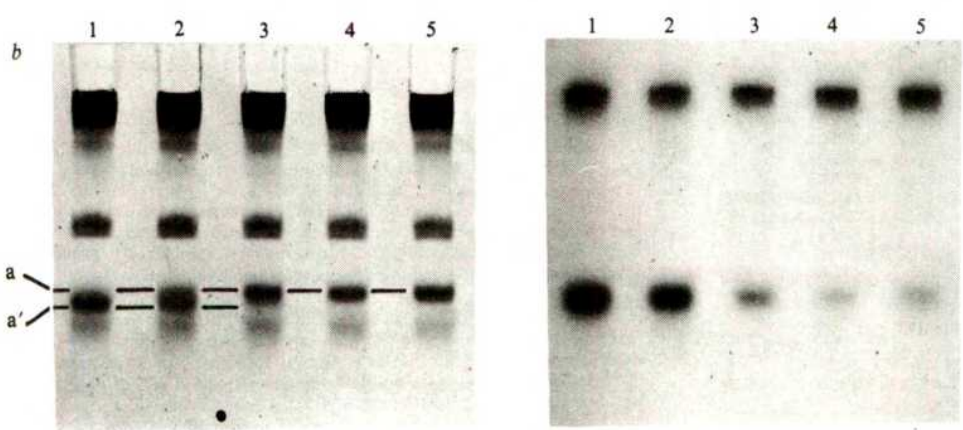

were studied in a Model 400 Lumi-aggregometer (Chrono-Log.), which simultaneously monitors aggregation and release of ATP[16,17]. A typical result is shown in Fig. 1. W-7 inhibited dose-dependently collagen-induced ATP release and aggregation. Two distinct phases of ADP-induced aggregation were evident and the inhibition by W-7 of the first phase was weaker than that of the second. The second phase of aggregation associated with ATP release was inhibited dose-dependently by W-7. Similar results were obtained when aggregation was induced by adrenaline, arachidonic acid or thrombin. When thrombin was added to the platelet suspension without stirring, ATP release occurred but there was no aggregation (Fig. 1). W-7 inhibited dose-dependently this thrombin-induced secretion of ATP, suggesting that the drug also inhibits stimulus-coupled secretion processes in platelets. W-7 had no effect on thrombin hydrolytic activity at concentrations as high as 200 μM.

To examine the effect of W-7 on protein phosphorylation in platelet aggregation and the release reaction, protein phosphorylation in platelets was measured by prelabelling with ^{32}P-orthophosphate and ^{3}H-serotonin and treating the stirred suspension of platelets with thrombin (0.25 U ml^{-1}). The platelet pellet formed after thrombin treatment was used for extraction of phosphorylated protein with a high ionic strength buffer, as described by Daniel *et al.*[6], and the supernatant was used for the assay of serotonin. Thrombin treatment of intact ^{32}PO$_4$-loaded platelets resulted in a four- to fivefold increase in phosphorylation of the 20,000-MW protein, when a high ionic strength extract was directly electrophoresed on SDS-polyacrylamide gel. The pattern of ^{32}P incorporation was similar to that described by Daniel *et al.*[6]. This 20,000-MW phosphoprotein was identified as the myosin light chain (MLC) by 8 M urea slab polyacrylamide gel electrophoresis[18]. The phosphorylated MLC migrates slightly faster than the unphosphorylated MLC in this electrophoresis system. The change in ^{32}P content of MLC correlated with the increased secretion of ^{3}H-serotonin rather than aggregation, as shown in Fig. 2. W-7 (100 μM) inhibited both the phosphorylation of 20,000-MW MLC and serotonin release from platelets.

We examined the effect of W-7 on calcium-dependent ^{32}P incorporation into the 20,000-MW MLC from [γ-^{32}P]ATP which constitutes the Ca^{2+}-sensitive regulatory mechanism of actin–myosin interaction. An actomyosin-rich fraction containing endogenous myosin light chain kinase and calmodulin (~50 units per mg protein) was prepared from human platelets by a modification of the method of Hathaway and Adelstein[11]. ^{32}P incorporation into the 20,000-MW MLC from [γ-^{32}P]ATP was observed in the presence of calcium ions (100 μM), and addition of EGTA to 2 mM inhibited ^{32}P incorporation into the MLC, indicating that this phosphorylation of MLC depends on calcium ions (Fig. 3*a*). Increasing the concentration of W-7 inhibited selectively the Ca^{2+}-dependent phosphorylation of the 20,000-MW MLC with an IC$_{50}$ value of 80 μM, as shown in Fig. 3*a*. Moreover, W-7 produced a concentration-dependent inhibition of Ca^{2+}-dependent ATPase of platelet actomyosin (IC$_{50}$ 100 μM) but did not inhibit Ca^{2+}-independent ATPase. Figure 3*b* demonstrates that the light chains of myosin have a greater electrophoretic mobility than other platelet proteins and that the Ca^{2+}-dependently phosphorylated 20,000-MW MLC migrates slightly faster than unphosphorylated MLC. Dose-dependent inihibition by W-7 of Ca^{2+}-dependent MLC phosphorylation was also demonstrated by using this urea gel electrophoretic analysis.

Calmodulin interacting agents such as W-7, N^{2}-dansyl-L-arginine-4-*t*-butylpiperidine amide (No. 233) and chlorpromazine inhibit Ca^{2+}-calmodulin-dependent enzymes, for example, myosin light chain kinase[14,15], cyclic nucleotide phosphodiesterase[13,19] and erythrocyte Ca^{2+}, Mg^{2+}-ATPase[20]. The pharmacological effects of calmodulin-interacting agents on platelets result from a combination of several types of molecular interactions and cannot be explained by a single mechanism. However, one of the important effects of calmodulin-interacting agents is the inhibition of calmodulin-dependent MLC phosphorylation. Our findings indicate that there is a calmodulin-mediated regulatory system in platelets similar to that in smooth muscle tissue. The calmodulin-interacting agent W-7 could be of interest clinically as it combines antithrombotic activity with vascular relaxant activity.

This work was supported in part by grant 448114 from the Ministry of Education, Science and Culture, Japan. We thank Y. Sasaki for his assistance and M. Ohara for criticism of the manuscript. W-7 was a gift from Banyu Pharmaceutical Co.

Optical properties of single elastin fibres indicate random protein conformation

B. B. Aaron & J. M. Gosline

Department of Zoology, The University of British Columbia,
2075 Wesbrook Mall, Vancouver BC, Canada V6T 1W5

In describing the properties of fibrous proteins it has been common practice to attribute the macroscopic mechanical properties to the organization at the molecular level. Hence, the high tensile stiffness of collagen and silk has been viewed as an inevitable consequence of their crystalline structure. For elastin, however, there has been considerable controversy and confusion in assigning a conformation to this rubber-like protein. The mechanical and thermodynamic properties of elastin are consistent with the kinetic theory of rubber elasticity[1–5], and this theory is based on an isotropic network of kinetically free, random-coil molecules. In contrast, numerous electron microscope studies of negatively stained elastins obtained by autoclave and alkali purification, as well as coacervates of the various soluble elastins, reveal a highly ordered (anisotropic) structure, consisting of 3- to 5-nm filaments that apparently run parallel to the long axis of elastin fibres[6–11]. These filaments have been accepted as evidence for an anisotropic molecular structure in elastin that is dramatically different from the random network of the kinetic theory. We have now used polarized light microscopy to distinguish these two types of structure. We find that both purified and unpurified, water-swollen, single elastin fibres are optically isotropic, in agreement with the predictions of the kinetic theory of rubber elasticity.

Polarized light microscopy is a useful technique because unlike electron microscopy it does not require any physical modification of the protein structure, and thus it reduces the chance of procedural artefacts. Further, the technique allows the evaluation of structure at two levels of organization: (1) at the molecular level as reflected by the intrinsic birefringence, and (2) at the submicroscopic level (that is, at the level of the 3- to 5-nm filaments) as indicated by the form birefringence. A

0028-0836/80/440865—03$01.00

general discussion of these types of birefringence is given by Bennet[12].

If elastin is totally isotropic, then this should result in a lack of both intrinsic and form birefringence. On the other hand, if elastin consists of isotropic filaments at the submicroscopic level, then it should exhibit an observable form birefringence. Finally, if these filaments are anisotropic at the molecular level, as is proposed in the anisotropic model of Urry[13], then there should be an intrinsic birefringence as well as a form birefringence. The determination of birefringence for test samples that are swollen in media of differing refractive index allows one to distinguish and quantify form and intrinsic birefringence[12]. Similar studies on collagen[14] and chitin[15] attest to the reliability of this type of analysis.

Single 6- to 8-μm elastin fibres were isolated from untreated bovine ligamentum nuchae and from ligament that had been purified by repeated autoclaving[16]. The fibres were viewed between crossed polarizers on a Wild M-21 polarizing microscope, and the retardation was determined at 546 nm using a Zeiss 1/30 wavelength rotary compensator. Birefringence was calculated by dividing the retardation at the centre of the fibre by the fibre diameter. The form birefringence curves were obtained from measurements on single elastin fibres and rat-tail collagen fibres swollen in liquids of known refractive index.

Both purified and unpurified single elastin fibres show an apparent positive birefringence of about 2×10^{-4} when swollen in distilled water ($n_m = 1.33$; see Fig. 1, solid square). The fact that autoclaved fibres show the same optical properties as unpurified ones argues strongly against the creation of any structural artefacts by this purification procedure. To put this low value of birefringence into perspective, curve *a* in Fig. 1 shows the birefringence expected for a system of parallel, isotropic cylindrical fibres swollen in a fluid medium of different refractive index, as predicted by an approximation of the Weiner equation derived by Stokes[17]. The volume fraction of the fibres ($v_f = 0.65$) used in this calculation has been selected to reflect the known water content of elastin and thus to provide a reasonable description of elastin structure if protein filaments separated by watery spaces actually exist. Clearly the birefringence of water-swollen elastin is many times smaller than the birefringence expected for a system of isotropic filaments.

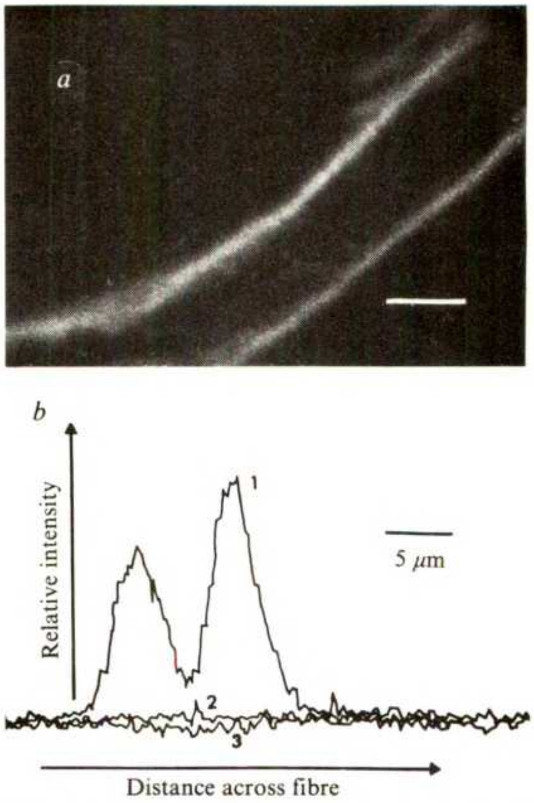

Fig. 2 *a*, Single elastin fibre ($n_f = 1.55$) in water ($n_m = 1.33$) photographed between crossed polarizers. Scale bar, 5 μm. *b*, Typical densitometer tracings for negatives of: 1, single elastin fibre in water; 2, water-swollen elastin fibre in immersion oil ($n = 1.52$); 3, control tracing of blank field.

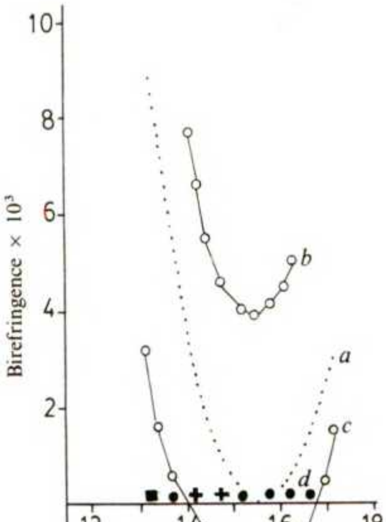

Fig. 1 (■) Birefringence of single, water-swollen elastin fibres, 2.5×10^{-4}. (●) Birefringence values for dry single elastin fibres immersed in organic liquids of different refractive index varying from $n_m = 1.36$ to 1.65. (+) Birefringence values measured for single elastin fibres swollen in ethelene glycol ($n_m = 1.43$) and glycerol ($n_m = 1.47$). Elastin swollen in these liquids retains its elastic properties. *Curve a*, Theoretical form birefringence for a system of parallel isotropic cylinders[17]: $B_F = (n_f - n_m)^2 v_f(1-v_f)/\bar{n}$, where B_F is the form birefringence, n_f and n_m are the refractive index of the fibre (1.55) and the medium (1.33 for water) respectively, with $\bar{n}$ being the value of their mean. v_f is the volume fraction of the fibres (0.65) (ref. 4). *Curve b*, Rat-tail tendon collagen fibres. *Curve c*, tannic acid-fixed collagen fibres[14].

If the small residual birefringence is actually inherent to the fibre, then one would expect the retardation to be proportional to the optical path length through the fibre and should therefore be highest at the centre of the fibre. Figure 2*a* shows a water-swollen elastin fibre (refractive index of elastin, $n_f \simeq 1.55$; refractive index of water, $n_m = 1.33$) between crossed polarizers. It is clear that the retardation, as indicated by the intensity, is greatest at the edges of the fibre. This suggests that the apparent birefringence at the centre of the fibre is not a property of the fibre itself, but results from the refractive index difference at the fibre–water interface. When this refractive index difference is reduced by suspending water swollen elastin fibres in immersion oil ($n = 1.52$) this apparent retardation virtually disappears (see the densitometer tracings in Fig. 2*b*). In fact the intensity (retardation) is indistinguishable from the background, suggesting that the true birefringence of elastin is actually zero or at least immeasurably small. We believe that this anomalous retardation created by the water–fibre interface is what has been measured by other workers[7] who have reported very high birefringence values for water-swollen elastin.

Although elastin appears to be completely isotropic, the possibility exists that the zero total birefringence is due to the summing of a positive form birefringence that is just equal to a negative intrinsic birefringence. This possibility is demonstrated in Fig. 1 for collagen fibres and tannic acid-fixed collagen fibres[14]. Collagen fibres, which are known to be anisotropic at both the molecular and the submicroscopic levels, show both positive form and positive intrinsic birefringence (Fig. 1, curve *b*). Tannic acid fixation reverses the sign of the intrinsic birefringence, and as a result of this, tannic acid-fixed fibres 'appear' to be isotropic (that is, show zero total birefringence) at n_m = 1.40 and n_m = 1.67 (Fig. 1, curve *c*). That the lack of birefringence in single elastin fibres does not occur as a result of this phenomenon is confirmed by the fact that elastin fibres swollen in a variety of solvents over a broad range of n_m show the same small birefringence as water-swollen fibres (Fig. 1, curve *d*). Thus, elastin shows neither intrinsic nor form birefringence, indicating an isotropic structure at both the molecular and the submicroscopic levels.

In conclusion, the extremely low residual birefringence values and the absence of any form birefringence leads us to believe that elastin does in fact possess a random conformation at the molecular level, similar to other known elastomeric materials. Although these data do not preclude the possibility that elastin contains randomly oriented filaments, there is clearly no evidence for the existence of the highly ordered, 3- to 5-nm filaments visualized by negative staining techniques in the electron microscope. We suspect that the filamentous organization seen for elastin may well be the result of drying elastin in the presence of the heavy-metal salts used for negative staining. It is also possible, however, that these filaments are cellulose contaminants, as suggested previously[18–20]. It is our opinion that the 120-nm subfibres which have been observed in the scanning electron microscope[21] are large enough to accommodate an isotropic random network structure, and thus are not in conflict with the idea of elastin being a typical kinetic rubber. However, the lack of form birefringence for elastin fibres suggests that these subfibres may only be due to a rough surface texture of the 6-μm fibres and may not extend through the entire thickness of the fibre. This interpretation is consistent with the appearance of elastin fibres seen in cross-section in the transmission electron microscope[22].

Motile flagellar axonemes with a 9+1 microtubule configuration

S. Marchese-Ragona & M. E. J. Holwill

Physics Department, Queen Elizabeth College, Campden Hill Road, London W8 7AH, UK

Electron microscope (EM) studies of the eukaryotic flagellum reveal that the organelle contains a 9+2 arrangement of microtubules, the axoneme, with nine doublets surrounding two singlets enveloped by a membrane which is continuous with that of the cell; various linkages and projections are associated with the microtubules[1]. Strong experimental evidence supports the idea that the forces required for bend formation on eukaryotic flagella are derived from active relative sliding of the peripheral doublets[2,3]. Dynein arms, which project from each peripheral microtubule and possess ATPase activity, interact with a neighbouring doublet and undergo conformational changes which induce sliding[4,5]. To form and propagate coordinated bends along a flagellum the sliding must be resisted in a controlled manner by structures within the axoneme. The regulatory mechanism responsible for the control of interdoublet sliding is not known in detail, but ultrastructural studies[6] suggest that interactions between the radial spokes attached to each doublet and the central complex of the axoneme may be involved. We report here the treatment of flagella with a 9+2 microtubular structure from the trypanosomid flagellate *Crithidia oncopelti* to produce motile axonemes with only one central microtubule. We conclude that the complete central complex is not involved in the conversion of microtubule sliding into axonemal bending, but may be both associated with the control of wave propagation and essential for bend initiation.

Cells from a 5–6-day old culture of *Crithidia* were demembranated by exposure to detergent using a procedure similar to that described by Holwill and McGregor[7], except that the chelating agents EGTA and EDTA were omitted from all solutions. Samples were removed from a particular preparation at periods of 1 min, 1 h and 4 h for structural examination by electron microscopy and for motility studies following reactivation with ATP. Samples were reactivated at room temperature on a microscope slide by gently mixing a drop containing demembranated cells with a roughly equal volume of reactivating solution containing 1 mol m^{-3} ATP. Reactivated cells were examined in a Zeiss WL Research microscope with stroboscopic illumination.

Structural studies of reactivated and non-reactivated cells were undertaken after an incubation period of 1 h; because no structural differences between the two preparations were detected, subsequent samples for electron microscopy were prepared without the addition of ATP. Transverse sections of axonemes were examined at the three sampling times specified above and classified according to the pattern of microtubules remaining. Four distinct categories could be recognized: 9+2, 9+1, 9+0 and A-microtubules held together in cylindrical arrays, presumably by nexin links (Fig. 1). The proportions of axonemes falling into these classes are presented in Table 1.

We have not established unequivocally which of the two central microtubules is removed first during the extraction process, but results obtained for other organisms suggest that it is probably CM3, as this microtubule is chemically less stable than CM8 (ref. 8). Because of their importance in motility the number of dynein arms in a section was determined and expressed as a percentage of the total expected. In practice, only the outer arms were scored, as these were solubilized before the inner arms and were easier to visualize. The results of these counts are presented in Table 1.

In assessing motility, only those cells which were propagating coherent bends were scored as motile; organelles with an oar-like or a local bending movement were considered to be non-motile. The proportions of motile cells observed in a typical experiment are shown in Table 1. In all cases, wave propagation was from base to tip, with the beat pattern similar to that described by Holwill and McGregor[7]. There were no major differences between the wave shapes displayed by flagella of a given sample, as judged by visual examination of the sample, but the beat frequency of motile cells was generally observed to

0028-0836/80/440867—03$01.00

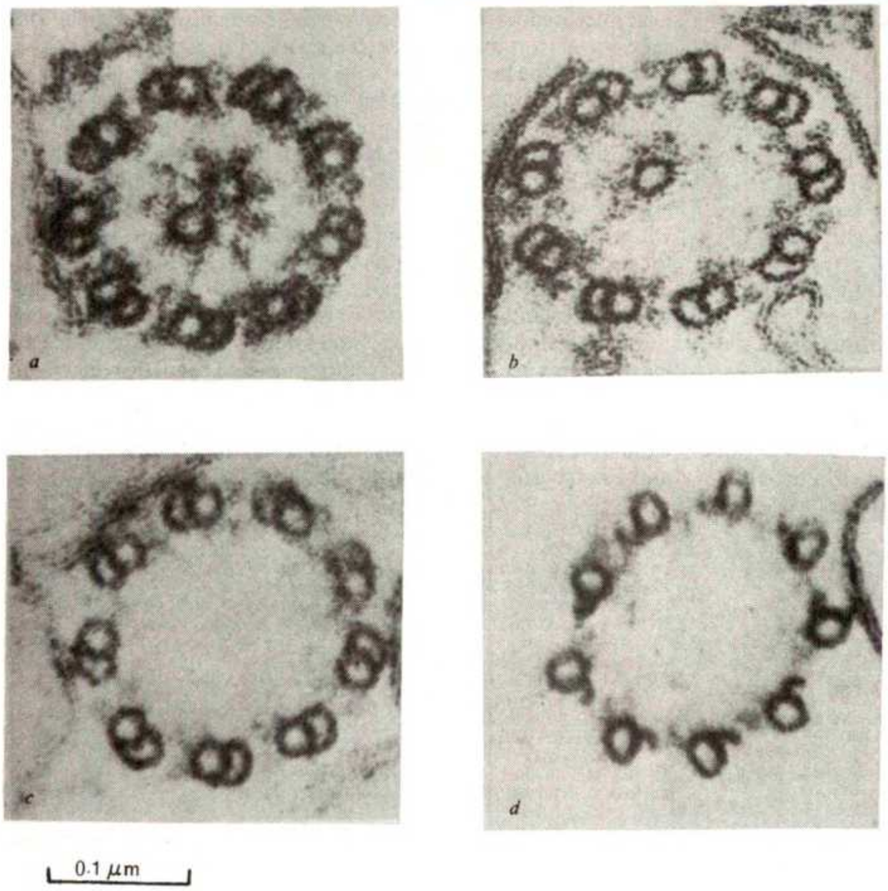

Fig. 1 Transverse sections of detergent-treated axonemes of *Crithidia oncopelti* showing the changes in microtubule arrangement which occur during degradation. *a*, Intact 9 + 2 axoneme; *b*, axoneme with one central microtubule missing; *c*, axoneme with both central microtubles missing; *d*, cylinder of A-microtubules. Membrane removal was performed at a ratio of 1 mg of cell protein (measured by the method of Lowry *et al.*[17]) to 1.0 cm^3 of 0.1% detergent solution, and the demembranated cells were incubated at 0 °C. The incubation periods for the axonemes represented by the sections shown were 1 h for *a* and *b* and 4 h for *c* and *d*. In preparation for electron microscopy, cells were fixed in 2.5% glutaraldehyde in phosphate buffer at room temperature, post-fixed in 1% osmium tetroxide, dehydrated and embedded in Spurr resin.

decrease with time. A detailed study of bend patterns is planned to determine whether subtle shape changes occur which may be attributed to variations in the axonemal structure.

Of particular interest in correlating structure with motility are the results obtained after 1 h of incubation. Whereas 83.2% of the sample was motile, only 15% of the axonemes examined had a 9 + 2 microtubular configuration. A large percentage of the axonemes with the 9 + 1 structure was therefore propagating bends at this time. After 4 h, the proportion of 9 + 1 axonemes in a sample is similar to that after 1 h, but the percentage motility has fallen by about 70. This decrease cannot be due to the 7% reduction in the number of dynein arms present at the later time, but could be due to a loss of functional integrity in these structures.

The fact that the axonemes with a disrupted central complex are capable of propagating bends leads to the question of whether any of the central complex is necessary for wave propagation. That 9 + 0 flagella may have been non-motile in the present study does not mitigate against this possibility, for structures other than the central complex could have been removed, without detection, during the treatment period, and this could be responsible for the lack of movement.

Although this is the first report of an axoneme which remains capable of activity after removal of a central microtubule, reports of undulating flagella with 9 + 0 (ref. 9), 6 + 0 (ref. 10) and 3 + 0 (ref. 11) microtubule configurations also indicate that central structures are not essential for movement. It may also be relevant that some insect spermatozoa have no central microtubules and yet are motile[12,13]; however, these spermatozoa have accessory components in addition to the nine doublets so that observations on these cells do not provide strong evidence that a cylinder of doublet microtubules alone is capable of coordinated bending activity.

That the integrity of the central complex may be important for motility is indicated by experiments on *Chlamydomonas* mutants which lack one or both of the central microtubules and seem to be incapable of bend formation and propagation[14,15]. Treatment of both mutant and wild-type flagella with trypsin, followed by ATP, induced identical disintegration processes which involved relative sliding of the peripheral microtubules, thus indicating that the dynein arms of the mutant organelles are able to generate shearing forces. Further observations which suggest that the central microtubules are necessary for bending movement have been made recently by Afzelius and Eliasson[16], who reported that spermatozoa from a man suffering from situs inversus lacked one of the central microtubules of the axoneme

Table 1 Results from a typical experiment to investigate motility of demembranated flagella of *Crithidia oncopelti*

	Microtubule configurations and associated outer dynein arms (D)* (%)									Sample size	
Incubation time (min)	9 + 2	D	9 + 1	D	9 + 0	D	A-cylinders	D	Motile cells (% + s.d.)	No. of EM sections	No. of cells observed in light microscope

* The values for the outer dynein arms are percentages of the total expected for that particular microtubule configuration.

and were immotile, and by Baccetti, Pallini, Mazzini and Ranieri (personal communication), who find that human sperm lacking both central microtubules are immotile.

The motile properties of the 9+1 axonemes of *Crithidia* reported here are not shared by axonemes with a similar structure from *Chlamydomonas* mutants, which are characterized by paralysis. A possible explanation for the different behaviour observed in the two cases is that features other than the central complex which are important for motility are affected in the mutant system. Changes in such features may be too subtle for detection by electron microscopy, as can be seen from the results presented here for axonemes at 1 and 4 h. The 9+1 cross-sections prepared from both samples appeared identical, but, when the number of other microtubule patterns are allowed for, it is clear that some of the 9+1 sections taken at 4 h are from non-motile flagella.

The data relating to microtubule arrangement presented in Table 1 can be interpreted in two ways: either (1) the percentages quoted represent the sample fraction in which each flagellum in its entirety has a particular structure, or (2) each flagellum in a sample contains a particular microtubule configuration for the appropriate percentage of its length. For example, at 1 h, interpretation (1) would have 15% of the sample with a 9+2 arrangement and 79.3% with a 9+1 arrangement, whereas according to interpretation (2), 15% and 79.3%, respectively, of each flagellum would have the 9+2 and 9+1 configurations. We have attempted to distinguish between the two alternative interpretations by electron microscopic studies of sections and of whole mounts, but our results are inconclusive. For example, serial sections taken over a portion of the axoneme 350–450 nm long (about 2% of the total axoneme length) were examined for 15 organelles with the 9+1 structure and all were found to have the same appearance.

Whichever of the two structural interpretations is correct, it is clear that coordinated waves can be propagated by an axoneme with a disrupted central complex, so that the conversion into bending moments of the shearing forces developed by the sliding peripheral microtubules is probably not achieved through interactions between the radial spokes and the central complex. This conversion could be accomplished if, as is thought to be the case, microtubules are associated with structures at the flagellar base which prevent their free relative sliding.

From a purely mechanical viewpoint, therefore, bend propagation could occur in the absence of any interaction between the peripheral and central microtubules. The interaction between these structures which seems to occur in the *in vivo* 9+2 flagellum may therefore be associated with the control of wave propagation (perhaps in determining the direction of bend propagation or the plane of bending in *Crithidia*) and not be involved directly in the mechanics of the conversion of sliding into bending.

If each axoneme contains a varying microtubule pattern (interpretation (2)), it seems reasonable to suppose that degradation of the axoneme occurs in an ordered manner, say from the flagellar tip, so that the axoneme shows progressive structural deficiency from base to tip. One possible interpretation of our results would then be that the full 9+2 complement of microtubules is required for bend initiation (as all bend propagation was from the base), but that bend propagation can be maintained by regions of the axoneme with 9+1 or, possibly, 9+0 microtubule arrangements. This situation could explain the difference in behaviour between *Crithidia* flagella and the *Chlamydomonas* or sperm mutants, which presumably have the 9+1 configuration along their entire length. On this interpretation, the results presented here suggest that a minimum length (between 4% and 15%) of the axoneme should contain the 9+2 arrangement of microtubles for successful bend initiation to occur.

S.M.-R. thanks the SRC for a CASE award with Unilever, where some of the electron microscopy described here was performed. This work was supported in part by a research grant awarded by the SRC to M.E.J.H.

Expression of a transposable antibiotic resistance element in *Saccharomyces*

Antonio Jimenez* & Julian Davies

Department of Biochemistry, College of Agricultural and Life Sciences,
University of Wisconsin-Madison, Madison, Wisconsin 53706

Some eukaryotic genes can be expressed in bacteria but there are few examples of the expression of prokaryotic genes in eukaryotes[1]. Antibiotic G418 is a 2-deoxystreptamine antibiotic that is structurally related to gentamicin[2] but has inhibitory activity against a much wider variety of pro- and eukaryotic organisms. In bacteria, resistance to G418 can be determined by several plasmid-encoded modifiying enzymes[3] and, in view of the broad spectrum of activity of G418, we considered that this antibiotic might be useful as a selective agent for the introduction of these antibiotic resistance genes into a eukaryotic organism such as *Saccharomyces cerevisiae*. Additional impetus for these experiments came from the knowledge that certain of the G418-resistance determinants in bacteria are carried on transposable elements[4]; a study of the properties of these elements in eukaryotes would be intriguing.

We have transformed *S. cerevisiae* spheroplasts[5] with a mixture of DNA of the yeast *leu*2 cloning vector pYE13 (ref. 6) and a colicin E1 derivative (pA043) carrying the transposable element Tn*601(903)*[4]. The latter encodes aminoglycoside phosphotransferase-3′(I) (APH(3′)-I) that phosphorylates and inactivates a number of aminoglycoside antibiotics containing the 2-deoxystreptamine moiety, at the 3′-hydroxyl position. We chose to use co-transformation with pYE13 and pA043 because selection of the leu$^+$ phenotype provided a control for efficiency of transformation, and in addition, we anticipated that subsequent recombination would lead to the formation of a hybrid plasmid. Following regeneration, prototrophic transformants were selected and screened for resistance to G418; the frequency of resistant transformants was about 8% of the leu$^+$ progeny. The G418-resistant colonies were capable of growth in the presence of $>1\ \mathrm{mg\ ml^{-1}}$ antibiotic. The untransformed parent, or strains transformed with the yeast vector pYE13 alone, were sensitive to low concentrations of G418 (Fig. 1). In separate experiments we have shown that *S. cerevisae* mutants resistant to low levels of G418 ($150\ \mu\mathrm{g\ ml^{-1}}$) appear spontaneously at low frequency ($<10^{-5}$) and that this frequency is drastically diminished ($<10^{-7}$) when one selects for higher resistance levels ($500\ \mu\mathrm{g\ ml^{-1}}$) of G418, as assayed by plating on media containing the antibiotic.

The presence of APH(3′)-I activity in these transformants would show that the G418 resistance was due to the expression

---

Table 1 Substrate specificity for the APH(3')I activity from G418-resistant yeast transformant

	c.p.m.	
Antibiotic tested	Yeast (JG13) extract	*E. coli* extract
Neomycin B	5,617 (100)	18,652 (100)
Lividomycin A	5,767 (102)	26,262 (140)
Butirosin	1,389 (25)	5,078 (27)
Tobramycin	353 (6)	30 (0)
G418	3,163 (56)	4,364 (23)

S. cerevisiae transformant JG13 was grown at 30 °C in 200 ml YEPD medium containing 200 μg ml^{-1} G418 to a density of 7×10^7 cells ml^{-1}. Cells were washed with water, resuspended in 0.7 ml 50 mM Tris-HCl, *p*H 7.6, 12.5 mM $MgCl_2$, 80 mM KCl, 1 mM dithiothreitol (DTT) buffer and disrupted by passing through a French pressure cell at 18,000 p.s.i. Cell extracts were centrifuged at 150,000 *g* for 2 h and the supernatant (0.5 ml) was passed through a Sephadex G-200 column (32 × 1.5 cm) using 10 mM Tris-HCl, *p*H 7.4, 10 mM $MgCl_2$, 1 mM DTT, 400 mM NaCl buffer. APH(3')-I activity eluted at a position corresponding to a protein of molecular weight ~60,000. *E. coli* KH802 carrying the plasmid pA043 was grown in 200 ml ML medium (1% tryptone, 1% NaCl, 0.5% yeast extract) to an A_{550} of 0.75. Cells were centrifuged, washed with saline, resuspended in 0.7 ml 10 mM Tris-HCl, *p*H 7.6, 1 mM $MgCl_2$, 0.15 mM EDTA and then disrupted as described above. The extract was centrifuged for 2.5 h at 150,000 *g* and the supernatant used as a source of APH(3')-I enzyme. APH(3')-I from the yeast transformant JG13 was assayed in 102-μl incubation mixtures containing, 14 mM Tris-HCl, *p*H 7.5, 32 mM NH_4Cl, 323 mM NaCl, 11.5 mM $MgCl_2$, 0.1 mM Na_2EDTA, 1 mM DTT, 0.06 mM [γ-^{32}P]ATP (Amersham, specific activity 10 Ci mol^{-1}), 80 μl of the peak fraction and 20 μg of the relevant aminoglycoside antibiotic. APH(3')-I from *E. coli* was assayed in 32-μl incubation mixtures containing 9 mM Tris-HCl, *p*H 7.1, 6 mM $MgCl_2$, 53 mM NH_4Cl, 0.2 mM DTT, 0.1 mM Na_2EDTA, 0.06 mM [γ-^{32}P]ATP, 60 μg ml^{-1} of the relevant antibiotic and 10 μl of *E. coli* KH802/pA043 extract. Reactions were incubated at 30 °C for 15 min and then 90- or 25-μl samples (for yeast or *E. coli* extracts, respectively) were spotted onto P-81 Whatman paper, washed with water and counted as described previously[7].

of the Tn*601(903)* gene. Accordingly, cell-free extracts from sensitive and resistant transformants were prepared and tested for their content of the enzyme using standard assay procedures[7]; the extracts were passed through Sephadex G200 before assay to remove ATPase activity that may limit the extent of aminoglycoside phosphorylation. Chromatography of extracts of G418-resistant transformants gave a peak of strong phosphotransferase activity. The substrate range of this enzyme activity corresponded to that of a typical APH(3')-I (Table 1). No such enzymatic activity could be detected in extracts of untransformed controls. Thus, we conclude that the phosphotransferase encoded on the element Tn*601(903)* can be introduced and expressed in yeast.

As confirmation of this we have established that G418-resistant transformants contain Tn*601(903)* sequences. Total cellular DNA was isolated from parental and transformed yeast strains, electrophoresed in an 0.7% agarose gel and transferred to nitrocellulose sheets according to the method of Southern[8]. The transferred DNA was hybridized to ^{32}P-labelled λ :: Tn*601* and pBR322 probe. As shown in Fig. 2*a*, the former probe, which has no homology with yeast, colicin E1, or pYE13 DNA, hybridizes specifically to DNA isolated from G418-resistant transformants.

Table 2 Stability of the G418-resistant phenotype in Tn*601* yeast transformants

	% No. of colonies			
Growth medium	YEPD	YEPD +G418	Minimal	Minimal +Leu
YEP	100 (340)	44 (150)	52 (176)	97 (330)
YEP + G418	100 (222)	70 (156)	73 (162)	96 (216)
Minimal	100 (316)	50 (158)	62 (196)	99 (312)
Minimal + leucine	100 (386)	61 (234)	67 (250)	108 (416)

Strain JG13 was grown for 10 generations in either YEPD or YEPD + 125 μg ml^{-1} G418 or for five generations in either minimal medium (0.76% Difco yeast nitrogen base w/o amino acids supplemented with 40 μg ml^{-1} histidine) or minimal supplemented with 40 μg ml^{-1} leucine. Serial dilutions of these cultures were plated onto selective media; numbers in parentheses represent total colonies scored on each medium.

The position of the sequences homologous to Tn*601* in the transformants is coincident with that of sequences hybridizing to pBR322 (Fig. 2*b*), which suggests that the transposable element Tn*601* is present in a hybrid pA043/pYE13 molecule. The intensity and the relative positions of hybridization of Tn*601* and pBR322 to DNA from JG13 and JG16 suggest that the putative chimaeras in the two transformants differ.

The G418 resistance of the yeast transformants is lost on growth in the absence of antibiotic (Table 2); this loss occurs at approximately the same frequency as loss of the leu^+ character encoded by pYE13, which suggests that *leu2* and Tn*601(903)* are associated. As confirmation of this, we have isolated recombinant pYE13/pA043 plasmid DNA from yeast transformants JG13 and JG16 and have used them for transformation of both *S. cerevisiae* and *Escherichia coli*, selecting either for leucine prototrophy or directly for resistance to G418. The plasmid DNAs from the two sources show differences in restriction digestion patterns, in agreement with the results of hybridization studies (A. J., unpublished observations).

The introduction of a bacterial resistance gene into yeast (as a transposable element) by direct selection of G418 resistance following transformation, raises some interesting possibilities for further study: (1) The control and expression of bacterial genes in eukaryotes; the use of the antibiotic modifying enzymes allows a simple assay for gene expression and could be used for the isolation of eukaryotic promoter sequences. (2) The expression and possible function of transposable elements: Tn5, for example, encodes aminoglycoside modification and several functions required for its own transposition[9]. It will be of interest to determine if these recombination capacities can operate in yeast and other eukaryotes. (3) G418 is an antibiotic with wide range inhibitory activity; it is a potent inhibitor of protein synthesis in cell-free extracts of bacterial, fungal, algae, plant and animal cells (S. Perzynski, unpublished). The combination of this antibiotic with any one of several bacterial resistance determinants should provide useful selection procedures for universal cloning vectors. Although, in principle, any of these

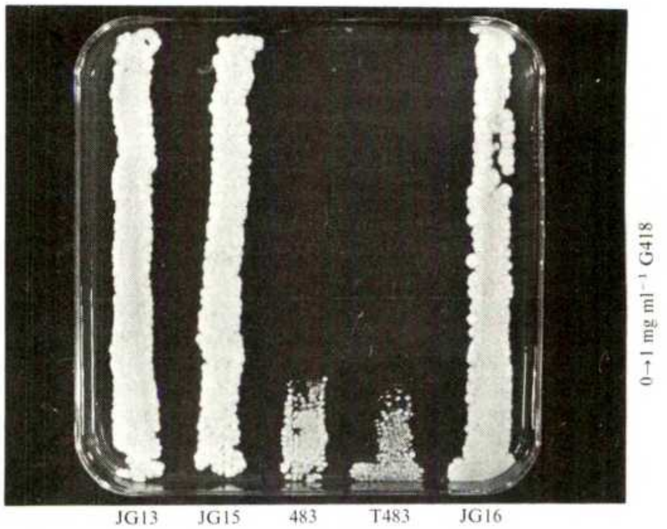

Fig. 1 Growth on G418 gradient plates of parental and transformed yeast strains. *S. cerevisiae* strain 483 (a, *leu2-3 leu2-112, his4, can1* was transformed as described by Hinnen *et al.*[5], using a mixture of 20 μg ml^{-1} each of pA043 (a Tn*601*-miniColE1 plasmid) and pYE13 (ref. 6) (a yeast-cloning vector containing the *leu2* gene), selecting for leucine prototrophy[5]. After 5 days incubation at 30 °C leu^+ transformants were streaked on YEPD plates containing 125 μg ml^{-1} G418 to screen for co-transformation of resistance to G418. About 8% of the leu^+ prototrophs were resistant to the drug. To examine levels of resistance, colonies were resuspended in YEPD medium at a density of 2×10^7 per ml and streaked onto an agar plate containing a gradient of antibiotic G418 from 0 to 1,000 μg ml^{-1}. JG13, JG15 and JG16 are G418-resistant co-transformants; T483 is the pYE13-transformed 483 strain and 483 is the *leu2-3* parental *S. cerevisiae* yeast strain used in the present work.

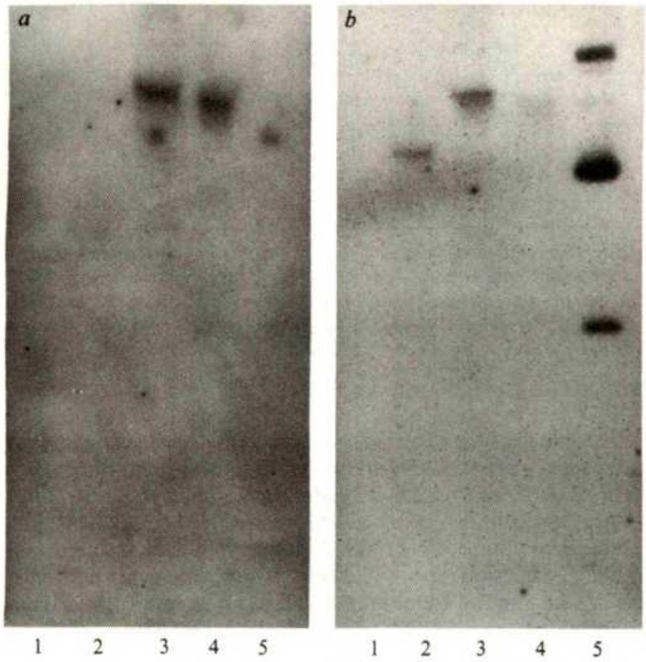

Fig. 2 Hybridization of total yeast DNA to ^{32}P-labelled (λ :: Tn*601* (*a*) and pBR322 (*b*) DNA probes. Yeast strains 483 (1) and T483 (2) were grown in YEPD medium and strains JGI3 (3) and JGI6 (4) were grown in YEPD medium containing 150 μg ml^{-1} G418. DNA was extracted from yeast spheroplasts, treated with α-amylase, pronase, pancreatic RNase and extracted with chloroform/isoamyl alcohol[10]. About 5 μg of each DNA sample was electrophoresed on two 0.7% agarose gels; well number 5 contained 0.2 μg pYE13 DNA. DNA was transferred from the gels to nitrocellulose paper by the blotting procedure of Southern[8] and was hybridized to ^{32}P-labelled λ ::Tn*601* (*a*) and pBR322 (*b*) DNA (provided by S. Stibitz). The filters were exposed to Kodak X-ray film for a suitable period of time, developed and scanned.

determinants could be used, we have found that, in yeast, the phosphotransferase of Tn*601(903)* is most effective. This may reflect some regulatory sequence peculiar to this gene. The resistance genes can be added to the appropriate plasmid or viral vector by transposition or by cloning (detailed restriction endonuclease maps are known for several of the G418-resistance determinants). For example, this could allow the cloning of replication origins by linkage to the resistance determinant.

The use of G418 for cloning vector selection should eliminate the necessity for special conditions (aerobic or anaerobic growth) or specially constructed recipients for transformation (auxotrophs); thus, this antibiotic resistance should be valuable in the genetic manipulation of industrial yeast strains. A wide variety of yeast species and genera are sensitive to G418 (unpublished observations).

We thank Dr Peter Daniels (Schering Corporation) for gifts of antibiotic G418 and many related compounds, and Gary Gray, Stephen Harford and Scott Stibitz for their help and advice. Dr Takeshi Oka provided an *E. coli* strain carrying pA043 and Dr J. Hicks provided both a source of the yeast vector pYE13 and the yeast strain 483. This work was supported by grants from the NIH (AI 12448) and the Comite Conjunto Hispano Norteamericano para la Cooperacion Cientifica y Tecnologica.

Note added in proof: Following submission of this manuscript, we were informed by C. P. Hollenberg (personal communication) that he had transformed *S. cerevisae* with a kanamycin resistance plasmid and had obtained kanamycin-resistant colonies.

Chelation of cadmium with BAL and DTPA in rats

M. George Cherian

Department of Pathology, Health Sciences Centre, University of Western Ontario, London, Ontario, Canada N6A 5C1

Cadmium is unique among non-essential metals in several of its toxicological effects because of its long biological half life, slow excretion and delayed action on the kidneys[1]. Although cadmium poisoning in humans is uncommon, there are reports of chronic cadmium poisoning in workmen[2–4] and also in others in certain polluted areas[5,6]. At present there are no suitable methods either to measure the body burden of cadmium or to treat cadmium poisoning[7]. The therapeutic effects of various chelating agents including 2,3-dimercaptopropanol (BAL) and its soluble glycosides have been studied without much success in acute cadmium intoxication[8–11]. However, those studies were done before anything was known of the specific binding of cadmium to metallothionein, an intracellular low molecular weight protein[12]. The potential role of this protein in the detoxification and toxicity of metals has been reviewed recently[13,14]. The induced synthesis of metallothionein has a marked effect on the pharmacokinetics of cadmium and other divalent metals[15,16]. Thus it is important to consider the intracellular binding of cadmium with metallothionein in developing a suitable chelation therapy for chronic exposure to cadmium[17]. The *in vivo* chelation of cadmium with BAL or BAL and diethylenetriamine pentaacetic acid (DTPA) from rats exposed to cadmium is reported here.

A group of male rats (150 g) was injected intraperitoneally (i.p.) with ^{109}CdCl$_2$ (1 mg Cd; 5 μCi) and kept in separate metabolic cages. Three days later they were divided into three groups and treated i.p. as follows for 5 d per week for 2 weeks: group 1 (11 rats) with BAL (50 mg per kg); group 2 (5 rats) with 50 mg each of BAL and DTPA, and group 3 (9 rats, control)

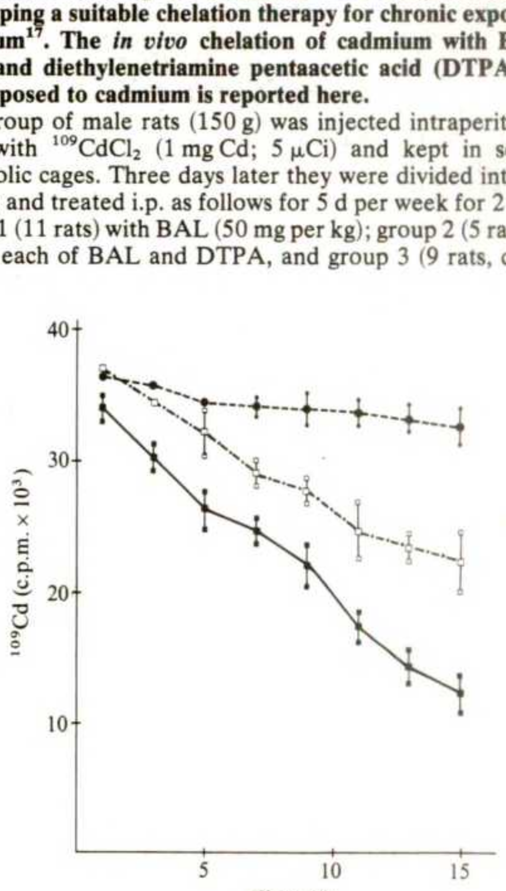

Fig. 1 Total body burden of cadmium. Rats were injected with ^{109}CdCl$_2$ (1 mg per kg; 5 μCi) and 3 d later were treated i.p. with BAL (group 1, □) or BAL and DTPA (group 2, ■) or saline (group 3, control, ●) for 2 weeks. The body burden of cadmium was determined from the whole body counting.

with normal saline. Urine and faecal samples were collected from each rat daily and the total excretion of cadmium was calculated from radioactivity. All rats were examined for ^{109}Cd radioactivity in a whole body counter[18] before and during the experiment.

Injections of BAL, both alone and in combination with DTPA, decreased the total body burden of cadmium in cadmium-exposed rats (Fig. 1), which retained only 57% and 40% of initial radioactivity, respectively. The control group on the other hand, retained about 92% of the cadmium. Thus the chelating agents effectively removed cadmium from the body when treatment started 3 days after injection of cadmium. In our previous *in situ* studies[17], BAL was the only chelating agent able to remove cadmium through the bile after the metal was bound to metallotheionein. Compounds such as 1,3-dimercaptopropanol and dimercaptosulphonic acid, which are structurally similar to BAL, had no effect. Therefore structural features, such as adjacent sulphydryl groups and lipophilic properties of chelating agents, are important for the chelation of cadmium from metallothionein *in vivo*.

Analysis of excreta for radioactive cadmium showed (Fig. 2) that the major route of excretion of cadmium after injection of chelating agents was in the faeces. The control group (group 3) excreted about 6% and 0.06% of the administered dose in faeces and urine, respectively, during the experimental 2 weeks. The group injected with BAL (group 1) excreted 28% in faeces and 1.4% in urine, while the group injected with a combination of BAL and DTPA (group 2) excreted 34% in faeces and 4.5% in urine. These results also suggested that the cadmium excreted through the bile after injection of BAL is not reabsorbed from the gut and is excreted in the faeces. Injection of DTPA with BAL increased both faecal and urinary excretion of cadmium.

The amount of cadmium in both liver and kidneys was significantly reduced after treatment with BAL or BAL and DTPA when compared with untreated rats (Table 1). The effect of BAL was more marked in the liver than in the kidneys. However, the mobilization of cadmium from the liver by BAL or BAL and DTPA together did not result in increased renal accumulation of the metal. In previous studies[8–11,17], when BAL was injected into animals before all the cadmium was bound to metallothionein, a major portion of cadmium associated with other bioligands was mobilized to the kidneys, increasing their content of cadmium. Thus the presence of metallothionein in the tissue may be an important factor in the effective therapeutic chelation of cadmium.

Our results provide the first evidence that BAL can be used successfully in proper conditions and at appropriate doses to mobilize cadmium from the liver without affecting its deposition in the kidneys, the critical organs in chronic cadmium toxicity. In reports from other laboratories[19,20] of chelation therapy for cadmium poisoning, chelating agents were administered within a short time of exposure to cadmium and the effect was measured by the rate survival of the animals. Those studies did not involve measurement of cadmium, and it was not clear whether the administered cadmium was either chelated or excreted from the body. One such study was later found to be invalid[21,22] and retracted[23]. Moreover, those studies do not have any relevance to the treatment of chronic poisoning. Our study reveals the potential use of BAL or BAL and DTPA together as a means of chelation of cadmium to remove it from the body without affecting the kidneys.

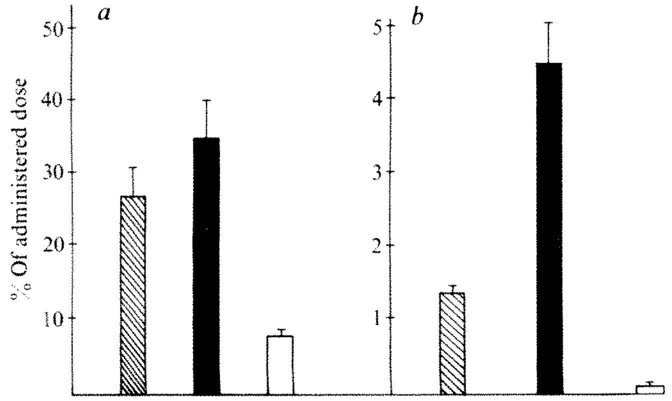

Fig. 2 Cumulative faecal (*a*) and urinary (*b*) excretion of cadmium in rats injected with $CdCl_2$ and treated with BAL (group 1, hatched columns) or BAL and DTPA (group 2, solid columns) or saline (group 3, open columns). Results are expressed as mean ± s.d.

Table 1 Tissue content of cadmium in rats injected with $CdCl_2$ and treated with saline or BAL and DTPA

Group	Concentration of Cd (μg mean ± s.d.)	
	Liver	Kidney
1	$2.95 \pm 0.4^*$	3.85 ± 0.3
2	$1.55 \pm 0.5^*$	$2.10 \pm 0.1^*$
3	9.30 ± 0.4	5.15 ± 0.6

All rats were injected with $^{109}CdCl_2$ (1 mg per kg; 5 μCi). Three days later they were injected i.p. with BAL (50 mg per kg, group 1) or BAL and DTPA (50 mg per kg, group 2) or saline (group 3) for 2 weeks. Rats were killed 2 d after the last injection and tissue concentration of cadmium was determined from radioactivity.

Errata

In the article 'A low resolution structure for the histone core of the nucleosome' by A. Klug, D. Rhodes, J. Smith, J. T. Finch and J. O. Thomas, *Nature* **287,** 509–516, the third line of the equation displayed on the right-hand column of p. 514 should read

$$(H3)_2(H4)_2 + 2 \times H2A\ H2B$$

Also, in the same article, line 2 of the legend to Figure 7 should read 110° in place of 115° and 90° in place of 95°.

BOOK REVIEWS

The point of acupuncture

Patrick D. Wall

Celestial Lancets: A History and Rationale of Acupuncture and Moxa. By Lui Gwei-Djen and Joseph Needham. Pp.427. (Cambridge University Press: 1980.) £45, $97.50.

THIS extraordinary book is a syncopated side step in the long march of Joseph Needham's writing of *Science and Civilisation in China.* He has completed five of the seven volumes planned, but so widespread is the current interest in acupuncture that this book is issued as a footnote to the next volume on the life sciences. I think it is also related to the final volume on the social background because one of the crucial questions for me is why it is that acupuncture has so suddenly emerged into the Western daylight. As this book shows, it has been practised for 2,500 years in China and it is no fresh news to the West. Extensive accounts were published in Europe by de Bondt in 1658, Cleyer in 1682 and ten Rhijne in 1683, and we can enjoy here the beautiful illustrations of their books. These early reporters who took part in the Dutch drive to the East were as enthusiastic as those *Time* magazine journalists who went with Nixon on his expedition to China: "The results with acupuncture in Japan which I will relate surpass even miracles", wrote de Bondt.

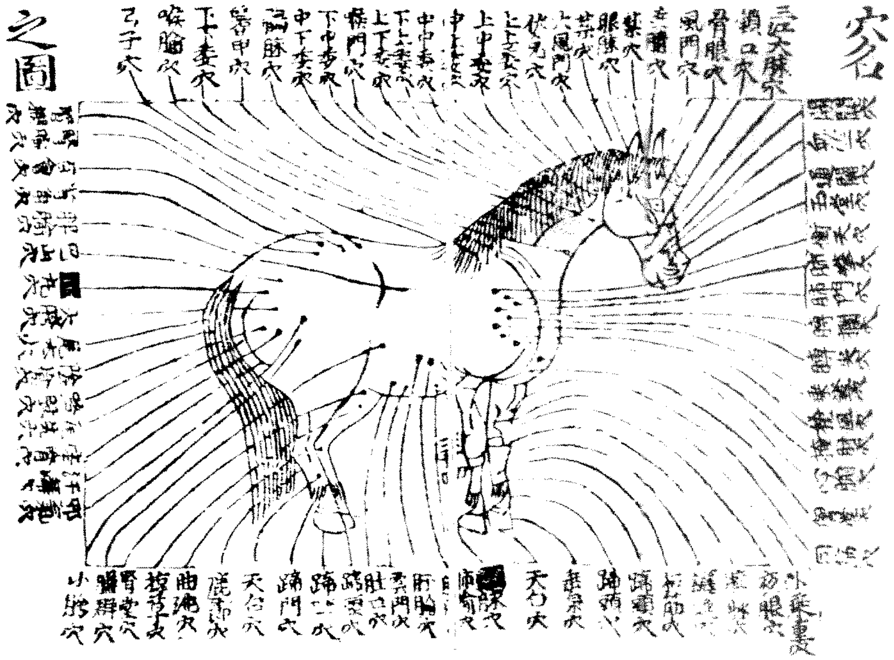
This raises a double question: why has acupuncture suddenly reappeared in the West, and how could it be that the West forgot for 300 years that all sorts of awful diseases could be abolished by simply sticking needles into the skin?

I believe there are three answers to the first question. The Chinese themselves swung away from their own traditional medicine in the last century and attempted with hopelessly inadequate numbers of doctors to introduce Western medicine. After the liberation of 1948, faced with the atrocious state of the medical services, all available resources were mobilized and traditional and Western practitioners were brought together. For the first time, surgeons and acupuncturists cooperated and the startling practice of major surgery under acupuncture emerged. Second, the Western media, searching for something good to say about China, latched on to the "miracle" since they could hardly praise communism. Third, there are many in the West, disillusioned with our ways of thought, and with science in general and medicine in particular, who were delighted to accept that the pompous and ponderous academic establishment had been missing the point.

This book is divided into three parts. It starts by detailing the practice of acupuncture in the various schools with their historical developments and rationales. It is not intended as a clinical textbook but relates very clearly what is done and what were the ways of thinking about the body and disease. It also describes the less well-known treatment of moxa where the dried herb *Artemisia* is burned at the same points used for needling. This practice is also old and is widespread in many cultures, especially in the Arab and African worlds where localized cautery is used for the treatment of a wide variety of conditions from deafness to diarrhoea. The second part deals with physiological interpretations where an attempt is made to bring the old practices and explanations into an understandable framework in terms of modern physiology. Lastly, there is a section on the influences of other cultures which again emphasizes that the genius of China was never held in isolation for long periods. It dominated Korea, Vietnam and Japan, merged with Russian thought over a huge area and influenced the successive waves of Western colonization.

Turning now to my second question of why acupuncture so strangely appears and disappears in the West, one must obviously ask first if it works. On this question, this enormously scholarly and careful book is curiously silent. Statistics are given for surgical anaesthesia which are impressive and coincide approximately with the observations of many Western teams of specialist observers. What is not mentioned is that these figures are taken from a highly selected group of patients and that many of these had been given powerful additional medication.

We are faced here with a real but rare phenomenon not to be explained by the simple action of physiological mechanisms which we all possess in common. A fairly frequent pain complaint associated with tenderpoints in muscles, the myofascial syndrome, does seem to respond to needling of these spots, and it is interesting that a number of the acupuncture points for pain coincide with the common sites of



Veterinary acupuncture: points on the body of the horse. A drawing from the *Ma Niu I Fang* of + 1399.

these tender points. For other types of pain, the results of only two clinical trials have been published and they are both negative. Other disease treatments have not been subject to anything but a creeping barrage of anecdote.

Before attempting an explanation, we badly need clear statements of what it is we have to explain. Acupuncture is liable to disappear from sight once more, under a heap of dissatisfied patients and impatient doctors: I hope we will not have to await its next rennaissance before it is put to properly conducted trials which specify where and when it is effective. I hope this book with its careful description of "what" and "why" will encourage others to carry out those tests. ☐

Patrick D. Wall is Professor of Anatomy at University College, London, and co-author of the gate control theory of pain which is used widely in this book as an "explanation" of acupuncture.

The fundamentals of chemical kinetics

C. F. Wells

Basic Chemical Kinetics. By H. Eyring, S.H. Lin and S.M. Lin. Pp.504. (Wiley-Interscience: 1980.) £19.15, $43.75.

I AM usually somewhat wary when I pick up a book with the word "basic" in the title, as I expect to find a highly simplified examination of the subject often without any pretence of rigour. This is very far from the case here, where "rigorous—fundamental" should be read for "basic".

After a brief introduction to rate equations and their integration, the authors devote their next chapter to potential energy surfaces. The dynamics of collisional processes are then considered, both from classical and quantum mechanical points of view. This is followed by a treatment of transition state theory, a theory to which Eyring has contributed so much, and of the theories of unimolecular reactions in the gas phase and their application to some experimental data. After a similar discussion of bimolecular reactions in the gas phase, the authors concentrate on photochemical reactions in condensed phases as well as in the gas phase. In the final chapter selected topics concerning kinetics in condensed phases are discussed. Four appendices complete the book: three devoted to an elaboration of mathematical treatments used earlier in the book, the fourth containing 79 problems covering aspects raised in all the chapters.

In one sense, this book is an extension and up-dating of the classic text, *The Theory of Rate Processes,* written by Eyring in collaboration with S. Glasstone and K. J. Laidler, and first published in 1941 by McGraw-Hill. This new book, too, should be of interest to all (particularly final-year undergraduates and research students) involved with the fundamentals of chemical kinetics. It will be invaluable to gas kineticists and to those concerned with photochemical kinetics, but perhaps has less direct application to the problems currently engaging solution kineticists. Chemists without an adequate mathematical background may find it hard going, and in this respect there are instances of undue compression of the text; for example l'Hôpital's Rule is referred to several times in Chapter 1 and is used in a problem in Appendix 4, yet nowhere is the Rule stated or defined.

Despite this reservation, the book is thoroughly recommended to all interested in the fundamentals of kinetic processes; it may well achieve "classic" status again for Eyring. ☐

C. F. Wells is Reader in Inorganic Chemistry at the University of Birmingham, and is especially concerned with the kinetics of inorganic reactions in solution.

The sinister phenomenon

Freda Newcombe

Neuropsychology of Left-handedness. Perspectives in Neurolinguistics and Psycholinguistics. Edited by J. Herron. Pp.357. (Academic: 1980.) $24.50, £13.80.

DEPARTURE from the usual pattern of right-handedness has often provoked annoyance, if not frank hostility, in the layman and has not inspired much in the way of scientific research until quite recently. There were occasional bursts of interest, ranging from a brief and hesitant question in a nineteenth-century anthrological journal ("is my parrot left-handed?") to the more unequivocal pronouncement of the venerable Dr Henschen on sighting the asymmetrical skull of a gorilla in University College Museum: "this gorilla was probably left-handed".

But these flashes in the dark, with their interesting implications of paw preference and morphological correlates, were not followed up by phenomenological studies or biological speculations until clinicians started to record anomalies of brain organization: speech disturbances due to damage to the *right* hemisphere of the brain, sometimes in left-handed patients. The work of Chesher, Penfield and Roberts, Subirana, and Luria developed the theme that the link between brain organization and handedness is less predictable in the non-right-handed members of the population: whereas some 98% of right-handed persons have speech functions represented in the left hemisphere, the proportion of left-handed people exhibiting this pattern is in the region of 60–66%. The remainder show the reverse pattern except for a very small minority that show bilateral representation. It is also suggested that a tendency to bilateral speech representation in the left-handed might be advantageous, in that the prognosis for recovery of speech after CNS damage may be better than that for the right-handed patient.

Despite this knowledge — provided both by neurological patients and by very large populations of ex-servicemen with focal brain-wounds — received wisdom and cultural prejudice are hard to eliminate. There are still members of the medical and teaching professions who believe that the functional organization of the brain of all left-handed people is the mirror image of that of the right-handed. Left-handedness, mixed handedness and 'crossed lateralization' have also become popular 'explanations' of such developmental disorders as dyslexia, stuttering and delayed language acquisition. Small-scale studies, based on biased clinical samples, appeared to buttress this notion until the more comprehensive investigations of Rutter, Tizard and Whitmore (*Education, Health and Behaviour.* Longman: 1970), and of Margaret Clark (*Reading Difficulties in School.* Penguin: 1970) cast doubt on its validity. It was clearly time to question the flimsy evidence available and to collect some hard data. Many neuropsychological studies in the past two decades have addressed this issue and most of them are at least referenced in this interesting book.

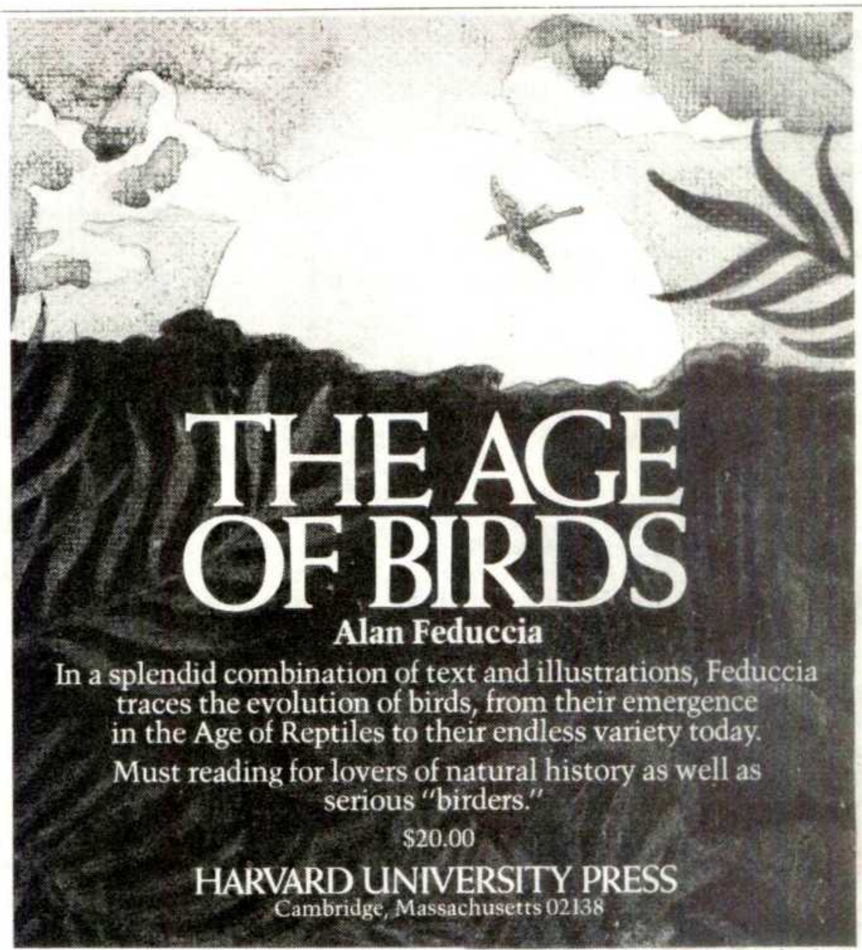
The chapters cover a wide range — historical, embryological and genetic, and experimental. Harris has a delightful contribution on the topic of early theories, facts and fancies; he has done the reader signal service in distilling the essence of an early literature that few of us have the time or energy to cultivate. Studies of neuroanatomical asymmetry are concisely reviewed by Witelson. There is an incisive critique of genetic models by Corballis, who accepts that of Annett as the most plausible; his conclusion that there is no convincing evidence to suggest that variations from the pattern of right-handedness and left cerebral control of speech "are due to anything other than environmental causes" is less compelling.

There are other contributions that illustrate the two strategies that determine much applied research in this area: the data-driven approach and the model-inspired design. The former has produced a quantity of perplexing material but at least illustrates a complex background to interpretation that must take into account both sex differences and developmental changes in hemispheric organization; studies by Herron, Kinsbourne and Kocel are apposite. Model-making is serving its heuristic purpose. Satz's theory of pathological left-handedness and Levy's biological and genetic speculations cannot be lightly dismissed although their empirical consequences lack — as yet — the support of consistent replication and large-scale studies. The search for a definitive genetic model must continue; and chapters by Boklage and by Springer and Searleman on embryological factors provide an important stimulus in this direction.

We continue to be handicapped by the impure quality of the data. 'Familial sinistrality' is probably an important variable but it is seldom defined in a way that permits the formulation of a rigorous genetic theory. Sample sizes are often inadequate and the criteria of handedness vary from study to study. For example, 'sighting' has been used as an index in this book despite Annett's evidence that one third of a large, right-handed 'normal' sample used the left eye for sighting.

This book does a service in fairly representing current work and thinking in the field. It reminds us that the programming of handedness may be sought in the embryo, that non-right handers are not a homogenous group, and that patterns of hand preference must be studied in the light of developmental change and gender differences. It provides a good source of reference material and it contains a reasonable supply of ideas for future research. It is not a definitive work but it is compulsory reading for neuroscientists with either theoretical or practical commitments in this field. □

Freda Newcombe is in the Neuropsychology Unit of the Department of Clinical Neurology, Radcliffe Infirmary, Oxford.



THE AGE OF BIRDS
Alan Feduccia
In a splendid combination of text and illustrations, Feduccia traces the evolution of birds, from their emergence in the Age of Reptiles to their endless variety today.
Must reading for lovers of natural history as well as serious "birders."

The inner alarm clock

Arthur T. Winfree

The Timing of Sleep and Wakefulness: On the Substructure and Dynamics of the Circadian Pacemakers Underlying the Wake–Sleep Cycle. Studies of Brain Function, Vol.3. By J.T. Enright. Pp.263. (Springer-Verlag: 1980.) Flexi DM49, $29.

THERE is a growing conviction among "clocks" physiologists that circadian behavioural rhythms in animals are generated in the central nervous system. It is also widely believed that in most organisms many different tissues independently determine circadian fluctuations of their individual function, and that the mechanisms may reside even in single cells. Add to this the astonishingly precise timing of some circadian rhythms, in the order of 3 minutes in a 23½-hour cycle for example, and you have arrived at J.T. Enright's stepping-off point for this monograph — the idea that thousands of nerve cells function as separate circadian "pacers" whose collective rhythmicity disciplines each one to enhanced regularity.

This is an old idea, going back at least to the first big "clocks" symposium at Cold

Spring Harbor in 1960. By 1970 the theoretical literature contained elaborate electronic mockups, computer simulations and mathematical analyses of such ensembles of mutually synchronizing, non-linear oscillators. What Enright ably brings to the discussion in 1980 is a detailed computer simulation, complete with noise statistics, built along lines suggested by his concept of pacemaker neurones. His "coupled stochastic systems" model, nicely summarized in Chapter 16, is distinguished from its forerunners by a curious feature: only the longer-period pacers actually synchronize; the others go their merry ways but in so doing provide a pool of potentially entrainable pacers whose contributions become important when the ensemble is exposed to stimuli that affect phases and periods. From this unique feature many of the observed peculiarities of vertebrate circadian rhythms seem to follow, but the extent to which they do so depends on a variety of adjustable quantities in the model. Enright is well aware of the implications of this:

> The weary reader may . . . begin to suspect that the model system under consideration shows embryonic symptoms of developing into an amorphous monster: one which can, like an amoeba, engulf and account for any set of data by modification of one parameter or another, but which thereby merely demonstrates its lack of backbone. Can any model with so many parameters lay legitimate claim to being a simple model?

He further argues that explanations that are simple in the sense of elementary physics simply would not be plausible in context of "the workshop of natural selection", which seems more likely to "assemble a reliable pacemaker out of components which are sloppy".

The reader will undoubtedly wonder whether sleep and wakefulness are really the same as rest and activity; whether circadian clocks really do function like pacemaker neurones, but a million times slower; and whether single cells do serve as independent clocks. But Enright's scepticism of his own model leaves little room for innovation by additional critics. Chapters 13 and 14 offer precise predictions for the outcome of feasible experiments which, if not fulfilled, will demand rejection or radical revision of the model. This detailed repartee between observation and interpretation is an edifying grace of Enright's monograph. In it we were treated to a thorough exposition of the present generalizations arising out of circadian physiology; and to a detailed exploration of the consequences of Enright's particular hypothesis.

What then is the upshot? Enright's model, based on observation of rest/activity cycles in birds and rodents, accounts for many of their peculiarities without having to resort to too many out-and-out *ad hoc* suppositions. It gives a reasonable vision of the kinds of mutual interaction among the pacers that would enhance their precision to the levels sometimes observed.

However, I suspect that much of the fitting to phase-resetting data and period-changing data could be managed with equal elegance by rather different models; there exists at present little of a factual nature to distinguish alternative visions of the internal organization of the central nervous system clock. Yet here we encounter what, from my present viewpoint among models of human circadian rhythms, seems a primary value of Enright's contribution. Research on sleep/wake rhythms is now in the midst of an explosive blossoming of discovery. Enright's model correlates definite facts and makes distinct critical predictions. This is just what we need, alongside the alternative visions of Wever, Kronauer and others, to catalyse the asking of sharp experimental questions.

Like almost all models in the behavioural sciences, Enright's is partly a fairy tale — in this case, a pleasing one, done with a sense of humour, but not frivolously. He remarks on p.249 that ". . . there is not the least doubt in my mind that the models as formulated will prove to be wrong; wrong because they are oversimplified; wrong because they have ignored one critical process or another; and wrong because some elements of the models arise from mistaken points of departure". But as Francis Bacon remarks in his *Novum Organum*, "truth will sooner come from error than from confusion". In my view, debate over Enright's facts and interpretations could take us a long way toward understanding one of the most conspicuous facts of human experience, the rhythm of sleep and wakefulness. ☐

Arthur T. Winfree is Professor of Biology at Purdue University, West Lafayette, Indiana.

With reference to variable stars

R. J. Tayler

Theory of Stellar Pulsation. By J. P. Cox. Pp. 380. (Princeton University Press: 1980.) Hardback £21.90, $50; paperback £7.50, $17.

FOR some time there has been a need for a new book on the theory of variable stars to consider the considerable developments in the subject that have taken place since the publication of Rosseland's *The Pulsation Theory of Variable Stars* (Oxford University Press, 1949). Now there are two new books: *Nonradial Oscillations of Stars* (Tokyo University, 1979) by Unno, Osaki, Ando and Shibahashi, which does not discuss the more widely studied and better understood radial oscillations, and the present book which covers the whole subject. J. P. Cox has written many review articles on variable stars and this, the book which has grown out of them, provides a thorough survey both of the foundations of the subject and of recent developments.

In 1949 it was clear that many intrinsic variable stars were pulsating radially, but important questions remained relating to the physical cause of the instability exciting the oscillation, to the observed phase relationships between light and velocity variations, to the processes limiting the instability to finite amplitude and to the evolutionary status of variable stars. The answers to all except the third of these questions are now reasonably clear. However, there is still considerable difficulty in deciding whether a star with a deep convective envelope will pulsate, because there is no good description of time-dependent convection, and there are arguments about whether the stellar masses required to give the correct pulsations agree with those implied by stellar evolution theory. Although there are clues to what produces the finite amplitude limitation of the instability, it is difficult to study the full non-linear problem without crude approximation. The study of non-radial oscillation is much more difficult than that of radial pulsation, but it is clear that non-radial oscillations are present in some stars and, indeed, convection is a non-radial oscillation of very high order. The study of non-radial oscillations has recently been stimulated by observations of small fluctuations in the properties of the Sun.

Cox gives a clear and detailed account of the subject, and this book is a very welcome addition to the literature. If I have any major criticism, it is that it is perhaps too detailed to be used as a textbook; for that purpose I would have omitted some references to topics which could not be discussed in detail. It will, however, be invaluable as a reference book. In particular, it contains a list of relevant papers which is more than 30 pages long. ☐

R. J. Tayler is Professor of Astronomy at the University of Sussex, author of three elementary astronomy textbooks and Managing Editor of Monthly Notices of the Royal Astronomical Society.

The British Museum (Natural History), in collaboration with John Wiley, have just published *Animal Identification: A Reference Guide* in three volumes. Each volume provides a listing of primary reference sources — Vol. 1 to marine and brackish water animals, Vol. 2 to land and freshwater animals (excluding insects), and Vol. 3 to insects — to assist non-specialists in identifying any animal. The three-volume set costs £31.

PETERSON, R.T. A Field Guide to the Birds East of the Rockies. 4th edn. Pp.384. Flexi ISBN 0-395-26619-X. (Houghton Mifflin: 1980.) $9.95.

ROSS, B. and GUDER, W.G. (guest eds). Biochemical Aspects of Renal Function. Proceedings of a Symposium held at Merton College, Oxford, September 1979. Pp.324. Flexi ISBN 0-08-025517-5. *(Pergamon: 1980.)* $55.

RUSSELL, P.J. Lecture Notes on Genetics. Pp.258. Flexi ISBN 0-632-00609-9. (Blackwell Scientific: 1980.) £6.80.

BARNES, R. K. and MANN, K. H. (eds). Fundamentals of Aquatic Ecosystems. Pp.229. Flexi ISBN 0-632-00014-7. (Blackwell Scientific: 1980.) £7.80.

BLOOM, F. E. (ed.). Peptides: Integrators of Cell and Tissue Function. Society of General Physiologists Series, Vol. 35. Pp.271. ISBN [illegible]-89004. (Raven: 1980.) $23.

BLOOMFIELD, J. A. (ed.). Lakes of New York State. Vol. III. Ecology of the Lakes of East-Central New York. Pp.[illegible]6. ISBN 0-12-10[illegible]5-3. (Academic: 1980.) $29.50.

BOURNE, G. H. and DANIELLI, J. F. (eds). International Review of Cytology, Vol. 66. Pp.374. ISBN 0-12-364466-6. (Academic: 1980.) $39.

BRICKELL, C. D., CUTLER, D. F. and GREGORY, M. (eds). Petaloid Monocotyledons. Horticultural and Botanical Research. Linnean Society Symposium Series No. 8. Pp.222. ISBN 9-12-133950-5. (Academic: 1980.) £26.80, $62.

DAVIES, D. D. (ed.). The Biochemistry of Plants: A Comprehensive Treatise. Vol. 2, Metabolism and Respiration. Pp.687. ISBN 0-12-675402-0. (Academic: 1980.) $65.

DE VICENTE, R. (ed.). Replies from Biological Research. Proceedings of the Symposium on Biology and Ethics. Pp.418. Flexi ISBN 84-00-04525-4. (Consejo Superior de Investigaciones Cientificas: Madrid, 1979.) Np.

DI BENEDETTA, C., BÁLAZS, R., GOMBOS, G. and PORCELLATI, G. (eds). Mulidisciplinary Approach to Brain Development. Proceedings of the International Meeting held in Selva di Fasano, Italy, April 1979. Developments in Neuroscience, Vol. 9. Pp.585. ISBN 0-444-80227-4. (Elsevier/North-Holland Biomedical: 1980.) $85, Dfl. 174.

DUMONT, H. G. and GREEN, J. (eds). Roataoria. Proceedings of the 2nd International Rotifer Symposium held at Gent, September 1979. Developments in Hydrobiology, 1. Pp.263. ISBN 906193754. (W. Junk: 1980.) Np.

DUNITZ, J. D. *et al.* (eds). Molecular Structure and Sensory Physiology. Structure and Bonding, Vol. 41. Pp.146. ISBN 3-540-09958-1. (Springer-Verlag: 1980.) DM 69, $40.80.

KIMBALL, F. A. (ed.). The Endometrium, Proceedings of the 8th Brook Lodge Workshop on Problems in Reproductive Physiology. Pp.350. ISBN 0-85200-525-3. (MTP Press: Lancaster, UK, 1980.) £15.95.

KITNEY, R. I. and ROMPELMAN, O. (eds). The Study of Heart-rate Variability. Pp.246. ISBN 0-19-857533-5. (Clarendon/Oxford University Press, 1980.) £25.

KLIEGEL, W. Bor in Biologie, Medizin und Pharmazie. Physiologische Wirkungen und Pharmazie. Pp.900. ISBN 3-540-93411-1. (Springer-Verlag: 1980.) DM 285, $168.20.

LAWRENCE, T. L. J. Growth in Animals. Pp.308. ISBN 0-408-10638-7. (Butterworths: 1980.) £20.

LURIA, A. R. Higher Cortical Functions in Man. 2nd Edn. (Basic Books: 1980.) $27.50.

MEZZICH, J. E. and SOLOMON, H. Taxonomy and Behavioral Science: Comparative Performance of Grouping Methods. Pp.178. ISBN 0-12-493340-8. (Academic: 1980.) $25, £10.80.

NAGORSEN, D. W. and PETERSON, R. L. Mammal Collectors' Manual. A Guide for Collecting, Documenting, and Preparing Mammal Specimens for Scientific Research. Pp.79. Flexi ISBN 0-88854-255-0. (Royal Ontario Museum: Toronto, Canada, 1980.) $6.50.

PFURTSCHELLER, G. *et al.* (eds). Rhythmic EEG Activities and Cortical Functioning. Developments in Neuroscience, Vol. 10. Proceedings of the International Symposium held in Schladming, Austria, September 1979. Pp.314. ISBN 0-444-80247-9. (Elsevier/North-Holland biomedical: 1980.) $48.75. Dfl. 100.

STEYN, P.S. (ed.). The Biosynthesis of Mycotoxins: A Study in Secondary Metabolism. Pp.432. ISBN 0-12-670650-6. (Academic: 1980.) $44.

STODDART, D.M. (ed.). Olfaction in Mammals. Symposia of the Zoological Society of London, No.45. Pp.364. ISBN 0-12-613345-X. (Academic: 1980.) £27.40 (UK only), $63.50.

TESTA, F. Leaves. Pp.28. ISBN 0-905478-74-6. (Andersen Press: London, 1980.) £3.50.

THOMAS, G., PODESTA, E.J. and GORDON, J. (eds). Protein Phosphorylation and Bio-Regulation. Friedrich-Miescher Institut and EMBO Workshop, Basel, December 1979. Pp.232. ISBN 3-8055-1168-X. (Karger: 1980.) SwFr.82. DM 98, $49.25.

WEINSTEIN, L. and FIELDS, B.N. (eds). Seminars in Infectious Disease, Vol.III. Pp.323. ISBN 0-913258-69-5. (Thieme-Stratton: New York, 1980.) $32.50.

Applied Biological Sciences

BASTENIE, P.A., BONNYNS, M. and VANHAELST, L. Recent Progress in Diagnosis and Treatment of Hypothyroid Conditions. Proceedings of the XVth International Congress of Therapeutics, Brussels, September 1979. Pp.155. ISBN 90-219-0448-9. (Excerpta Medica: 1980.) Np.

BOURNE, G.H., DANIELLI, J.F. and JEON, K.W. (eds). International Review of Cytology, Supplement 11A. Perspectives in Plant Cell and Tissue Culture. Pp.253. ISBN 0-12-364371-6. (Academic: 1980) Np.

BOURNE, G.H., DANIELLI, J.F. and JEON, K.W. (eds). International Review of Cytology, Supplement 11B. Perspectives in Plant Cell and Tissue Culture. Pp.257. ISBN 0-12-364372-4. (Academic: 1980.) $29.50.

CANTOR, C.R. and SCHIMMEL, P.R. Biophysical Chemistry, Part III. The Behaviour of Biological Macromolecules. Pp.524. Hbk ISBN 0-7167-1191-5; pbk ISBN 0-7167-1192-3. (W.H. Freeman: 1980.) Hbk £22.40; pbk £11.90.

COHEN, E.P. and KÖHLER, H. (eds). Membranes, Receptors, and the Immune Response. 80 years after Ehrlich's Side Chain Theory. Progress in Clinical and Biological Research, Vol.42. Pp.404. ISBN 0-8451-0042-4. (Alan R. Liss: New York, 1980.) $34. Available in Europe and the Middle East from European Book Service, Flevolaan, Holland, Dfl.102.

CROFT, L.R. Handbook of Protein Sequence Analysis: A Compilation of Amino Acid Sequences of Proteins with an Introduction to the Methodology. 2nd Edn. Pp.628. ISBN 0-471-27703-7. (Wiley: 1980.) £38.

CROFT, L.R. Introduction to Protein Sequence Analysis. Pp.157. Flexi ISBN 0-471-27710-X. (Wiley: 1980.) £4.95.

DAVIS, W., HARRAP, K.R. and STATHOPOULOS, G. (eds). Human Cancer: Its Characterization and Treatment. Advances in Tumour Prevention, Detection and Characterization, Vol.5. Proceedings of the 8th International Symposium on the Biological Characterization of Human Tumours. Pp.420. ISBN 90-219-0458-6. (Excerpta Medica: 1980.) $90.25, Dfl.185.

DAVISON, A.N. and CUZNER, M.L. (eds). The Suppression of Allergic Encephalomyelitis and Multiple Sclerosis. Based on the Proceedings of the Liversidge Symposium, held in October 1979. Pp.292. ISBN 0-12-206660-X. (Academic: 1980.) £14.80, $34.50.

ELLIS, G.P. and WEST, G.B. Progress in Medicinal Chemistry, 17. Pp.280. ISBN 0-7204-0669-2. (Elsevier/North-Holland: 1980.) $63.50, Dfl.130.

FRIEDLANDER, M. (ed.). Immunological Approaches to Embryonic Development and Differentiation, Part II. Current Topics in Developmental Biology, Vol.14. Pp.381. ISBN 0-12-153114-7. (Academic: 1980.) $39.50.

GREEP, R.O. (ed.). Recent Progress in Hormone Research. Proceedings of the 1979 Laurentian Hormone Conference, Vol.36. Pp.629. ISBN 0-12-57136-0. (Academic: 1980.) $54.

Psychology

HERSEN, M., EISLER, R.M. and MILLER, P.M. (eds). Progress in Behavior Modification, Vol.9. Pp.296. ISBN 0-12-535609-9. (Academic: 1980.) $29.50.

LANE, H. and GROSJEAN, F. (eds). Recent Perspectives on American Sign Language. Pp.170. ISBN 0-89859-053-1. (Lawrence Erlbaum: Hillsdale, New Jersey, 1980.) $16.50.

LEEDS, M. and MURPHY, G. The Paranormal and the Normal. A Historical and Theoretical Perspective. Pp.239. ISBN 0-8108-1278-9. (Scarecrow Press: Metuchen, NJ, 1980.) £9.45.

LEVI, I. The Enterprise of Knowledge. An Essay on Knowledge, Credal Probability, and Chance. Pp.462. ISBN 0-262-12082-8. (MIT Press: 1980.) $27.50.

MAGARO, P.A. Cognition in Schizophrenia and Paranoia: The Integration of Cognitive Processes. Pp.339. ISBN 0-89859-028-0. (Lawrence Erlbaum: Hillsdale, New Jersey, 1980.) $24.95.

O'CONNELL, A.O. and O'CONNELL, V.F. Choice and Change; the Psychology of Adjustment, Growth, and Creativity. Revised edn. Pp.543. Pbk ISBN 0-13-133066-7. (Prentice/Hall: 1980.) £9.05.

SARASON, I.G. (ed.). Test Anxiety: Theory, Research, and Applications. Pp.432. ISBN 0-89859-022-1. (Lawrence Erlbaum: Hillsdale, New Jersey, 1980.) $24.95.

ST. CLAIR, R.N. and GILES, H. (eds). The Social and Psychological Contexts of Language. Pp.338. ISBN 0-89859-021-3. (Lawrence Erlbaum: Hillsdale, New Jersey, 1980.) $27.95.

VAN DIJK, T.A. Macrostructures. An Interdisciplinary Study of Global Structures in Discourse, Interaction, and Cognition. Pp.317. ISBN 0-89859-039-6. (Lawrence Erlbaum: Hillsdale, New Jersey, 1980.) $24.95.

WALLER, T.G. and MACKINNON, G.E. Reading Research: Advances in Theory and Practice. Vol.1. Pp.262. ISBN 0-12-572301-6. (Academic: 1979.) $20.
